Preface

This 61st volume of the TRANSACTIONS of the American Institute of Electrical Engineers marks the end of the transition to the improved publication procedure adopted in August 1940. In accordance with the provisions of that procedure, this volume contains all approved technical-program papers and related discussions presented during the calendar year. Pages 1–312 and 763–892 comprise the papers published in the Transactions Sections of the monthly issues of ELECTRICAL ENGINEERING, and pages 313–762 and 893–1076 comprise papers and discussions that appeared in advance in the June and December 1942 "Supplements to Electrical Engineering—Transactions Section," respectively.

The technical papers and discussions in this volume were presented at these AIEE conventions and District meetings:

1. 1942 winter convention, New York, N. Y., January 26–30, 1942.
2. North Eastern District meeting, Schenectady, N. Y., April 29–May 1, 1942.
3. 1942 summer convention, Chicago, Ill., June 22–26, 1942.
4. 1942 Pacific Coast convention, Vancouver, B. C., Canada, September 9–11, 1942.

In addition, this volume contains:

1. "Bibliography on Circuit-Interrupting Devices, 1928–1940," prepared under the sponsorship of the AIEE committee on protective devices.
2. "Bibliography on Electrical Safety 1930–1941," prepared by the AIEE committee on safety.
3. "Bibliography on Automatic Stations 1930–1941," prepared by the AIEE committee on automatic stations.
4. Report, "Simplified Calculation of Fault Currents," prepared by a working group under the sponsorship of the AIEE committee on protective devices.
5. 1942 annual report of the AIEE board of directors.
6. A complete listing of AIEE officers and committees for 1942–43.

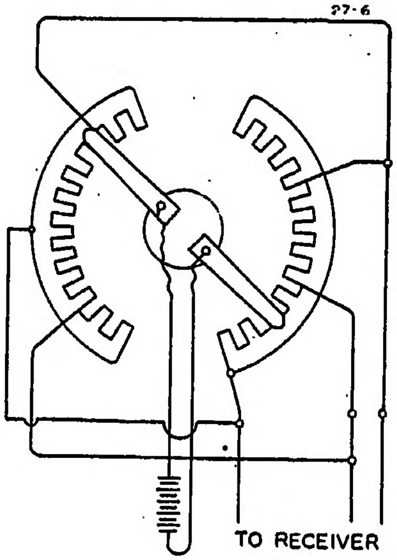
Full correlation of all material in this volume has been accomplished by means of the multientry index beginning on page 1157. Reference to any of the several subject entries for a technical paper will lead directly to the paper and to any published discussion on that paper.

Errata

1. Page 139, column 3, paragraph 1, line 1. "*C*" should read "*B*".

2. Page 315, Figure 4. There should be no connection on the lower lead marked "To Receiver."

3. Page 315, Figure 6. One interconnecting lead was omitted from the illustration; it is included in the revised figure below:



4. Page 315, Figure 7. The word "Power" should read "Pointer."

5. Page 554, Figure 2. Curve 5 is for Helena and curve 6 for Bismarck.

6. Page 1026, column 1, paragraph 6, lines 14 and 15. The statement, "...the procedure described by Boehne and Linde..." should read "...the procedure described in a previous paper..." Added to the reference list should be:

4. A New Principle of Cable Design, William A. Del Mar. AIEE Transactions, volume 60, 1941, May section, pages 206–10.

7. Page 1038, column 1, last paragraph, line 12. The word "voltage" should be deleted.

Field Tests and Performance of a High-Speed 138-Kv Air-Blast Circuit Breaker

PHILIP SPORN
FELLOW AIEE

H. E. STRANG
MEMBER AIEE

Synopsis: Since 1926 many significant field tests on high-voltage circuit breakers have been made on the American Gas and Electric Company's central system, which have served as an important aid in high-voltage circuit breaker development. Such tests have also served as a means for studying and checking the behavior of this large power system under short-circuit conditions.

A 138-kv air-blast breaker of novel design has recently been given a series of field tests both for normal interrupting duty and for ultrahigh-speed reclosing service. Circuit interrupting ability at least equal to that expected of any modern oil breaker of conventional design was obtained and, in addition, an unusual superspeed reclosing performance was obtained which points the way to a possible liberalization of existing derating factors for this kind of service.

While still somewhat of an innovation in the high-voltage field, the air-blast circuit breaker undoubtedly has certain basic advantages. It is believed that these tests are an important step forward in developing the possibilities of the air-blast breaker for high-voltage service and that they have brought the entire electric power industry closer to the possibility of benefit from an application of this interrupting principle.

Description of Breaker

AT the 1941 winter convention there was presented before the AIEE, a paper[1] describing a new high-voltage air-blast circuit breaker, known as the conserved-pressure type. As built for 138 kv, this breaker has two interrupting units of the axial or longitudinal blast type in series per pole. Each of these units, as shown in Figure 1, consists of an enclosing thick-walled tube of insulating material, containing a stationary and a movable contact, an orifice into which the arc is drawn, and a piston and cylinder for actuating the moving contact. This assembly is housed in a vertical porcelain shell for weather protection. Two such columns plus a disconnecting member comprise a pole unit of the 138-kv breaker. Each pole has a storage tank in which sufficient air for two complete close-open operations is stored at 350 pounds per square inch. The three tanks are coupled together by a common header and connected to a central air compressor plant through a double-acting check valve. Each pole has its own electrically operated blast valve to control the flow of air to the contacts. One pneumatic cylinder with electrically actuated control valves operates the three isolating switches through an enclosed system of push-pull rods between phase units.

The interrupting action of this breaker is unique in that the arc is drawn into a space deliberately maintained at high pressure, instead of into the free air as has been common for other types of air breakers. This back pressure, which is maintained by regulating the size of the vent from the arcing chamber, provides a medium having a dielectric strength several times that of air at atmospheric pressure in which the interrupting contacts are separated.

Referring to Figure 2, the action of the breaker in interrupting a circuit is as follows:

1. The protective relay energizes the coils of the three blast valves, causing them to open, admitting air to the passage leading to the interrupting units.

2. Contacts are separated by action of the pistons in each unit.

3. The arc is drawn into the insulating orifice through which air is passing, where it is extinguished; the moving contact continues on into the area of high pressure and high dielectric strength which prevents the arc from restriking.

4. A definite time after the blast valves have been energized (they are interlocked pneumatically to require action of all three valves) air is admitted to the disconnect actuating cylinder

5. After the disconnect has started to open,

Paper 42-9, recommended by the AIEE committee on protective devices for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted July 9, 1941; made available for printing November 3, 1941.

PHILIP SPORN is vice-president in charge of engineering of the American Gas and Electric Service Corporation, New York, N. Y. H. E. STRANG is engineer of the switchgear department of General Electric Company in Philadelphia, Pa.

blast air is cut off, allowing the interrupting contacts to return to the normal closed position after the isolating switch has opened.

The closing action is performed entirely by the isolating switch, its action being fast and controlled by a positive driving force, so that it is capable of closing repeatedly against currents as high as 6,000 to 10,000 rms amperes at 132 kv without harmful effects.

Background of Field-Test Experience

Inasmuch as the facilities of the American Gas and Electric Company's systems, and especially its central system have been lent for the making of interrupting tests on several previous occasions and at the cost of certain extra operating expense and some disturbances to service, it is pertinent at this time, before describing the present series of tests, to review briefly what this background of testing has produced in the way of results and benefits.

While the earliest tests on 138-kv breakers, made in 1926 and 1927[2] produced some real benefits in proving and strengthening the interrupting devices of that time, it remained for later tests, first made in 1930 and later in 1937 and 1938, to bring about important developments in speed. The 1930[3] tests brought to completion the successful development of the 8-cycle breaker, which since has become standard, replacing the 15- to 18-cycle breaker in use up to that time. This improvement in speed was particularly valuable at that time as it permitted taking full advantage of improved high-speed relaying, such as the carrier systems, and in materially reducing the clearing time of faulted transmission circuits. These developments in turn made possible the first attempts at ultrahigh-speed reclosing[4] which has since become a most important tool in the art of transmission. In addition, these tests, made at the full 1,500-megavolt ampere rating of the breaker, disclosed certain weaknesses in design or construction which were thereupon remedied, resulting in greatly increased reliability of breakers in service.

A series of tests, begun in 1937 and completed in 1938[5] resulted in the successful development of a still faster breaker, the 5-cycle multibreak interrupter, which has since formed the basis for most of the ultrahigh-speed reclosing installations on this system. The extra speed of this interrupter over the standard 8-cycle breaker has made possible the overall reclosing cycle, including the time from initial short circuit to final reestablishment of the circuit, of 18 to 20 cycles.[6] This has been accomplished both by the installation of new breakers, as well as by rebuilding existing breakers with the new interrupters.

The 1937–38 tests were further noteworthy in that satisfactory performance was obtained at a duty of 2,000 megavolt amperes, or 33 per cent above the design rating of the breaker. This result has been of real economic value in more ways than one. First, it has formed the basis for a saving in physical size, and consequently in the cost of large 138-kv circuit breakers. Where the 2,500-megavolt ampere breaker was formerly made with a 72-inch tank, with the new interrupter it is now made with a 66-inch tank. Second, it has made possible a rebuilding of a considerable number of existing 66-kv breakers at Windsor for an increased rating well above that for which they were originally designed and at a very substantial saving below the cost of buying new breakers. In this instance, where the normal modernization could offer a rating of not more than 500 megavolt amperes, according to existing standards, a single breaker was rebuilt and successfully withstood a test in the field considerably above this value, and fully adequate for the requirements on these breakers. It is fairly safe to say that without the background of experience gathered in these tests, as well as in the 1930 tests at Philo, the rebuilding and testing of the Windsor breakers for an interrupting duty so much above the maximum previously considered available would never have been initiated.

While all of this background of experience in field testing has proved that the benefits received fully justify the cost, nevertheless, the undertaking of a further series of tests, particularly at this time of increased load requirements, was a matter for serious consideration. For several reasons, however, these tests were believed to be of sufficient importance to justify the actual cost and the inconveniences involved. The development of an outdoor, oilless, high-voltage circuit breaker, which to some may appear to be of only academic interest at the present time, may emerge as a timely, significant, and much needed undertaking. It is not at all inconceivable that restrictions of one form or another may be encountered in the use of oil for future breakers. This leads pertinently to a discussion of some of the advantages and disadvantages of oil as used in conventional oil circuit breakers.

It cannot be denied that oil has proven to be an excellent mediu breakers, and that it has h them to the present high velopment. Some of the oil may be listed as follows:

* Indicates 15-second duty cycle.

performing this duty. In order to find wide application, therefore, any new type of circuit breaker must be capable of clearing a fault promptly, reclosing preferably in less than 20 cycles, and then clearing again in the event the fault on the line still persists.

The circuit breaker field test program, therefore, consisted of two parts:

1. Interrupting tests.
2. Reclosing tests.

The test breaker was rated 138 kv, 1,500 megavolt amperes, 8 cycles with a reclosing time of 20 cycles. All tests were made at approximately 138 kv.

As in the case of both the 1930 tests, and the 1937–1938 tests, these tests were conducted at the Philo plant on the system of The Ohio Power Company. The system setup was substantially the same as that shown in Figure 4 of the reference paper describing the 1937–1938 tests,[5] and for that reason will not be repeated here. As in the case of previous tests, the system connections in so far as possible were so arranged that service areas near the Philo plant would not be directly connected to the short-circuited bus, except on the final, full-capacity shots. Service disturbances were thereby kept to a minimum. A view of the breaker setup for test is shown in Figure 3.

Results of Tests—Breaker

The results of the first series are shown in Table I. Except for the first preliminary test, they were all three phase-to-ground tests, the tabulated values of current and operating time being maximums of the three phases. All tests were made as originally scheduled in a total elapsed time of eight hours, during which there was no inspection of the breaker. Tests 10–11 and 16–17 were made on the standard duty cycle with a 15-second interval. During none of the tests was there any visible fire from vents of the interrupting units. On the closing-opening tests there was a moderate flash from the disconnecting switch contacts, but after ten such operations, of which seven were practically at or above full rating, the blades showed only moderate burning, and so located as not to interfere in any way with their current carrying ability or other normal function.

Following this series of seventeen tests, an inspection of the contacts and interrupting chambers showed them to be in such condition that they were all put back in for the reclosing tests without dressing up or replacement of any parts.

During this first group of tests covering a range of duty from 10 per cent to 125 per cent of the interrupting rating of the breaker, the operating time, measured from energizing the trip coil till the arc was interrupted ranged from 4.6 to 6.3 cycles, including a dead time (to contact separation) of approximately 4 cycles.

It has been shown that in service the minimum reclosing time, without increasing the probability of restrike, is a function of the duration of the original fault, hence of breaker operating time as well as relay time. This gives added impetus to the desire for a fast clearing breaker. Prior to the reclosing tests, it was found possible to make a substantial

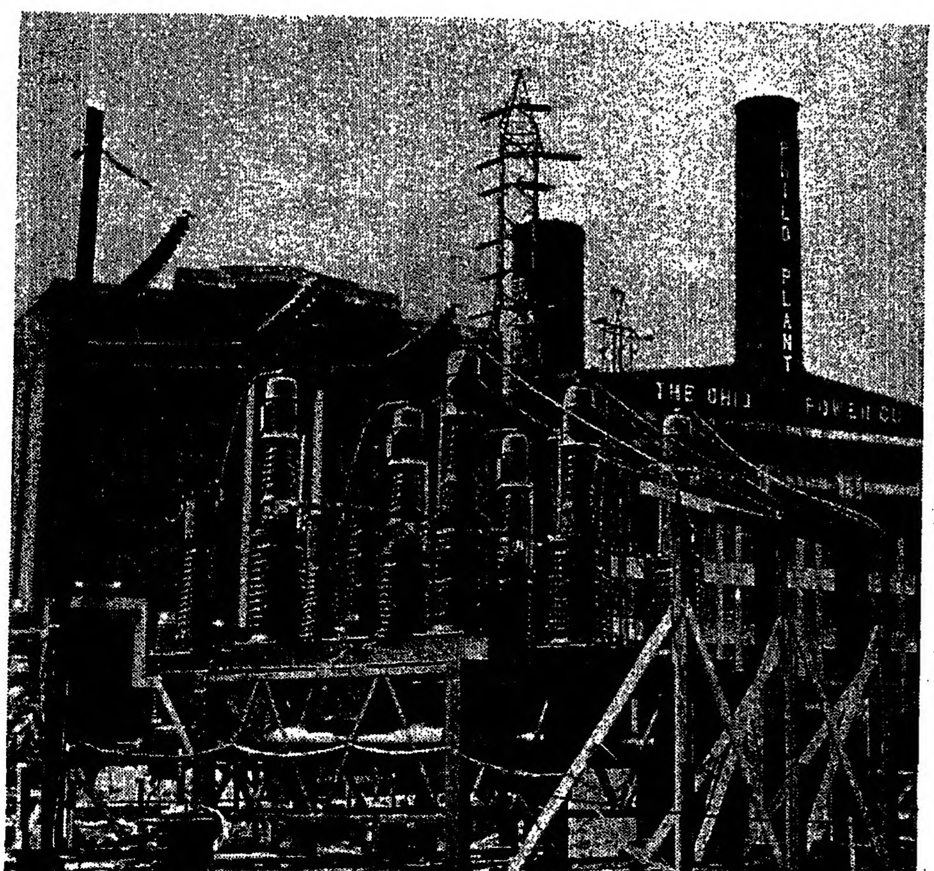

Figure 3 (left). Test setup of 138-kv breaker at the Philo plant

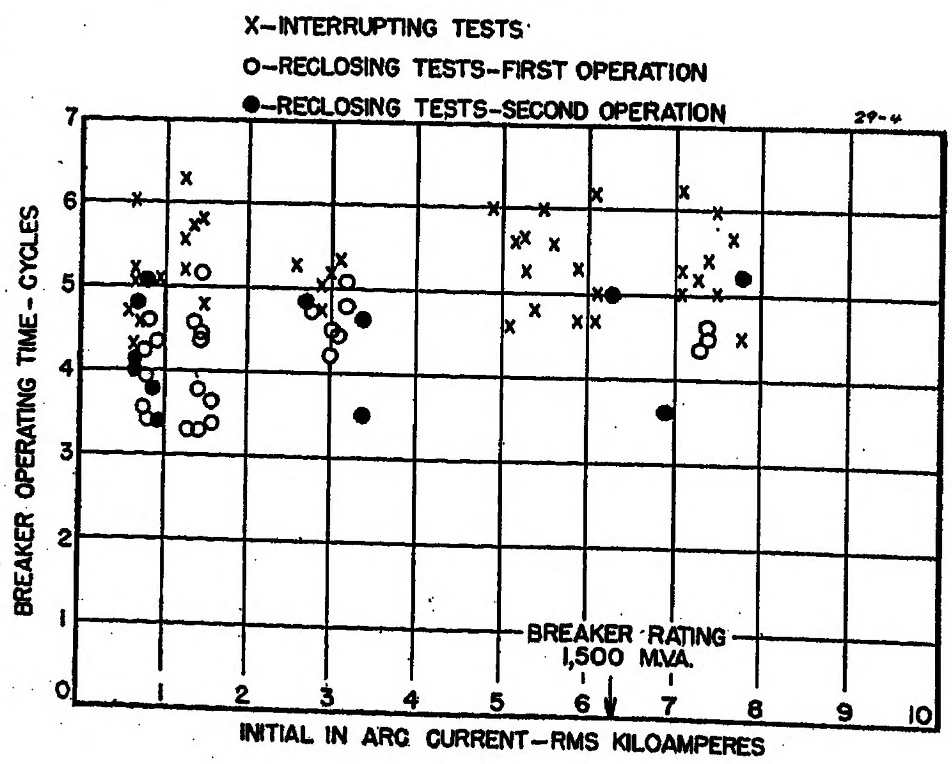
Figure 4 (below). Diagram of breaker performance for both interrupting and reclosing tests



reduction in the breaker dead time by some simple changes and adjustments, thereby reducing the maximum breaker time to approximately five cycles.

The results of the reclosing tests are shown in Table II. During tests 18 to 22 inclusive, difficulties with the temporary control system prevented obtaining complete operation, but did give some interrupting operations showing the effect of the improvement in contact parting time. These control difficulties were remedied, and tests 23 to 25 were completed. In the first operation in each of these tests marked "*a*" in the Table, the fault was initiated by a backup breaker and cleared by the test-breaker interrupting units. The reclosing control was so arranged that instead of the normal sequence of opening the isolating switch next, the blast valve was promptly deenergized, thus cutting off the interrupting air, and allowing the arcing contacts to reclose. This reestablished the fault, causing operation of the protective relays again, opening the blast valves a second time, this time followed by the conventional operation of the isolating switch. After final adjustments, the reclosing time (defined as that measured from energizing the trip coil until the breaker arcing tips contact on reclosing) ranged from 17.7 to 20 cycles. Test 23 represented interruption of light current followed by reclosure on what corresponds practically to normal load current, whereas test 25 demonstrated that the breaker could interrupt a current appreciably beyond its rating, reclose into that fault in less than 20 cycles, and interrupt again with the same operating time for the second operation as for the first.

Following these reclosing tests, the contacts, which had been subjected to a total of 25 operations, were somewhat rounded off, but had not suffered any measurable loss of length. The throats had been enlarged in diameter $^1/_{16}$ inch. As in the previous inspection, all parts were suitable for further operation without replacement.

The chart shown in Figure 4 gives a complete record of all tests showing the operating time of each individual pole unit against current interrupted. Both the first and second operations on the reclosing tests were included in order to determine if there was any significant difference in time between them. The effect of the change in dead time between the interrupting and the reclosing test is clearly shown since the overall breaker time for the reclosing tests ranged from 3.8 to 5.2 cycles compared with a maximum of 6.3 for the previous 17 interrupting tests.

Figure 5 is an oscillogram from closing-opening test 15, interrupting 1,800 megavolt amperes; this may be considered typical of the performance on the first series. Figure 6 shows the results of test 25 in the reclosing series, interrupting 1,770 megavolt amperes, reclosing in 17.7 cycles and then interrupting 1,870 megavolt amperes.

Results of Tests—System

By comparison of the results obtained on these tests, as shown in Tables I and II, with the results obtained on the 1937–1938 tests,[5] it will be seen that the total operating time of the air-blast breaker, particularly in the series of straight interrupting tests, was somewhat longer than the corresponding breaker time of the multiple-break breaker in 1938. For example, on the heavier shots on the oil circuit breaker, breaker time was on the order of 4 cycles, while the duration of short circuit, including relay time, was approximately 5 to $5^1/_2$ cycles. In the air blast tests, however, the actual breaker time for the heavy shots varied between 5 and 6.2 cycles; after adding relay time of approximately 1 cycle, this represented a maximum duration of more than 7 cycles.

As a result of the longer duration of short circuit on these tests, it was to be expected that the disturbing effects on the system would be somewhat greater than those experienced in 1937 and 1938. That this was actually the case was evidenced by a number of reports from nearby areas which would be most affected by the final tests involving a complete system short circuit. These reports were concerned almost entirely with the shutting down of motors having instantaneous undervoltage protection. ·

Philo are considered. This was seen from the records taken on the permanently installed automatic oscillographs at Lima, Howard, and Torrey substations. An indication of the relative severity of voltage dips was also obtained from recording voltmeter charts taken at various locations, although the accuracy of these comparisons is questionable because of the variable damping characteristics of the different instruments.

Discussion of Results

As compared with the time which has been spent in developing oil circuit breakers to their present state of satisfactory performance, it is remarkable that in such a comparatively brief time an entirely new principle of arc interruption has been developed and incorporated in a successful breaker which gives substantially five-cycle performance on its first real system test. In other words, while it took thirty years to get the present five-cycle oil circuit breaker, this has been practically realized with air blast in some two years of development work.

This comparison may appear even more striking when it is pointed out that in all previous field tests on oil circuit breakers on this system, it has never been possible to complete an initial series of tests on a new design without disclosing some difficulty in the breaker itself, not of basic importance, it is true, but still sufficient to prevent the completion of the tests until such difficulties were remedied. These tests on the air-blast breaker were, therefore, the first series of tests which was ever undertaken on the American Gas and Electric Company systems in which the breaker in its original condition successfully completed an entire scheduled series without any adjustments, difficulties, or inspections throughout. It is true that on the reclosing tests it was not possible to complete the program as first planned, but this was due entirely to external relay characteristics which had nothing to do with the breaker itself. With proper adjustments in the relay setup, tests were carried through without incident. This is believed in itself to be an unusual performance in the light of past experience with oil circuit breakers and in view of the radically new design of circuit breaker being tested.

Figure 5. Oscillogram from test 17

Open-close-open operation interrupting 1,860,000 kva

Conclusions

1. The high-voltage air-blast breaker tested has demonstrated an interrupting performance at least the equivalent of that expected from any modern oil breaker of conventional design. It may reasonably be expected that present ideas entering into mechanical design and construction will undergo changes during the next few years, but a successful interrupting principle has again been established beyond doubt.

2. With the extension of ultrarapid reclosing applications on the American Gas and Electric Company systems, the adaptability of any high speed breaker to reclosing is obviously an indispensable qualification. The present air-blast breaker has this inherent adaptability, as demonstrated by tests at reclosing speeds at least equal to, and at short-circuit duty far beyond, any similar tests ever made on oil breakers. Based on prevailing standards, the interrupting ratings of 138-kv oil breakers are subject to a reduction of 15 to 25 per cent when applied on 20-cycle reclosing service. Although it may be too early to form definite conclusions, even a conservative interpretation of these test results points the way to a probable downward revision of such derating factors as applied to air-blast breakers in the future.

3. The current-transformer problem is decidedly more complex for the air-blast breaker than for the conventional oil circuit breaker since the relatively simple and economical procedure of applying bushing current transformers to oil circuit breakers cannot be carried out

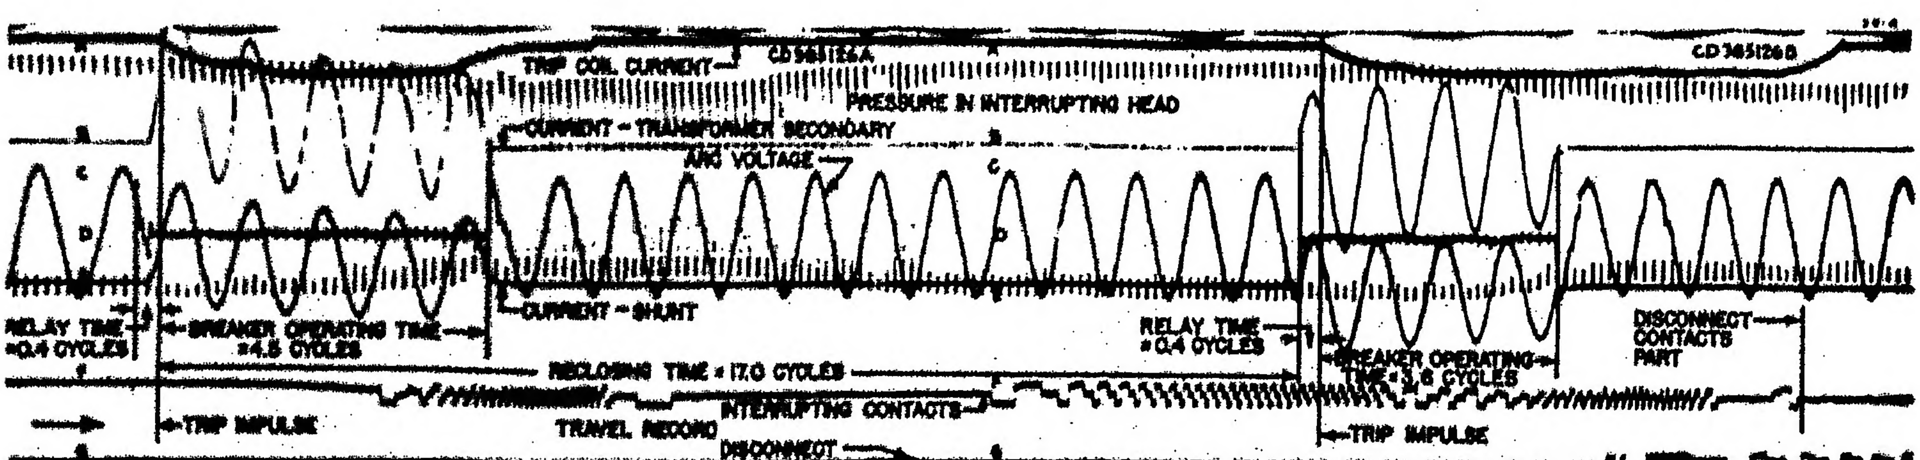

Figure 6. Oscillogram from test 25

Interrupting 1,770,000 kva, reclosing in 17 cycles, and interrupting 1,870,000 kva

in the case of the air-blast breaker. It would be highly desirable, therefore, in the interests of the future development of this type of circuit breaker, if a more economical solution of this problem than the separate current transformer could be found.

4. The success of this development on 138 kv points encouragingly to the prospect of developments at higher voltages, such as 230 kv, or even higher. The economic picture here might be even more favorable to the air-blast breaker, considering the physical dimensions and large quantities of oil required in the conventional breakers for such voltages.

5. As regards the possible difficulties in what may be considered an experimental period in the use of air and the equipment required for handling the air, there is no doubt that practical experience is needed. The only way to get this, of course, is through trial installations. This will be done with this breaker and, it is hoped, with others, with the view of acquiring the necessary field experience to handle air successfully.

Fortunately, the existence of reliable oil circuit breakers makes it possible to carry out such a program at least in the moderately high-voltage class like 138 kv, systematically and without delay, but unhurriedly.

Synopsis: The need for an improved method of measuring starting torque of large induction starting synchronous motors as compared to the power input and dynamometer methods, has led to the use of the acceleration oscillogram. A low ripple, permanent magnet type d-c generator is driven by the motor, and traces a time-speed oscillogram, from which acceleration, and the torque producing it, may be calculated. Comparative torque tests, at full and reduced voltage, made by this and the other methods on the dynamometer coupled motor, showed the definite advantage of the acceleration tests in combined convenience and accuracy. Interesting facts about synchronous motor starting torques, not accurately shown by previous tests, have been brought to light. The acceleration or deceleration oscillogram is also applied to the measurement of torques or losses of very small high-speed motors by using other methods of rotation indication, involving no loading of the motor.

THERE has been need in our motor testing departments for a simpler and more accurate means of obtaining speed-torque curves of various types of motors. Particularly this need has been felt in the a-c synchronous motor section, building synchronous motors (induction starting) of from approximately 25 to 1,000 horsepower rating.

Two methods have been used, one based on measurement of power input, and the other on the dynamometer. The first is rather inaccurate because several variable factors can be accounted for only in an arbitrary manner, and the second involves a rather elaborate test setup, including a dynamometer of sufficient torque to load the motor at all speeds.

The method we will describe gives results of accuracy comparable to the dynamometer test. It is taken at full voltage with no corrections, and requires only a simple test setup. It is based on the simple principle that the torque developed in a motor while accelerating from standstill to full speed is absorbed by friction and windage and acceleration of the rotating parts. If only useful output torque is to be determined, friction and windage are not considered, and the required results are obtained from acceleration figures only.

Paper 42-5, recommended by the AIEE committees on instruments and measurements and electrical machinery for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1941. Manuscript submitted August 25, 1941; made available for printing October 30, 1941.

C. R. Atkinson is in the motor and generator engineering department and E. G. Downie is in the works laboratory of General Electric Company, Fort Wayne, Ind.

The Tachometer Generator

Speed-acceleration data may be obtained graphically from a time-speed curve, or directly from the proper electric circuit. The first requirement in producing an accurate time-speed curve is a tachometer generator which produces a d-c voltage, free from commutator and rotational ripple, exactly proportional at all times to the rotational speed of the motor. Any ripple in the voltage becomes confused with pulsations from actual speed surges in the starting motor, and makes the resulting curve difficult to analyze.

The use of a satisfactory d-c generator has largely made possible the accurate results we have obtained. The generator is a permanent magnet field type, specially built with a large number of commutator segments for minimum commutator ripple and the best possible armature construction for low rotational ripple. With a 100-microfarad filter condenser, no ripple is visible in the oscillographic trace of the output voltage. The coupling used to connect the generator to the motor must be rigid in torsion, and must not exert any axial or radial force on the generator shaft extension. Any deflection of the generator shaft introduces rotational ripple. The coupling being used is of the common leather ring type, with provision for mounting the motor half by three tapped holes and cap screws on the truly faced end of the motor shaft. Best results were obtained by not clamping the generator too rigidly in position, thus allowing any slight radial deflection to be absorbed by the whole unit, rather than the shaft alone.

The oscillogram method of torque test is especially convenient for the synchronous motor, for other starting data may be obtained on the film. Line current and field discharge current are recorded on the film as well as the speed indicating voltage from the generator.

Torque Calculations From Oscillograms

Calculations from the time-speed oscillogram begin with speed and time calibrations, in terms of revolutions per second per millimeter and seconds per millimeter. The quotient of these two is a constant which may be multiplied by the tangent of the measured slope angle of the speed curve at any point to determine the acceleration. The moment of inertia of the motor and tachometer generator (unless negligible compared to the motor), and normal full load torque may also be included, to give a constant to be multiplied by the slope to give direct values of percentage of full load torque, the term commonly used by motor engineers. (See appendix *A*.) The speed curve is divided into a convenient number of equal sections along the time axis, and the slope and amplitude measured at each section. The results are data for a complete speed-torque curve, percent synchronous speed versus per cent full load torque.

Comparative Tests

A small educational two-unit dynamometer set was chosen for its convenience in illustrating this method of torque test and comparing the results with those of other methods. Both units were the same electrically, rated $7^1/_2$ horsepower as motors; but one (normally the motor) had a phase-shifting stator mounting, and the other was cradled as a dynamometer.

The input and dynamometer test readings were taken simultaneously over the speed range at reduced voltage (appendix *B*). Starting oscillograms were taken at full and reduced voltage, with the motor coupled and uncoupled to the dynamometer unit. Deceleration oscillograms, coupled and uncoupled, gave data on friction and windage torque at all speeds.

Figures 1 and 2 show starts at full voltage with the dynamometer coupled, from a standstill (1), and with the rotor coasting slowly in reverse rotation before the start (2). The method of Figure 2 permits the transient effect of power application to pass before zero speed is reached. The first, however, gives a better indication of available breakaway torque. This transient starting torque in induction motors has been discussed by Wahl and Kilgore.[1] Figure 3 shows a full voltage start of the motor unit alone, without the added inertia of the dynamometer unit. It can be seen that for accuracy in analysis, when average torque readings are required, the slower start, as obtained with added inertia, is desirable. A reduced

voltage start, for direct comparison against reduced voltage data from the other methods, is recorded on Figure 4. The tendency of the machine to hunt is shown on the starting curves by the speed pulsations above and below synchronous speed, which did not die out until after the end of the oscillogram.

The speed-torque curve obtained from Figure 4 is plotted on Figure 6, with points added from input and dynamometer tests, all at 140 volts on the 220 volt connection. Agreement is fairly good between acceleration and dynamometer tests but the input method does not show the half-speed dip in torque which is unquestionably present. Figure 7 is for full voltage starting with acceleration torque data from Figure 2 and added points from input and dynamometer tests, with rechecks at some speeds, corrected for 220 volts. Again the dynamometer tests are in best agreement, with input tests not showing the half-speed dip (appendix *C*). Acceleration oscillograms show friction and windage torque (both units) of 4.1 per cent at 600 rpm and 5.8 per cent at 1,200 rpm. These values should be added to the acceleration torque values for exact comparison with input test values.

Variations of the Method

Acceleration may be shown directly on the film by passing the charging current to

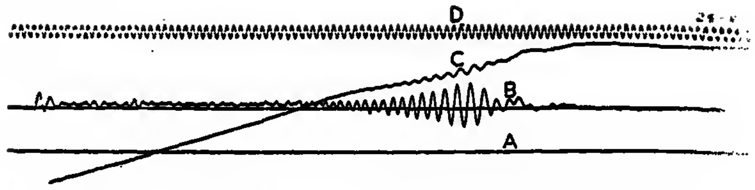

Figure 5. Starting oscillogram with direct acceleration indication (coasting backward before start)

A—Zero speed *B*—Acceleration *C*—Speed *D*—60-cycle timing wave

a condenser (from the d-c tachometer generator) through an oscillograph galvanometer. It can be shown (appendix *D*) that:

Acceleration

$$\frac{d^2r}{dt^2}=\frac{I}{CK_G}+\frac{R}{K_G}\times\frac{dI}{dt}$$

where

I = capacitor charging current
C = capacitance of capacitor
R = total circuit resistance
K_G = volts per revolution per second of generator

The term $I/(CK_G)$ is dependent only on current magnitude and is obtained directly from galvanometer deflection on the film. Correction for the other term would be tedious so it must be kept small by low circuit resistance and low current. The obvious requirement then is a high sensitivity, low resistance galvanometer element.

Figure 5 shows acceleration by this direct method. Unfortunately, the acceleration deflection was not set high enough for accurate reading on smooth acceleration, but shows clearly its value in recording torque pulsations such as those in the synchronous motor approaching synchronous speed. We have found slope measurement of a speed curve more generally useful, because of simplicity of taking the oscillogram, ease of calibration, and the need for average rather than instantaneous torque values.

A speed-torque curve may be traced directly on the screen of a cathode-ray oscilloscope during the starting of a motor by applying the tachometer generator voltage to one pair of plates, and passing the capacitator charging current through deflecting coils (or a shunt and d-c amplifier) to produce torque deflection in quadrature with the speed deflection. This has been done experimentally with good results but has not yet been applied to production torque testing.

The general principle of speed oscillograms for determination of starting, and friction and windage torque has been applied to a number of applications where the tachometer generator could not be used, and speed indication is obtained on the film by other means. Some tests involve high speeds (up to 20,000 rpm) and many do not permit any loading effect by the indicating device. Three methods have been used successfully:

1. Small magnets on the motor shaft generate a voltage in a stationary coil, which is amplified and applied to an oscillograph galvanometer.
2. A mirror on the motor shaft reflects a light directly on the oscillograph film, while a galvanometer traces a timing wave.
3. A mirror or shutter mechanism on the motor shaft controls light on a photocell, and the resulting impulses are amplified and applied to an oscillograph element.

In all of the cases, speed is calculated at any point by counting revolutions per unit time, or measuring time elapsed per revolution.

Conclusions

1. Neither the power input nor dynamometer torque tests are entirely satisfactory in the analysis of synchronous (or induction) motor starting characteristics.
2. The acceleration oscillogram torque test is simpler to set up and run, is taken at full voltage with no corrections, gives consistent, accurate results through the whole speed range, and may be used to determine transient as well as average torque.
3. Variations in the method allow it to be applied to many types and sizes of motors, for determining losses as well as starting torques.

Appendix A. Derivation of Acceleration Formula

Consider a point on the time-speed curve, H millimeters on the horizontal time scale and V millimeters on the vertical speed scale.

t = time in seconds
r = revolutions
k_h = time calibration, seconds per millimeter
k_v = speed calibration, revolutions per second per millimeter
θ = slope angle of curve
WR^2 = moment of inertia of rotor, pound-feet^2

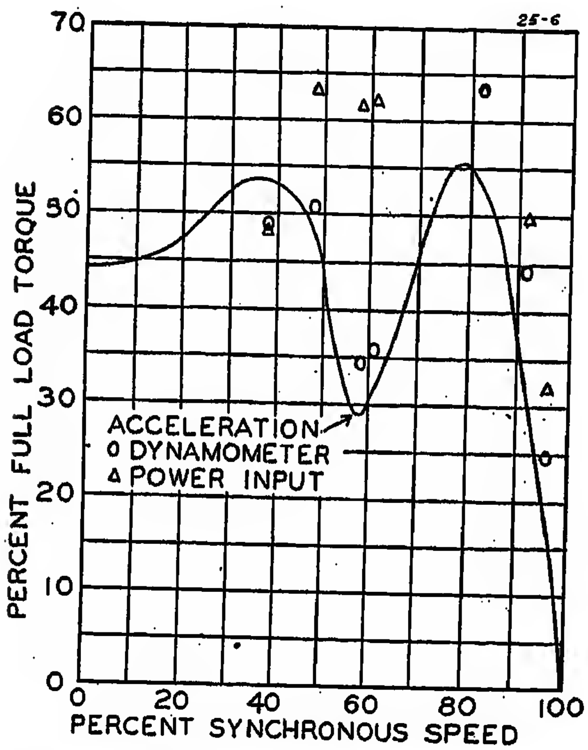

Figure 6. Reduced-voltage (64 per cent) starting torque by various methods

G = acceleration of gravity, feet per second per second

$$\frac{dr}{dt} = VK_v \quad t = HK_h$$

$$\frac{d^2r}{dt^2} = \frac{dKV_v}{dt} \quad dt = dHK_h$$

$$\frac{dr}{dt^2} = \frac{dVK_v}{dHK_h} = \frac{K_v}{K_h} \tan\theta$$ acceleration, revolutions per second per second

$$\text{Torque (pound-feet)} = \frac{WR^2}{G} \times 2\pi \times \frac{d^2r}{dt^2}$$

$$= \frac{WR^2}{G} \times 2\pi \times \frac{K_v}{K_h} \tan\theta$$

$$= K \tan\theta$$

Appendix B. Input and Dynamometer Test Methods

For the input method readings the cradled unit with the dynamometer attachment was connected synchronously to a variable frequency source of sufficient capacity to afford practically infinite bus to the test machine. The motor then was coupled to the dynamometer and connected electrically to a variable-voltage 60-cycle source for

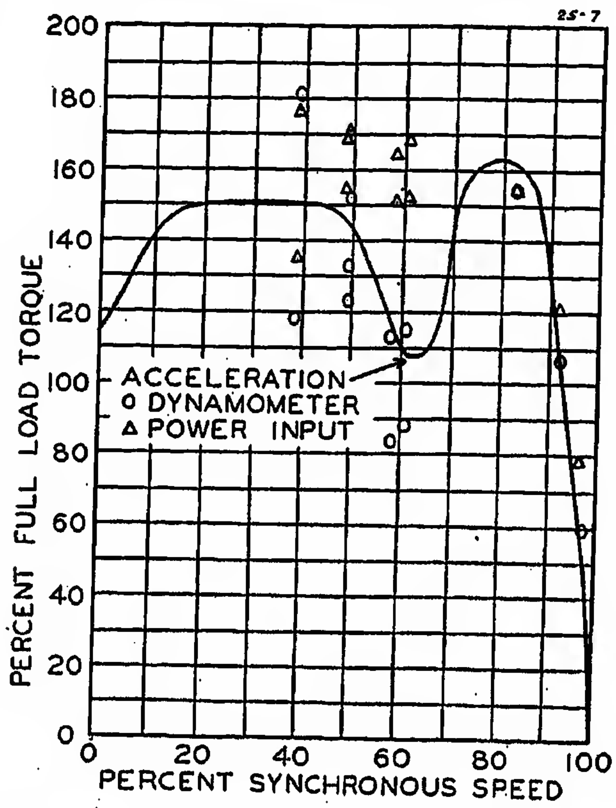

Figure 7. Full-voltage starting torque by various methods

short periods during which time the input and torque readings were made. This setup should have provided an ideal arrangement for taking torque tests by either input or dynamometer method, but practically it left much to be desired. Briefly, the range of frequency control was limited, frequency or speed control at very low speeds (including standstill) was not available, and the torque reading on the dynamometer scale varied throughout a reading period, due perhaps to change in the torque characteristics of the armature and amortisseur windings from heating.

Appendix C. Peculiar Motor Characteristics Shown

The agreement in the lower speed portion of Figure 7 was not good, particularly near half speed, but this was pretty much to be expected. In fact, queer antics of synchronous motors at and near half speed often have been hard to explain in the light of heretofore obtainable tests. In some cases one was inclined to doubt the accuracy of the test readings, in others, the inherent accuracy of the method. We anticipate therefore that this new method of recording torque directly and instantaneously will confirm some previous observations that one hardly dared to believe.

For instance, some motors have shown a tendency to lock or synchronize at half speed (in fact a great many show a slight tendency in this respect). Others seem to show such a characteristic only when being started on a voltage considerably reduced from their rated voltage. A torque test on such a motor by the power input method, at more nearly rated voltage might indicate a peak of torque at half speed. Knowing when to believe such an observation will go far in helping to determine the cause.

Appendix D. Derivation of Acceleration-Current Formula

E_G = tachometer generator voltage (open circuit)
E_C = capacitor voltage
I = capacitor charging current
C = capacitance of capacitor
R = total circuit resistance
K_G = volts per revolution per second of generator

$$E_C = E_G - IR \qquad E_G = K_G \frac{dr}{dt}$$

$$I = \frac{CdE_C}{dt} = C\,\frac{(dE_G - RdI)}{dt}$$

$$I = \frac{CdE_G}{dt} - CR\,\frac{dI}{dt}$$

$$I = \frac{CK_G d\,\dfrac{dr}{dt}}{dt} - CR\,\frac{dI}{dt}$$

$$\frac{d^2r}{dt^2} = \frac{I}{CK_G} + \frac{R}{K_G} \times \frac{dI}{dt} = \text{acceleration}$$

Temperature and Electric Stress in Impregnated-Paper Insulation

J. B. WHITEHEAD
FELLOW AIEE

W. H. MacWILLIAMS, JR.
ENROLLED STUDENT AIEE

THE effect of temperature elevation on impregnated paper insulation is to increase conductivity and dielectric loss and to accelerate such chemical action as may be possible among the constituent paper, oil, and adjacent electrodes. Both effects increase rapidly above, say 60 degrees centigrade, but are relatively small at ordinary atmospheric temperatures in dry and air-free insulation.

The effect of high stress is also well known. Power-factor-voltage curves in thoroughly impregnated paper (no gaseous ionization) are generally flat up to 300 or 400 volts per mil at temperatures up to 40 or 50 degrees centigrade and at higher stresses rise only slightly until breakdown is approached. Further temperature elevation is immediately reflected not only in large increases in power factor but in characteristic changes[1] in the shape of the power-factor-voltage curve. These immediate (as distinguished from long-time) effects have usually been considered from the standpoint of the values of dielectric loss reached and permissible limits of temperature elevation.

Little attention has been paid to the study of the long-time effect of combined high temperature and high stress. The slow increases in power factor and loss in cables operating at relatively low values of stress and temperature have usually been attributed to chemical changes inherent in the constituent materials and to increasing gaseous ionization. Safe restrictions are placed upon these in design with due reference to the influence of temperature.

However, such time changes have been noted by manufacturers' engineers but, as is so often the case, not published. Time changes in power factor in laboratory samples have been reported by one of the present authors.[1,2] Perhaps the most conspicuous data are those of Proos.[3] In a series of load-cycle studies on power cables he noted the following:

(*a*). Electric stress at low temperature for long time, no permanent change in power factor at high stress.

(*b*). Load (and temperature) cycles plus high stress, large permanent changes in power factor at high stress.

Proos apparently had his eye on gaseous ionization, and says nothing as to possible chemical changes. This paper reports the results of a careful laboratory study of the matter. Although only one oil has been studied so far, and others may show different behavior, the results have seemed to the authors so striking that they are being reported at once.

Test Samples

The tests were made on samples consisting of 10 flat circular layers of 0.004-inch wood pulp cable paper, specific gravity 0.997, made by a well known manufacturer. The 6.25-inch diameter samples were placed in a circular parallel-plate capacitor with brass electrodes and with the usual guards. The outside diameter of the high-voltage and guard electrodes is 5.13 inches. The capacitor was mounted in a Pyrex glass dish so that the impregnated specimen was under oil at all times. The capacitor and dish were mounted in an outer brass cell, with thermostatic control, which could be heated to 105 degrees centigrade and which could be evacuated to a pressure of 0.05 millimeters of mercury. Connections were provided for measuring and for guard electrodes and for voltage up to 15 kv on the high-voltage electrode. A-c measurements were made by a transformer bridge modified to permit rapid determination of power-factor-stress characteristics. Further details of the capacitor and other auxiliary measuring equipment will be found in an earlier paper.[2]

The oil used was prepared by a well known manufacturer for cables of the solid type. The principal properties are given in Table I.

The paper in all cases was vacuum dried and degassed at a pressure of 0.05 millimeter of mercury and a temperature of 105 degrees centigrade for 60 hours, with appropriate measurements of d-c conductivity and 60-cycle power factor at intervals to insure uniformity of final conditions. The oil was stored in a steel drum under nitrogen, and as needed was degassed and dehydrated at 0.15 millimeter mercury.[2] Some of the samples tested were impregnated with oil which had been exposed for 65 hours to oxygen at a pressure of five centimeters mercury, and a temperature of 80 degrees centigrade. The paper for these samples was dried in the usual manner, the oxygen at a pressure of five centimeters was admitted to the impregnating cell, and thereafter the oil saturated with oxygen at the same pressure was admitted. After 12 hours air was admitted to the cell at atmospheric pressure and so maintained for the duration of the test. Under these conditions, the oil contained 0.7 per cent of oxygen by volume, or about five hundred times as much oxygen as that contained in the normal air-dried specimen. Further details as to the oxidation process and measurements may be found in an earlier paper.[2]

The Tests

The principal tests were a comparison of the power-factor-stress and temperature characteristics of specimens subjected to two sets of conditions,

(*a*). Without electric stress, and at a temperature of 80 degrees centigrade.

(*b*). Under an a-c stress of 400 volts per mil, at the same temperature.

These runs lasted approximately one week each, and were interrupted at intervals of approximately 24 hours for the measurement of power-factor-stress relations between 25 and 400 volts per mil. At the end of approximately a week the tests were interrupted and the temperature lowered to that of the atmosphere and another power-factor-stress curve taken. The specimen was then dismantled and power-factor measurements made on individual layers at atmospheric

Paper 42-10, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE winter convention New York, N. Y., January 26–30, 1942. Manuscript submitted September 24, 1941; made available for printing November 5, 1941.

J. B. WHITEHEAD is director of the school of engineering and W. H. MACWILLIAMS, JR. is associated with the school of engineering of the Johns Hopkins University, Baltimore, Md.

temperature and a stress of 50 volts per mil.

Results

Test 1. No Stress, No Oxygen, 80 Degrees Centigrade

Figure 1 shows the results of a test run of an air- and oxygen-free sample maintained at 80 degrees centigrade for a period of one week. Time was measured from the termination of the impregnation period. It will be noted that the curves are relatively flat and of low absolute value. The slight increase in power factor at 150 volts per mil over the period of seven days is 0.0005. The curves show the beginnings of a characteristic of all such curves at higher temperatures; namely, a maximum in the neighborhood of the stress mentioned. The power-factor-stress curve, at room temperature and after the test, is absolutely flat. The layer power-factor curve is in no way suggestive of action at the electrodes.

Test 2. Sustained A-C Stress at 400 Volts Per Mil, 80 Degrees Centigrade—No Oxygen

As will be seen in Figure 2 the power-factor stress curve at the start is approximately flat at a relatively low value and comparable with the initial curve of test 1

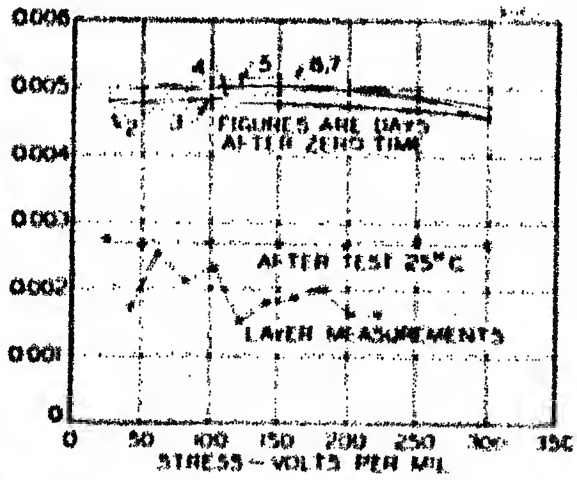

Figure 1. Changes in power factor due to temperature (80 degrees centigrade) alone. No oxygen

However, the curves taken on succeeding days

(*a*). Indicate a rapid increase of power factor with time.

(*b*). Take on the characteristic form indicated in Figure 2.

The salient features of these curves are the rapid increase in power factor at low stresses, with maximum values at approximately 125 volts per mil, and thereafter the continuous decrease of power factor up to and beyond 400 volts per mil. The increase in the maximum value is approximately linear with time in the lower range, with some indication of a more rapid increase beyond 48 hours. The overall increase in power factor for the period of the run is 0.022, or about 0.0056 per day, which may be compared with the practically negligible increase of test 1 (not greater than 0.00013 per day). The power-factor-stress curve at atmospheric temperature, after the test, is close to the initial curve at 80 degrees and rises slightly with increasing stress, this indicating a permanent change in the dielectric as a result of the run at high stress and 80 degrees centigrade; compare with Figure 1. Again the layer power-factor curve contains no special suggestion of action at the electrodes.

Test 3. Sustained A-C Stress at 400 Volts Per Mil, 80 Degrees Centigrade, No Oxygen

Figure 3 shows three power-factor-stress curves on a specimen similar to that in test 2. Results similar to those of test 2 were obtained in this test which was

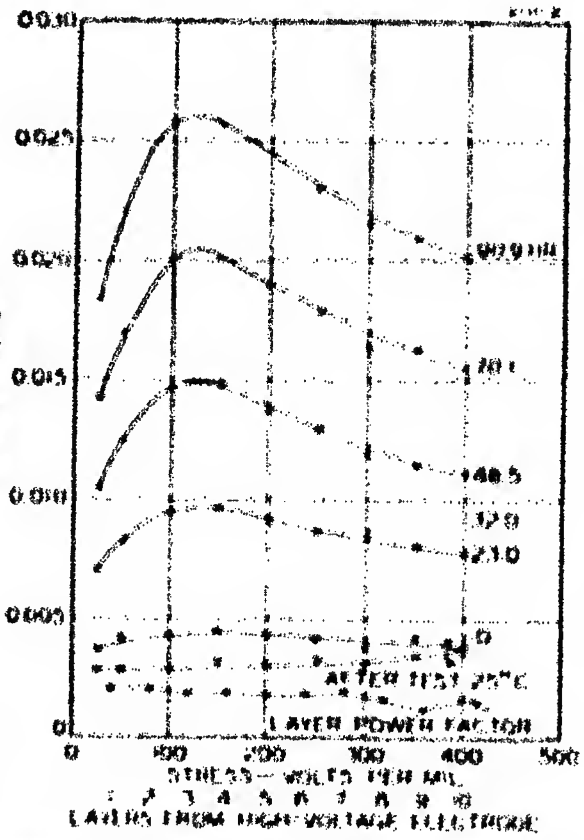

Figure 2. Changes in power factor due to combined temperature (80 degrees centigrade) and stress (400 volts per mil). No oxygen

continued to 112.9 hours. After 112.4 hours at 400 volts per mil, curve *A* was taken. After an additional half-hour at 400 volts per mil, stress was removed, and after a further period of 20 hours without stress curve *B* was taken. After a further 24 hours without stress curve *C* was taken. The three curves of Figure 3 indicate that, while rapid increases in power factor accompany any prolonged application of stress, these increases cease almost immediately upon removal of stress. The high values reached appear to be permanent, indicating a definite deterioration of the insulation. Changes in the power-factor-stress curves at decreasing values of temperature following a run of 91 hours at 80 degrees centigrade and 400 volts per mil are indicated in the curves of Figure 4. As seen, the characteristic maximum in the power-factor curves does not appear below 60 degrees. There is, however, the suggestion that these maxima might appear at 60 degrees centigrade (or lower), if the stress were carried to higher values.

Test 4. Sustained A-C Stress at 400 Volts Per Mil, 60 Degrees Centigrade, No Oxygen

The procedure in this test was identical with that in test 2, except that the sus-

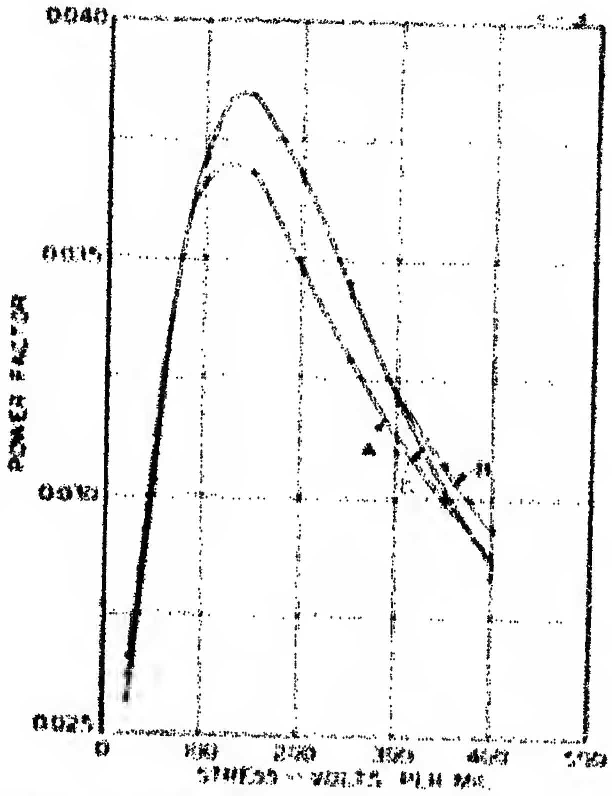

Figure 3. Changes in power factor after removal of stress (80 degrees centigrade). No oxygen

A—112.4 hours under stress
B—112.9 hours under stress, 20 hours off
C—112.9 hours under stress, 43.9 hours off

tained temperature was 60 degrees centigrade. The results of the test of 92 hours duration are shown in Figure 5. The trend of the power-factor-voltage curves is similar to that found for the temperature of 60 degrees in Figure 4. Moreover, there is the steady increase of power factor with time at each value of stress. The increase is practically uniform as shown by the graph giving the increasing values at 125 volts per mil. The rate of increase of power factor, 0.000336 per day, is noticeably less than the corresponding figure of 0.0056 per day for temperature 80 degrees centigrade found in test 2. In this case the power-factor-stress curve at room temperature was perfectly flat, at the approximate value 0.003, as com-

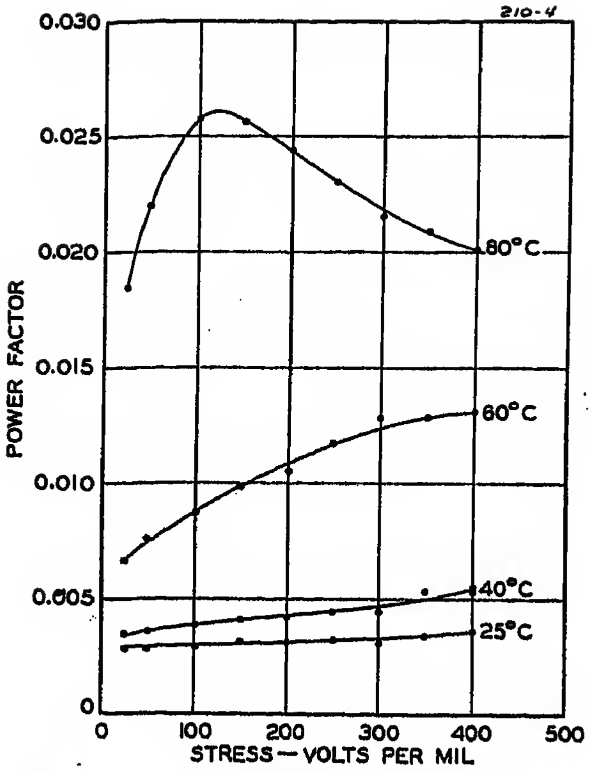

Figure 4. Changes in power factor with temperature after removal of stress. No oxygen

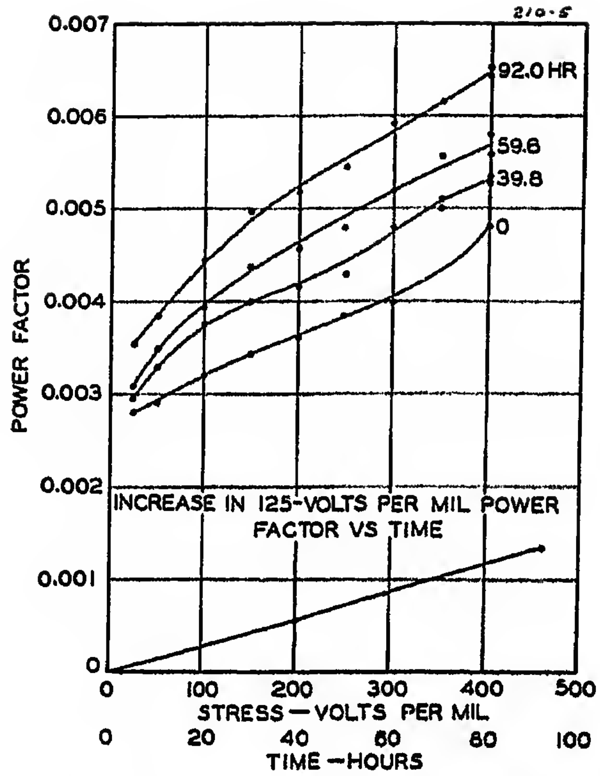

Figure 5. Changes in power factor due to combined temperature (60 degrees centigrade) and stress (400 volts per mil). No oxygen

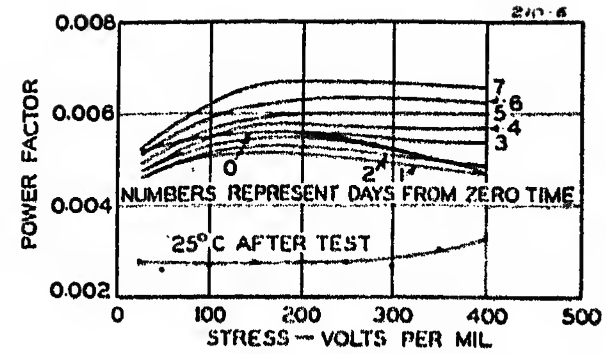

Figure 6. Changes in power factor due to oxidation at 80 degrees centigrade

monly observed for all specimens throughout the course of the work.

Test 5. Sustained A-C Stress at 400 Volts per Mil, 40 Degrees Centigrade, No Oxygen

In a similar series of tests over a period of seven days the power-factor-stress curves are all approximately flat and have approximately the same value, the curves being grouped irregularly within the range 0.0027 and 0.0035 at 125 volts per mil. No uniform variation was found, and for the purpose of discussion in this paper, it is assumed that the time variation of power factor in this test is negligible. (0.00011 per day overall average as compared with 0.0056 per day for 80 degrees at 400 volts per mil.)

Test 6. Oxygen, No Stress, 80 Degrees Centigrade

This specimen was impregnated with oil which had been saturated with oxygen at a pressure of five centimeters mercury and a temperature of 80 degrees centigrade for 65 hours; impregnation also took place in an atmosphere of oxygen under the same pressure. The power-factor-stress curves over a period of seven days are shown in Figure 6. The steady rise in power factor (0.0017 overall) is more than three times greater than that of Figure 1 (0.005), which may be attributed to the continuous process of oxidation. There is also a suggestion of the appearance of maxima similar to those in Figure 2. The decrease in power factor between curve "0" day and "1" day is due to the change of atmosphere from oxygen at five centimeters to air at a pressure of 76 centimeters of mercury. The curve for 25 degrees centigrade following the main test remains at low value, but shows an upward tendency at higher stresses.

Test 7. Oxygen, 400 Volts per Mil, 80 Degrees Centigrade

The specimen was impregnated with oil saturated with oxygen at a pressure of 5 centimeters of mercury and 80 degrees centigrade, as in test 6, and subjected to sustained stress at 400 volts per mil for 116.5 hours. Figure 7 shows the power-factor-stress curves. The curves for "0" hour and that at 25 degrees after test, are practically coincident with that of test 6 (oxygen, no stress). Otherwise, the behavior is closely the same as test 2 (stress, no oxygen), the characteristic maxima appearing at about the same values of stress, and the rate of overall time increase being slightly lower than that for the oxygen-free specimen. The time increase of power factor is closely linear in each case, being 0.0056 per day for the oxygen-free specimen and 0.0051 per day for that containing oxygen. The curve for layer variation of power factor again shows no evidence of electrode activity. Figure 8 shows the power-factor-stress curves at decreasing values of temperature following the time-run at 80 degrees. The behavior is closely the same as that shown in Figure 4.

Rate of Power-Factor Increase Versus Temperature—No Oxygen

In Figure 9, based on the data of the foregoing tests, the rate of increase in power factor per hour under sustained stress at 400 volts per mil is plotted as ordinate with temperature as abscissa. As will be seen, an appreciable steady increase is found at 60 degrees, the hourly or daily rate increasing rapidly above that temperature, the increase between 60 degrees and 80 degrees being approximately seventeen times.

Discussion of Test Results

The outstanding result of the tests is the very great increase in the time rate of increase of power factor, when high temperature and high stress are applied simultaneously, over the rates observed when the effect of each is observed separately. The relative rates of power-factor increase are: at 80 degrees centigrade and no stress, 0.0005 per week; at 80 degrees centigrade and 400 volts per mil, 0.0392 per week, an increase of at least 78 times in the rate of power-factor increase This figure is startling. Temperatures up to 80 degrees centigrade are not uncommon in high voltage cables. While 400 volts per mil is somewhat high, stresses up to one-half that value are now in use, the higher values are spoken of.

The question immediately arises as to the nature of the underlying phenomena. Within the ranges of temperature and stress here studied, there is a uniform linear rate of increase of loss, hence of conductivity, hence in the number of free ions present. Apparently oxygen plays a relatively small part, an increase of 500 times in the amount of oxygen actually causing a slight reduction in the rate of power-factor increase (which suggests the elimination of possible small active components). We thus fall back on the question of possible interaction among the three constituent materials—paper, oil, and metal.

It has long been known that oil withdrawn from contact with paper and metal electrodes suffers a deterioration as indicated by increased values of power factor and loss. Whitehead and Jones[4] made separate studies of the influence of the contact of oil with paper, with brass, and

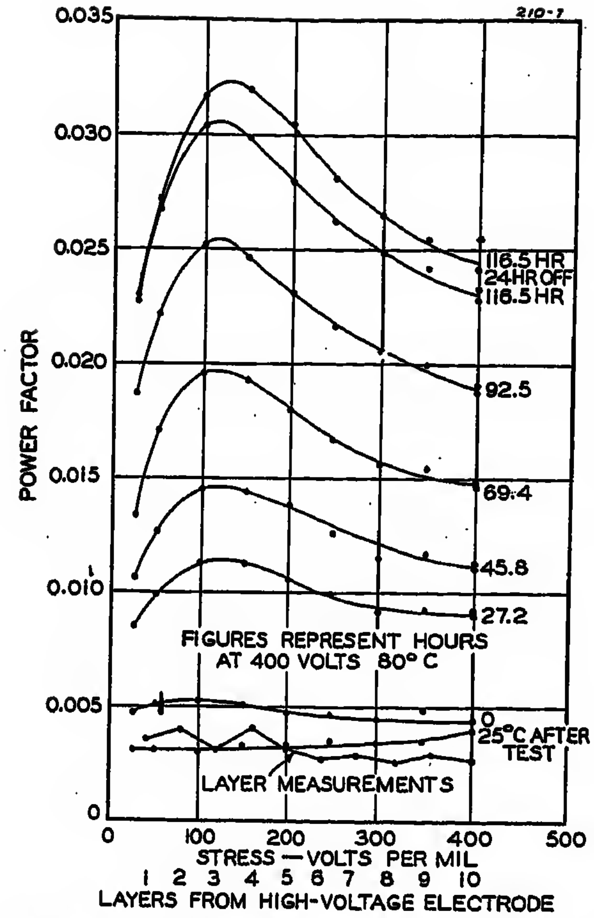

Figure 7. Changes in power factor due to combined influence of stress, temperature, and oxidation. Oil contains 0.7 per cent by volume of oxygen

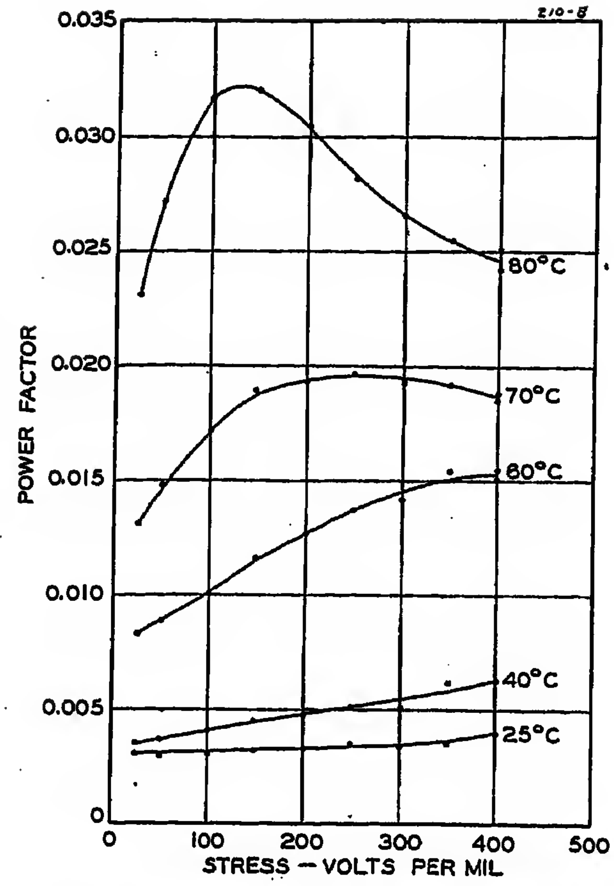

Figure 8. Changes of power factor with temperature after removal of stress. Oil contains 0.7 per cent by volume of oxygen

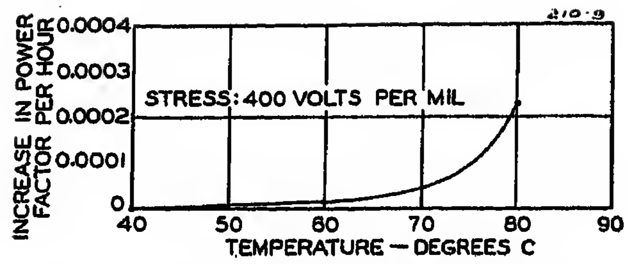

Figure 9. Rates of increase of power factor due to combined influence of stress and temperature

with both, and found that the increase in power factor over the range 20 degrees to 80 degrees centigrade was greater than the changes caused by 0.013 per cent by volume of oxygen in the oil. Thus, even with substantial amount of oxygen in the oil, observed values of the rate of deterioration up to 80 degrees centigrade are entirely accounted for by the contact of the oil with paper and with metal.

It is commonly assumed that there is no inherent electrolytic dissociation in insulating oils. Chemists are very positive in their statement that pure hydrocarbon liquids are free from such dissociation and that insulating oils should also be found in this class. However, it is well known that most such liquids, and certainly the purest insulating oils, have some residual conductivity. This has commonly been attributed to residual electrolytic impurities, but all attempts to identify such impurities, to measure them, and to eliminate them, have failed, and the liquid still shows a residual conductivity. On the other hand, some chemists[4] have maintained that all such liquids should show some electrolytic dissociation and conductivity, albeit of very low values. More recently,[5] studies of the large increase of conductivity of insulating liquids in contact with metals and under high stress have been attributed to large increases in the electrolytic dissociation with in the liquid.

If an electrolytic dissociation for an insulating oil is admitted, an explanation of the results of this paper seems to be within sight. The powerful influence of temperature in increasing electrolytic dissociation is well known. If to this we add the effect of high stress as a powerful influence for upsetting the stable equilibrium of a complex oil molecule, it is easy to see that in the combined influence of temperature and stress we might find some form of cumulative increase with time of the number of ions present. The deteriorated condition at high temperature appears to remain when the stress is removed. When the temperature is lowered loss and power factor are greatly reduced but the oil does not return to its original condition. This behavior is not inconsistent with the tentative picture presented.

It is a suggestion, therefore, of this paper, that the results reported are due to the fact that the oil itself has, or perhaps acquires as a result of contact with paper and metal, an inherent electrolytic dissociation, and that the rapid changes due to the simultaneous application of temperature and stress are due to the well known influences of these conditions on electrolytic action.

The shape of the power factor–stress curves of Figures 2 and 5 may be explained as follows: increasing stress in the low range is accompanied by increase in the lengths of the excursions of the free ions present in oil spaces, and consequently increases in conductivity and loss. However, as the voltage increases, more and more ions reach the paper barriers until all are active in each cycle, and the loss component tends to a limiting value. The capacitance component of the current increases with stress and ultimately more rapidly than the loss component. Consequently, with increasing stress the power factor passes through a maximum and then begins to decrease as shown. Power factor–stress curves of this shape were reported by one of the authors in an earlier paper,[1] and substantially the same explanation suggested. C. G. Garton and P. Böning have also discussed curves of this type.

It is hoped to continue similar studies with other oils.

Conclusions

1. Chemical instability and deterioration of impregnated paper insulation, due to the combined influence of temperature and electric stress, may begin earlier and increase more rapidly than commonly supposed.

2. Using a high grade insulating oil and a standard cable paper, the time rate of increase of dielectric loss, at 80 degrees centigrade and 400 volts per mil, is over 50 times greater than the rate of increase at 80 degrees without stress, or at 400 volts per mil stress and temperature 40 degrees centigrade. It is recognized that different values may pertain to other oils.

3. Oxygen plays only a relatively small part in the chemical changes in the oil here reported.

4. It is suggested that the behavior reported is due to electrolytic dissociation in the oil, inappreciable at low stresses and temperatures, but increasing rapidly for values which are now being approached in the operation of high-voltage cables.

Progress Report of D-C Testing of Generators in the Field

E. R. DAVIS
ASSOCIATE AIEE

M. F. LEFTWICH
ASSOCIATE AIEE

Synopsis: For many years the company with which the authors are associated endeavored to find some satisfactory method of testing generator insulation in the field. With this in mind, it was decided to experiment with higher d-c potentials. Several d-c testers were built and a series of tests made. This paper describes the progress during the first ten years of testing generators in the field with high d-c voltage.

Testing Equipment

3,000-Volt D-C Tester

A 3,000-volt d-c tester was built in 1931 using the simplest of rectifying tube circuits. This tester consisted of two rectifying tubes, filament and plate transformers, and necessary rheostats for voltage control. For purpose of measuring leakage current through armature insulation to ground, a milliammeter was used. A voltmeter was installed for measuring applied potential. Rheostats were installed in the input side of the filament and plate transformers which permitted close control of d-c test voltages from 0 to 3,000.

8,000-Volt D-C Tester

Due to the need for a higher test voltage, an 8,000-volt, one-kilowatt tester, Figure 1, was built in 1934, using practically the same rectifying tube circuit as the 3,000-volt tester. This tester permitted testing with d-c voltages ranging from 0 to 8,000.

14,000-Volt D-C Tester

In order to obtain capacity and voltage believed necessary to test the larger capacity units, a 14,000-volt 2-kw tester was built in 1940, Figures 2, 3, 4, and 5, using a standard bridge rectifying tube circuit.

Test Procedure

3,000-Volt Tests

The first routine tests were made April 6, 1932, on armatures of 3,750-kva 2,300-volt generators and on 18,750-kva 6,600-volt generators. The d-c test voltage applied was 3,000 for the 3,750-kva generators and 2,500 for the 18,750-kva generators. Test voltage between winding and ground was applied and gradually increased, the milliammeter being observed closely for any indication of excessive leakage or breakdown, until specified test voltage was reached at which point the current was read and recorded. The test voltage was then removed and generator armature grounded to discharge winding. If, however, during the initial application of test voltage, evidence of undue leakage or breakdown was noticed, test voltage was immediately removed and reapplied, slowly increasing voltage to determine the point at which this indication was observed.

8,000-Volt Tests

A new series of tests was instituted June 12, 1934, using same procedure and recording milliampere readings as described before. The d-c test potential applied on these tests was as follows:

3,000 volts for generators rated at 2,300 volts.

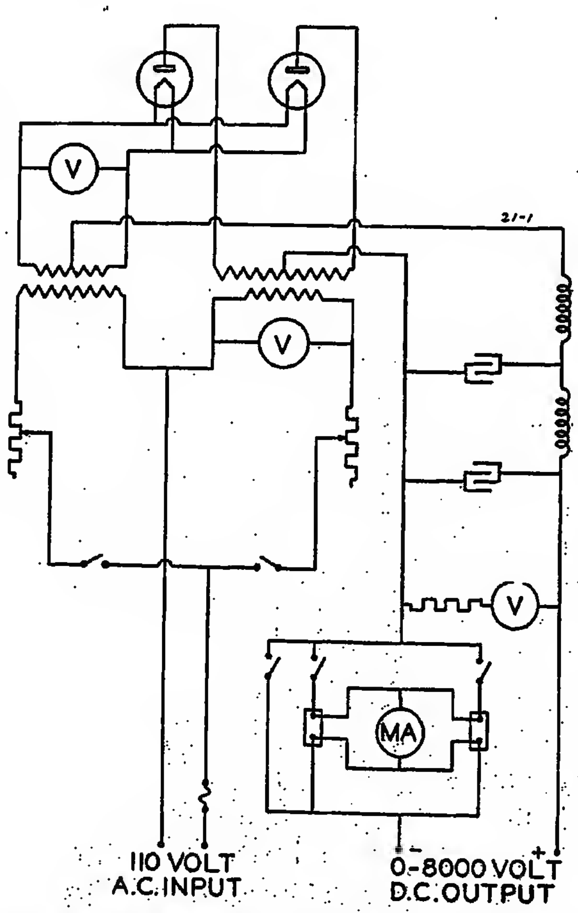

Figure 1. Schematic diagram of high-voltage d-c tester

8,000 volts for generators rated at 6,600 and 13,000 volts.

After considerable experience in testing and recording data, using both 3,000 and 8,000 volts, it became apparent that the spot readings which had been recorded heretofore were not indicative of the true insulation resistance or characteristics. Consequently, a series of special tests was undertaken in order to determine the time necessary for initial charging of the winding at various temperatures (Figure 6) before the true insulation leakage current could be accurately observed. D-c potential was gradually increased to the specified test voltage and then held constant continuously on the armature for remainder of test with a current reading recorded at the end of the first minute of the specified test voltage application and continuing with each minute of test. The specified test voltage applied for this series of tests was 3,000 for the generators rated at 2,300 volts and 8,000 for the generators rated above 2,300 volts. In addition to current readings, data on relative humidity, barometric pressure, and core iron temperature were also recorded. The generator winding was grounded prior to beginning of tests and also between each five- or ten-minute test of a series.

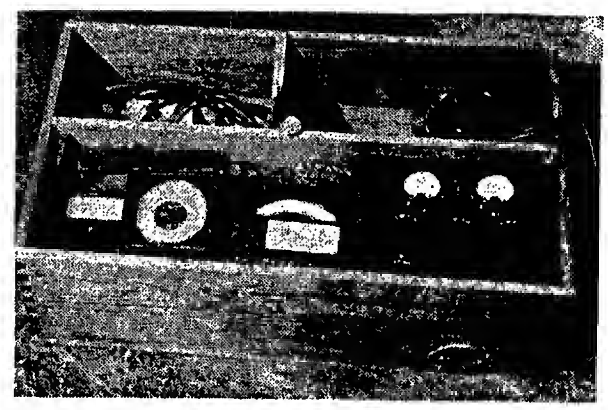

Figure 2. Testing instruments showing carrying case

From experience it was found that high per cent relative humidity during test periods has no bearing upon the test readings provided the temperature of the generator under test is higher than ambient. However, if any outdoor bus is included in the test, high per cent relative humidity will cause the milliampere readings to increase sharply, thus giving false indications of insulation leakage or resistance.

The age of insulation appears to have no effect upon the magnitude of milliampere test readings except in a new machine or new windings in old machines. It is evident that the new insulation goes through an aging process and becomes dryer. This aging condition is illustrated by curves, Figure 8.

Paper 42-1, recommended by the AIEE committee on electrical machinery for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted May 15, 1941; made available for printing October 14, 1941.

E. R. Davis and M. F. Leftwich are both with the Duke Power Company, Charlotte, N. C.

Results

3,000-Volt D-C Tests

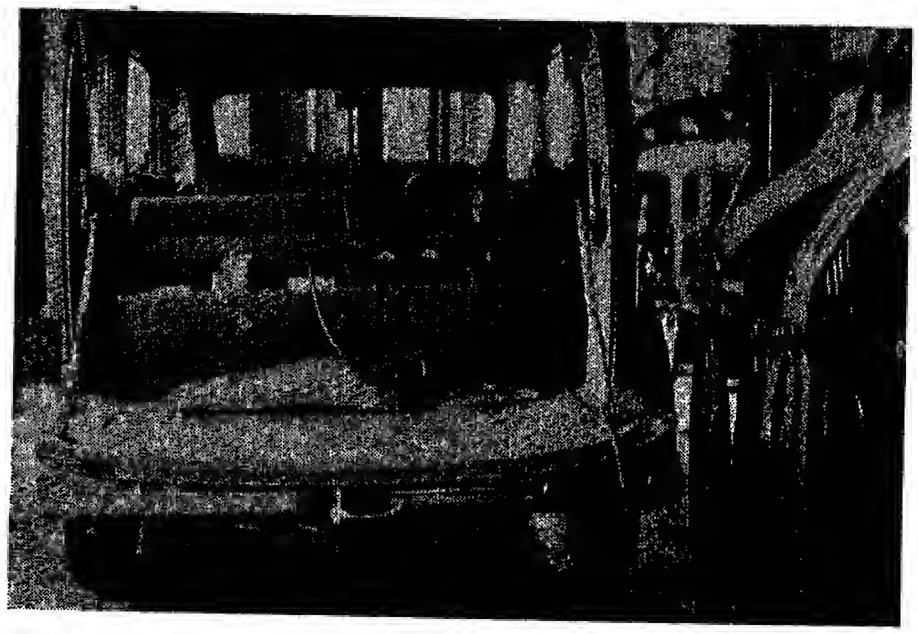

Figure 4. Field testing of an 18,750-kva 6,600-volt generator

During the course of the first routine testing, one breakdown occurred on a 3,750-kva, 2,300-volt bar-wound generator at a d-c test potential of 2,500 volts. On inspection of the point of breakdown, it was apparent from the condition of the surrounding insulation that leakage had been occurring at this point for some time. Eventually, the winding would have failed at this point with probable severe damage to core iron and adjacent coils. One new armature bar was installed in repairing the generator.

An 18,750-kva 6,600-volt lap-wound generator broke down on d-c test at 1,500 volts. The generator was then tested with a conventional tester which showed the insulation resistance to ground to be 150 megohms. The insulation of this winding consists of partly mica and partly varnished cambric which is more commonly known as "composite" insulation. Upon close inspection of the winding, a broken piece of core iron was found to have cut into a coil. The probable reason breakdown did not occur while generator was in service was that this coil was located near grounded neutral. Six new coils were installed in repairing the generator.

8,000-Volt D-C Tests

The use of the higher d-c test voltage proved beneficial in that several cases of excessive leakage were observed on routine test, which would not have been noticeable had the lower test voltage been used. In one case, the milliammeter read off-scale, 100 plus at 4,000 volts on routine d-c test of an 18,750-kva 6,600-volt lap-wound generator, when for this generator the current, as indicated from test records, should have been approximately 0.12 milliampere at 8,000 volts. In this generator the insulation in the slot portion is mica and the coil ends are of class *A* (fabric). This reading immediately indicated serious leakage to ground. The phases were separated and leakage located in slot portion of a coil midway between top and bottom of core iron. Upon examination of coils when generator was dismantled, it was found that at some time a nut had dropped down between the rotor and stator while generator was in service, cutting into core iron and coil insulation in the front of the coils (Figure 7) but not quite through to the copper. Four new coils were installed in repairing the generator.

In another case, on 8,000-volt d-c test of an 8,000-kva 11,000-volt turbogenerator, the current reading was 8.5 milliamperes which began climbing steadily after about 15 seconds from beginning of test and had increased to 16.0 milliamperes within one minute; therefore, the test voltage was removed. The test voltage was reduced to 4,000 and the current reading remained constant at 3.7 milliamperes for the entire ten-minute period of test voltage application. Next, the test voltage was increased to 6,600 at which the initial current was 6.5 milliamperes but began to rise rapidly as before, so test voltage was removed. Finally, the test voltage was slowly increased from zero in order to determine at what applied d-c voltage the current to ground began to increase, and this was found to be at 6,500 volts. The generator lead cables were disconnected and the generator was again tested with breakdown occurring at 3,500 volts. The end connectors were removed and the generator tested at 8,000 volts with the current varying from 2.64 to 2.5 milliamperes at 58 degrees centigrade within the standard ten-minute test period. Upon examination of the end connectors there was evidence of slight arcing

from one end connector to metal supporting bracket. The end connectors were repaired and replaced and final test at the end of the ten-minute test period at 8,000 volts showed a current leakage of 0.84 milliampere at 23 degrees centigrade.

14,000-Volt D-C Tests

Up to the time this paper was written, no higher d-c test voltage than 8,000 has been used. However, all d-c tests since 1940 have been made using the 14,000-volt test apparatus. It is planned at some later date to make tests on the 13,200-volt machines at nearer rated voltage than has been done before. The results of these tests when they are performed are merely a matter of conjecture, but from previous experience in testing, it is believed that the higher d-c voltage will prove more satisfactory than that used at present on the higher-voltage machines.

Initial High Charging Current

The curves shown in Figure 8 illustrate initial high charging current with the current gradually decreasing to a constant value and remaining constant for several minutes toward the end of the standard ten-minute test period. These curves are quite interesting because they were taken from the time the generator was new, June 28, 1938, up to January 3, 1941. Curves 1, 2, and 3 show the average of periodic tests, and, from a study of these curves, it is evident that the insulation leakage current has made a noticeable decrease over an operating period of approximately two and one-half years. The foregoing curves are of a generator rated at 68,750 kva 13,200 volts, having an average loading factor during this period of 95 per cent. The insulation of this generator is continuous mica tape, ASA classification *B*.

In all tests represented by curves shown, an attempt was made to duplicate as nearly as possible the temperature conditions of previous tests.

Defective Auxiliary Apparatus

Defective apparatus was found on test such as metering and synchronizing potential transformers, cracked bus insulators, and, in one case, an insect's mud nest on bus insulators caused high milliampere readings. In another case, a defective 13,000-volt potential transformer was found on a routine d-c test at 8,000 volts. The milliampere readings were found to increase steadily with each minute's duration of test voltage application. The curves shown in Figure 9 illustrate this condition as compared with previous test on this particular generator. This increase immediately indicated trouble because, as has been shown previously, the current is higher at the beginning of the test, dropping to a constant value as the test period continues. The potential transformer fuses were removed and the current immediately dropped to 0.10, showing definitely that the excessive leakage was due to the defective transformer.

Test Summary

A summary of the d-c testing in the field by the company with which the authors are associated is shown in Table I, in which the total number of tests and failures is listed as compared with number of generators tested.

A detailed listing of generator failures and some miscellaneous troubles found as a result of periodic high-voltage d-c testing is shown in Table II.

The method of correlating periodic tests on individual generators by a comparison of milliampere readings and temperatures is given in Table III.

The considerable variation between some of the periodic readings can be attributed in most cases to long periods of complete shutdown. When any abnormal increase in milliampere readings is found, further investigation is carried on by testing each phase separately to ground. During this test the remainder of the winding is grounded. This individual phase test has recently been incorporated as an annual test along with the regular periodic test schedule.

A comparison of generator failures while in service and on d-c test is shown in Table IV.

Conclusions

In a series of periodic readings on any one generator at approximately the same temperature with identical test voltage applied, any change in magnitude of milliampere readings denotes a change in the insulation characteristics. In order to determine the normal leakage or to detect changes in leakage current, accurate records must be kept of tests on each generator so that a comparison of periodic readings may be made.

Average	85	974,523	36,012	3.74	13,223	1.33

Averages calculated as of December 31, 1941. Maximum capacity of generators tested—68,750 kva.
Minimum capacity of generators tested—250 kva.

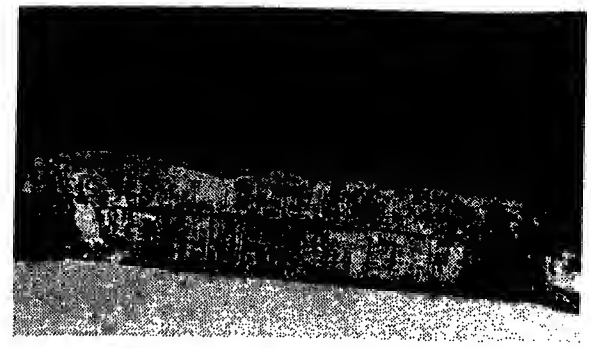

Figure 12. Defective section of coil insulation of a 12,500-kva 6,600-volt generator located with d-c tester

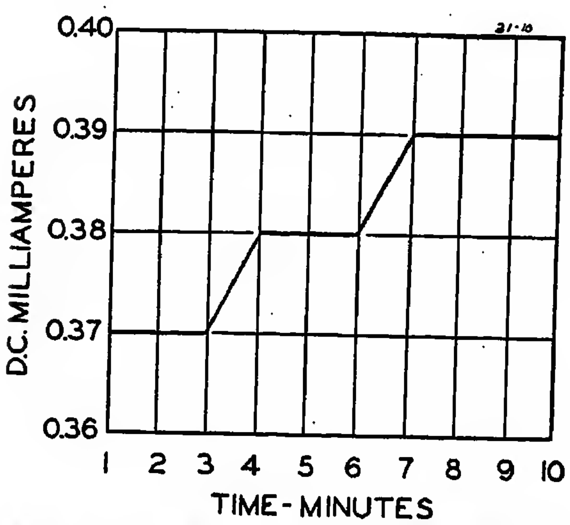

Figure 10. Characteristics of defective insulation

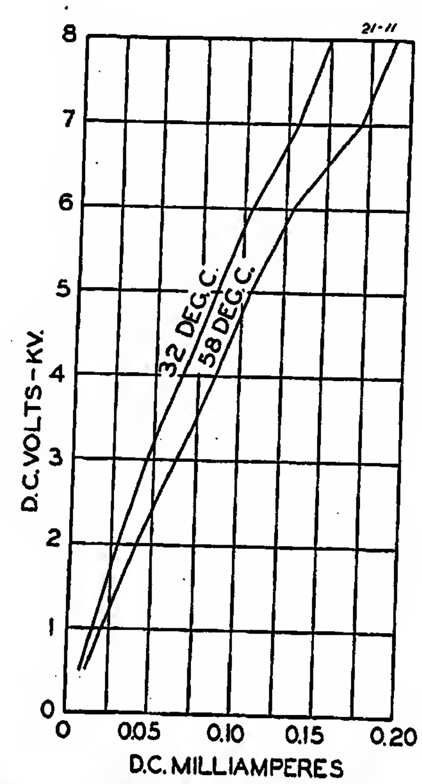

Figure 11. The relation between leakage current and applied voltage

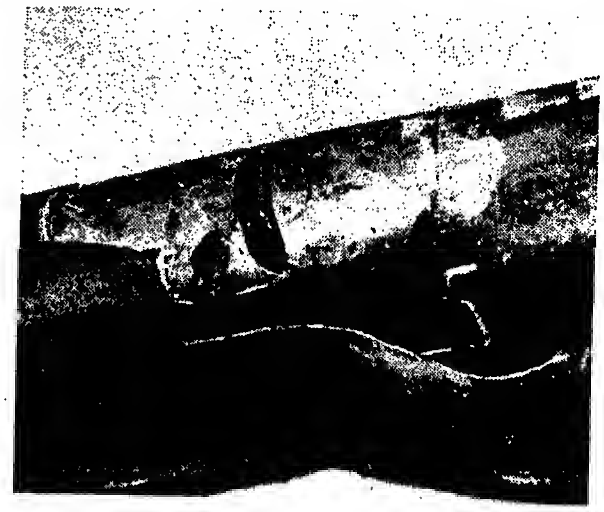

Figure 13. Defective section of coil insulation of an 18,750-kva 6,600-volt generator located with d-c tester

It was found that the 3,000-volt d-c test voltage will give excellent results in testing generators rated at 2,300 volts, 3,750 kva and below. No definite conclusions have been made as to the proper test voltage to be used for testing larger-capacity generators rated at 6,600 volts and above, although 8,000 volts has given very good results so far.

From a series of special tests it was found that the length of time required for the current to reach a constant value which is taken as the criterion of insulation resistance varied with the size, voltage, and coil insulation of the generators. Thus, the following conclusions for time of application of test potential were reached:

Five minutes at 3,000 volts for generators rated up to and including 3,750 kva, 2,300 volts

Five minutes at 8,000 volts for generators rated up to and including 18,750 kva, 6,600 volts

Ten minutes at 8,000 volts for generators rated up to and including 68,750 kva, 13,200 volts

From a study of curves (Figure 11) it may readily be seen that more accurate readings can be obtained at the higher d-c voltages. This permits using a rugged, portable milliammeter which increases the practical value of the testing unit. The values given in these curves were taken on a 22,500-kva 6,600-volt hydrogenerator which was out of service for repairs and was kept heated with space heaters so that no change in temperature occurred between readings. The generator winding was grounded for ten minutes before each voltage test. Each test voltage was applied for the standard ten-minute test period with a current reading taken each minute. The final reading at the end of the test period under each test voltage was plotted so that these curves show no initial charging current to the winding.

It has been the ultimate goal in this testing to detect, if possible, insulation weaknesses before actual failure occurred; therefore, higher d-c voltages have decided and definite possibilities in generator testing because actual breakdown of incipient insulation weaknesses was accomplished which had hitherto not been done with conventional testers. A definite indication of subsequent failure of generator insulation is denoted by a steady or sudden increase in magnitude of milliampere test readings during the test period (Figure 10). This condition, when found, demands immediate investigation. These latent weak spots were found without serious damage to adjacent coils and core iron, which would have occurred if the generator had been allowed to fail in service.

From our experience in d-c generator testing, considerable knowledge has been gained concerning the causes of generator failures and it is believed that the beginning of a majority of generator failures may be traced directly to some mechanical defect.

The testing of generators and the location of troubles before failure in service with the higher d-c voltages over a period of ten years has given us excellent and economical results.

Relative Value of Different Types of Overcurrent Protection for Distribution Circuits

G. F. LINCKS
ASSOCIATE AIEE

LINE sectionalizing in the main feeder and individual protection at branch line junctions offers a practical solution to the problem of service interruption caused by overcurrent faults on distribution lines. Actual operating data have shown that as high as 90 per cent of all consumer minutes outage (minutes of outage per consumer per year) are caused by faults out beyond the substation, with 85 to 90 per cent of the outage time resulting from faults occurring on the primary lines. These faults are divided between those which persist so as to require servicing by a line crew (permanent faults) and those which are temporary, so that they cause a negligible momentary opening of the circuit or a momentary collapse of the voltage.[1] Operating experience shows that the percentage of temporary faults varies from 15 to 85 per cent of the total,[2] depending on local conditions and the amount spent on such things as tree trimming and pulling up slack.

The judicious use of overcurrent protective relays and breakers, reclosers, and fuse cutouts depends upon a knowledge of the function and characteristics of these devices[3] and the relative benefit each affords. Automatic opening and reclosing of the circuit can be accomplished with all three types. The relay and some types of reclosers reset automatically after a temporary fault, whereas other types of reclosers and reclosing fuse cutouts require manual resetting or the installation of a new fuse link after a prescribed number of operations. Operating records (Table I) show that the first reclosing of the circuit is the most effective in service restoration, tapering down substantially for subsequent reclosures.[3]

Successful line sectionalizing and branch protection depend on the adequacy of available equipment to meet operating requirements. Advancements in the design and manufacture of fuse links for distribution cutouts have made them approach the high degree of accuracy and dependability of the induction relay.[4] Service records of selectivity of operation over four or five years are being secured with fuse links connected in series and in series with relays, revealing no improper operations.

The major problem is, therefore, when and how best to apply these different devices to provide the best service continuity that can be justified economically. There is a real need for actual operating data evaluating the benefits numerically. This would provide information on the devices under the differing conditions of the various systems. It would not, however, give a comparison of the relative benefits of the different devices under identical conditions. It seems there is little prospect of an early investigation being conducted in service to determine this relationship, so a mathematical study has been substituted. Naturally, this study is limited by the very rigidity of the assumptions, even though they are made as closely as we know how, to operating experience. However, we believe the study should provide a greater knowledge of the relative improvements in service continuity provided by available equipment. This will aid in the selection and application to suit the needs and economics of a particular circuit.

Calculations and Presentation of Data

Separate studies were made on two different setups of the distribution lines, namely: one for branch protection, as in Figure 1, and another for line sectionalizing with protective devices connected in series, as in Figure 2. Using the assump-

* From operating experience of the New York Power and Light Corporation, Albany, N. Y., covering portions of the lines to first sectionalizing point on the feeder. The values after "reclosure" indicate the number for which service was restored, or after "lockout" the number for which a permanent outage occurred.

Paper 42-2, recommended by the AIEE committees on power transmission and distribution and protective devices for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted April 15, 1941; made available for printing October 28, 1941.

G. F. Lincks is electrical designing engineer in the distribution fuse cutout section of General Electric Company, Pittsfield, Mass.

The author wishes to thank those who co-operated in making this study, especially Charles R. Craig who did many of the detailed calculations.

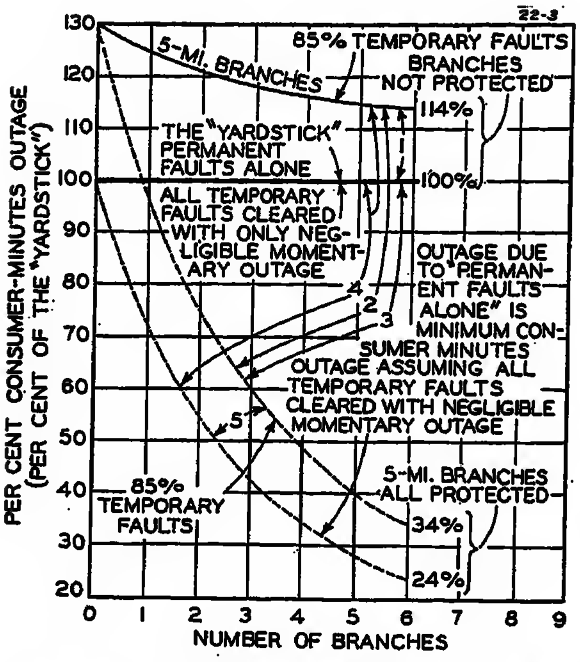

Figure 3. How to read the curves of Figures 4 to 13 inclusive

The curves shown duplicate those of Figure 4 for a nonreclosing substation breaker and single-element fusing at the branches

The "yardstick" equals the best service continuity obtainable with substation equipment alone (see Table II)

The upper pair of solid-line curves gives consumer minutes outage without branch protection and the lower pair of dash-line curves with branch protection. The important observations to be made in this and succeeding figures are (see reference figures on curve):

1. That the consumer minutes outage for the actual substation protection alone is higher than the "yardstick" because the breaker trips on some or all temporary faults as well as on permanent faults (see assumptions and Table IV in the appendix)
2. The improvement over actual substation protective equipment alone
3. The improvement over the "yardstick"
4. The improvement when permanent faults alone produce outages with branch protection—or line sectionalizing (this may be the improvement over the "yardstick" or over the actual substation protection)
5. The consumer minutes outage for manual restoration of service because temporary faults actually cause prolonged outages by tripping both the breaker or the branch or line sectionalizing device (note that for branch protection Figures 4 through 9, this is less than observation 1)

These observations can be converted into actual numerical values, as:

Per cent of ultimate improvement attainable =

$$\frac{\text{observation 2}}{\text{observation 4}}=\frac{114-34}{114-24}=86.7 \text{ per cent}$$

Table II. Calculated Values of Consumer Minutes Outage for Permanent Faults Alone With and Without Line Sectionalizing

(Based on Assumptions as Outlined in Appendix)

Number of Sectionalizing Points	Per Cent Temporary Faults: 25	50	60	75	85	0–99.9+
	Consumer Minutes Outage for Permanent Faults Alone					*Per Cent Consumer Minutes Outage
♯ None (the "yardstick")	2,137.5	1,425	996.25	712.0	427.5	100
1	1,363	919	638.0	456.0	273.8	64.0
2	1,138	758	552.5	380.2	228.0	53.3
3	1,025	682	478.0	342.0	205.5	48.0
4	951	633	442.5	316.0	189.9	44.4
5	906	602	421.5	302.0	181.0	42.3
6	874	583	407.5	291.5	175.0	40.9

$$\text{* Per cent}=100\times\frac{\text{Actual consumer minutes outage calculated for setup}}{\text{The "yardstick"}}$$

$$=100\times\frac{\text{Consumer minutes outage caused by permanent faults alone with line sectionalizing}}{\text{Consumer minutes outage caused by permanent faults alone without line sectionalizing (or branch protection)}}$$

For example:

$$=\text{for 1 sectionalizing point 25\% temporary faults}\frac{1{,}363}{2{,}137.5}=64.0\%$$

$$=\text{for 1 sectionalizing point 75\% temporary faults}\frac{456.0}{712.0}=64.0\%$$

♯ In a corresponding table for branch protection, the consumer minutes outage equivalent to these values—for "permanent faults alone" with no branch protection will vary with each different length and number of branches and will thus compensate for the increasing length of the total line (Figure 1). Consequently, the percentages can be compared, as in Figures 4 to 9, inclusive, to determine the relative improvement.

Table III. Maximum Number of Sectionalizing Points Possible With One-, Two-, and Three-Element Cutouts

Type of Cutout	To Secure Proper Sequence of Operation: Minimum Spread Between Fuse Ratings	*Maximum Number Sectionalizing Points Possible
One-element	Every second rating	7
Two-element	†Every second (sometimes every third)	Generally 7 (sometimes between 4 and 7)
Three-element reclosing	Every third or fourth rating	♯3 or 4

* Based on 14(N) ratings of fuse links available from 10 to 100 amperes; 10-ampere assumed to be minimum sectionalizing fuse employed.

† See reference 7.

♯ Always at least one less than for two-element cutouts.

tions outlined in the appendix, the number of minutes outage per consumer per year (consumer minutes outage) on the whole circuit was determined for each type and for practically all combinations of types of protective devices now in general usage.

Generally, the problem of whether to use protective devices connected in series on the main feeder or on the branches centers around the advisability of combining these protective devices with nonreclosing equipment at the substation. Thus the "yardstick," chosen for comparison of the relative values of the different equipments and applications, relates everything to the best service continuity obtainable with substation protection alone, that is, without any line sectionalizing or branch protection.

In determining the best service continuity, it was taken into consideration that something might be done about automatic restoration of service after temporary faults, but permanent faults require the time and the work of a line crew before service can be restored. Thus when the consumer minutes outage caused by "permanent faults alone" is the "yardstick," it represents the minimum consumer minutes outage that can be attained with substation protection alone. Such a "yardstick" is universally applicable to any system and, therefore, was used as the 100 per cent base to which all types of protection were related in terms of a percentage of this base.

$$\text{Per cent}=100\times\frac{\text{Actual consumer minutes outage calculated for specific setup}}{\text{The "yardstick"}}$$

$$=100\times\frac{\text{Consumer minutes outage caused by permanent plus temporary faults for any specific system setup}}{\text{Consumer minutes outage caused by permanent faults alone with no branch protection or line sectionalizing}}$$

Comparisons made in terms of this percentage tend to eliminate the effect of variations of actual practice from the assumptions employed in the study, in so far as this is possible. With any specific system setup, comparisons to the "yardstick," to each other, and to the ultimate attainable can be made of the following:

1. The improvement obtainable with reclosing versus nonreclosing relays and breakers.

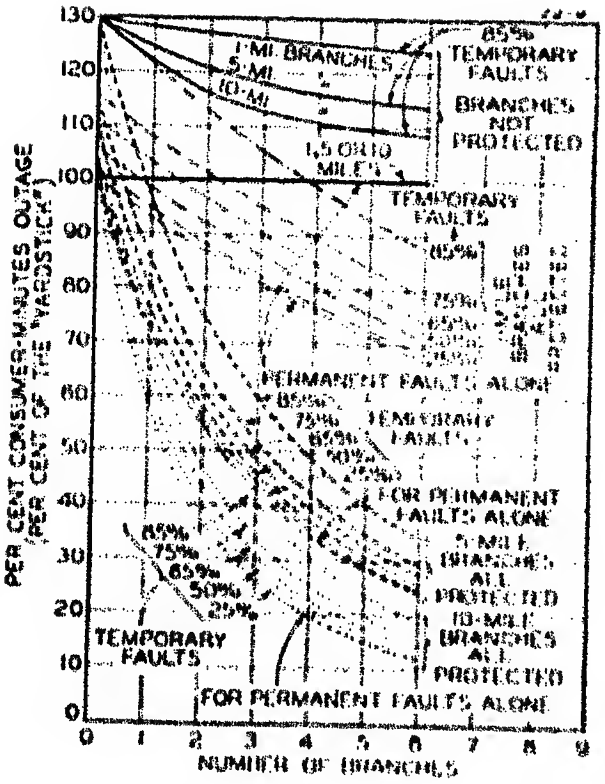

Figure 4 (left). Single-element fusing at branches with nonreclosing breaker at substation

The curves for no branch protection exceeds 100 per cent, because the nonreclosing breaker opens on temporary faults. Five observations should be made:

1. The very large reduction in consumer minutes outage for the "permanent faults alone" with branch protection and the very small additional outage time caused by the branch fuses blowing or breaker operation on temporary faults

2. The longer branches show much greater benefits in reduction of outage time

3. The spread between the curves for permanent faults alone and 85 per cent temporary faults is substantially less for the longer branches

4. The outage time due to temporary faults opening breakers or blowing branch fuses does not reach substantial values until 50 per cent, or until the temporary faults become greater in number than the permanent faults

5. Above 50 per cent the increased outage time on temporary faults increases much faster

2. The additional benefit with various amounts of branch protection or line sectionalizing.

3. The benefit of different combinations of substation and line equipment.

4. The effect of maintenance of line to reduce the percentage of temporary faults.

Curves Provide for Studying Individual Problems

It will be impossible to discuss adequately in the span of one paper all phases of the problem covered by this study. Even if this were attempted, there would be many other questions that would present themselves in actual operating practice on different systems. Therefore, curves (Figures 4 to 9 inclusive for branch protection, and Figures 10 to 14 inclusive for line sectionalizing with a number of protective devices connected in series) have been plotted, in view of their future usefulness in studying specific problems on different systems that may not be covered in the general conclusions to be drawn. The curves present a large share of the data compiled in this study, which may not fit a specific system exactly but should provide a fairly close approximation. The curves for one particular system setup, such as branch protection with nonreclosing breakers, Figures 4 and 8, are all plotted on one or two curve sheets to permit visual determination of the relative benefits with different equipments, percentages of temporary faults, lengths of branches, and so forth. Numerical values can be determined or visualized as described in Figure 3 on "How to Read the Curves."

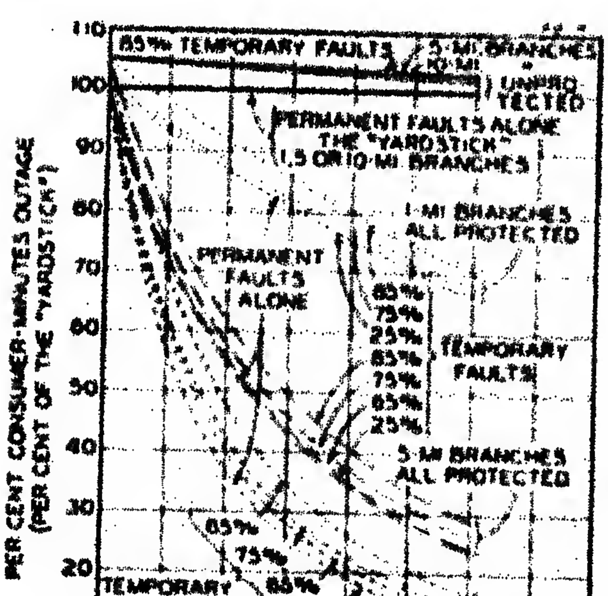

Figure 5 (lower left). Single-element fusing at branches with reclosing breaker at substation

The reclosing breaker obviously reduces to a negligible value the outage time when clearing temporary faults. Observe three things:

1. That the outage time caused by the blowing of branch fuses on temporary faults is of not much importance up to 75 per cent or even 85 per cent values

2. That the spread for temporary faults covers a very narrow range and does not vary materially with the length of the branch as it did in Figure 4

3. That the improvement provided by the reclosing breaker is not so great with an increasing number of branches, because the branch protective devices afford this improvement with the nonreclosing breaker

For example, compare the top line (for 85 per cent temporary faults) of the groups marked "five-mile branches all protected" in Figures 4 and 5. With 0 branches the curves start at 130 per cent in Figure 4 and at 104 per cent in Figure 5 or a difference (improvement) of 26 units. With three branches the improvement is ten units (60 per cent in Figure 4 and 50 per cent in Figure 5) and with six branches it is six units (34 per cent in Figure 4 and 28 per cent in Figure 5)

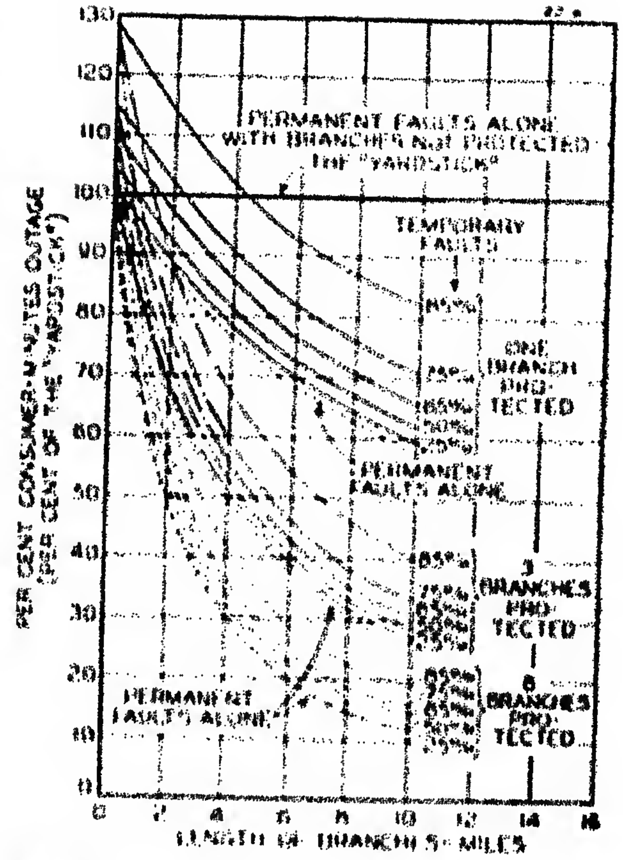

Figure 6. Value of branch protection with different lengths and number of branches with single-element fuse cutouts. Nonreclosing breaker at substation

These curves are similar to those in Figure 4, except that the variable is the length rather than the number of branches. A reclosing breaker at the substation would show, of course, the same improvement over the values in Figure 5 as the above shows over Figure 4. Observe that, while the major improvement is provided with branches four to ten miles in length, there is an appreciable gain over substation protection alone, even with branches one mile long especially where there are several of them

The Effect of Feeders Shorter or Longer Than 30 Miles

The curves in Figure 14 are intended for modification of the other curves (Figures 10 to 13 inclusive) when sectionalizing feeders shorter than 30 miles. If the percentages in Figure 14 are added directly to the values of Figures 10, 11, 12, and 13, the result will be reasonably accurate. For rural feeders longer than 30 miles the reduction from the percentages of Figures 10, 11, 12, and 13 would be so small that they can be neglected.

Combining Branch Protection and Line Sectionalizing

Individual protection of several comparatively short branches and of line sec-

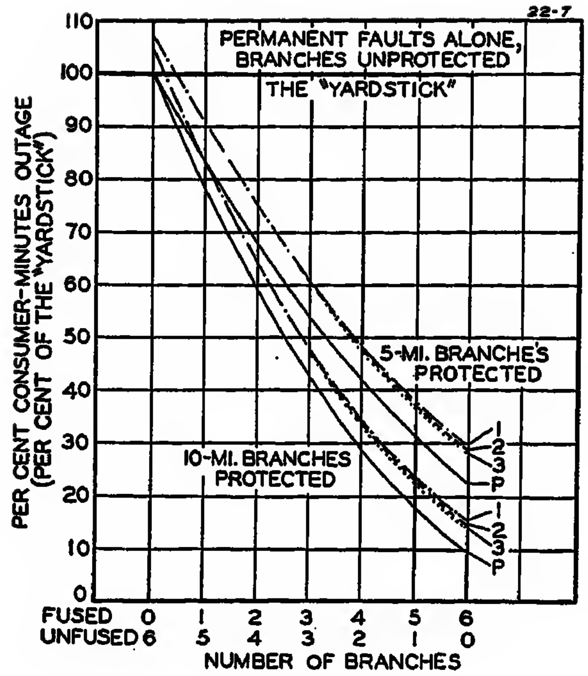

Figure 7 (left). Partial branch fusing, using similar cutout at substation—75 per cent temporary faults

1 = Single-element fuse
2 = Two-element fuse
3 = Three-element fuse
P = Permanent faults alone

Many rural lines employ the same type of protection at the substation as that used on the branches, as is illustrated by these curves. It is obvious from these curves that all the branches should be protected. For the effect with less than six branches see Figure 8. Observe that two- or three-element fuses do not show much improvement over single-element fuses

Curves for the resetting recloser would fall just below those for the three-element fuses as in Figure 8

tionalizing with overcurrent protective devices connected in series, was studied separately. The cumulative benefit resulting from a combination of these can be approximated. The curves for such a combination (drawn similar to Figures 4 to 9 inclusive) would start at a percentage value for zero branches which is identical to that shown for the degree and type of sectionalizing employed in Figures 10, 11, 12, and 13. The whole curve would not be moved down bodily as the improvement would decrease with an increasing number of branches.

With a circuit comprising several long branches, the effect of the individual branch protection will be governed by the data in curves of Figures 4 to 9 inclusive. The use of devices connected in series on individual branches should be studied by treating each branch separately in accordance with the data in Figures 10 to 14 inclusive.

Some Protective Devices Can Be Connected in Series in Greater Numbers Than Others

An important factor that should not be overlooked in comparing different equipments, when employed for line sectionalizing, is the number that can be connected in series and still provide proper selectivity of operation[5-6] from the service entrance fuse to the feeder relay and breaker. For example:

1. In comparing two- and three-element reclosing fuse cutouts, it is possible to secure discriminative operation with more of the two- than of the three-element devices connected in series. If an equal number could be employed, the extra reclosure of the third element would account for 10 to 18 per cent reduction in consumer minutes outage (at 85 per cent temporary faults) tapering down to zero (at 25 per cent temporary faults) as shown in Figures 10 and 11. However, splitting the line up into a greater number of sections with the two-element cutouts[6-7] (see Table III) generally affords as good or better service continuity than with three-element cutouts. Sometimes an attempt is made to secure closer fusing by allowing an individual fault to blow two or more section fuses simultaneously, depending on the reclosing fuse nearer the source of supply to maintain service. This voids the benefit of the reclosing cutout closer to the substation, unless all such blown fuses are always renewed before an outage occurs.

2. In regard to automatic resetting reclosers, there are several different ratings available, such as 3, 6, 12, 25, and 50 amperes. Generally, all of these will co-ordinate properly when connected in series. However, it is not always practicable to provide automatic selectivity of operation between the smaller size reclosers and the transformer fuse. This either limits the minimum rating of the recloser usable, and thus the number of sectionalizing points, or necessitates manual closing of the circuit through a fuse shunting the recloser, in order to blow the transformer fuse and thereby locate the fault. In this latter case, the values determined in this study do not apply, since the transformer faults would slightly increase the number of line outages with the reclosers, above the one per mile used for the other types of equipment or system setup. The amount of decrease in the value of the recloser as shown in the data obtained in this study, would depend upon the ratio of transformer-to-line faults. The number of transformer faults which would cause lockout of the recloser are, in general, substantially less than the number of line faults.

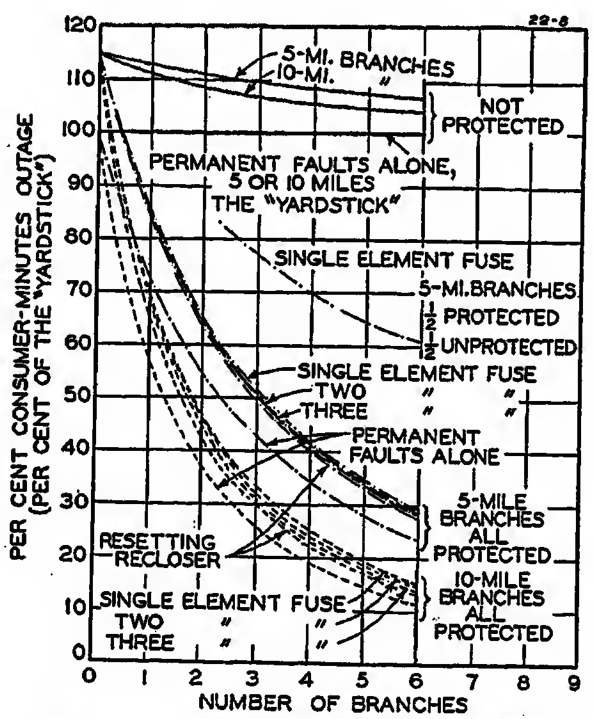

Figure 8. Different types of branch protection with nonreclosing breaker at substation for 75 per cent temporary faults

If a reclosing breaker were used at the substation, the curves would be shifted as in Figure 5. Observe that the reduction in outage time by the reclosing devices below that provided by single-element fuse is very small, due to the few consumers affected by the outages on one branch, caused by temporary faults that otherwise would have had service restored automatically by the reclosing devices (this difference would increase slightly with 85 per cent temporary faults and become negligible at lower percentages)

For Reclosers Which Do Not Reset Automatically

The conclusions drawn and the data in the curves for reclosing fuse cutouts apply

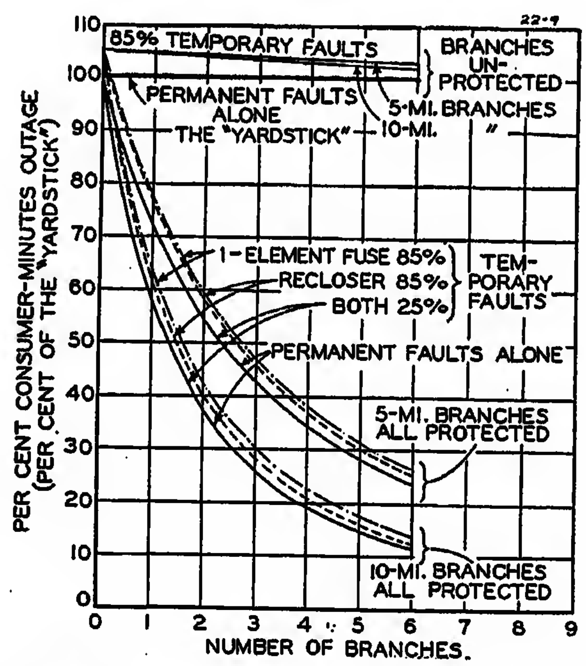

Figure 9. Branch protective devices delayed beyond first instantaneous opening of reclosing substation breaker

The curves start above 100 per cent at zero branches and 85 per cent temporary faults, because the breaker locks out on some temporary faults. The curves for two- and three-element fuses would fall between those for the single-element fuse and the resetting recloser, but, as the range is too narrow, they were not plotted. The curves for 25 per cent temporary faults are so close to those for "permanent faults alone," that they are plotted as one curve. The curves for 50, 65, and 75 per cent temporary faults would fall between those for 25 and 85 per cent about proportionately to those in Figure 5. Observe that here again the outage time is not reduced much below Figure 5

to any type of apparatus with an equal number of reclosers and without the feature of automatically resetting after clearing a temporary fault.

Conclusions

The study permits drawing general conclusions, which may be helpful in system planning.

Is Substation Protective Equipment Enough?

1. Combining overcurrent branch protection or line sectionalizing—with reclosing breakers at the substation—provides a cumulative reduction in consumer minutes outage that neither method alone can provide (compare curves of Figures 4 with 5, 8 with 9).

2. The cumulative reduction from this combination is not so great as with an increasing number of branches or sectionalizing points, but a number of branches do provide substantial combined benefit (see discussion in captions of Figures 5 and 11).

3. Overlapping the substation reclosing protection with line protective devices provides some additional improvement with branch protection and a major improvement with line sectionalizing. With such overlapping, the breaker trips and recloses once, without the branch or line protective device opening for all faults out to the ends of the line, and then the relay provides time delay, so that the branch or line sectionalizing protective device disconnects the faulted portion of the circuit ahead of the second tripping of the relay. Single-element fusing at the branches or sectionalizing points with this overlapping protection approaches very closely to providing the minimum consumer minutes outage attainable for the specific system setup.

4. Where such overlapping protection as in paragraph 3 reaches only part way out on the line, the improvement over a reclosing breaker will be approximately proportional to the percentage of the line so protected, that is, if half the line is so protected, the improvement will be about one half of the difference in percentages between that percentage with a reclosing relay Figure 5 or 11, and that with the overlapping protection covering the whole line, Figure 9 or 12 respectively.

Of What Value Is Branch Protection?

1. Overcurrent protection of individual branches provides a greater improvement over substation protection alone, than is provided by line sectionalizing (compare corresponding curves Figures 4-9 with Figures 10-13).

2. The length of the branch has a major effect on the benefit secured (see Figures 4, 5, and 6).

3. Protecting even a number of short branches provides a cumulative improve-

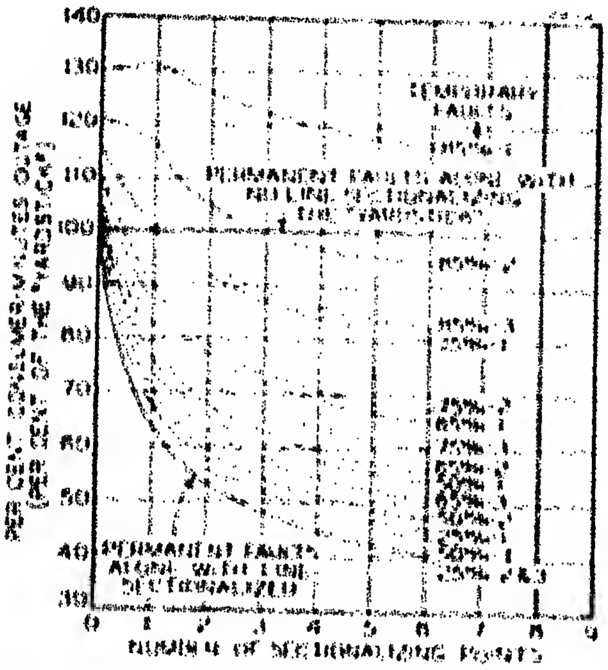

Figure 10. Line sectionalizing with single-element fuse cutouts and with two- and three-element reclosing fuse cutouts with same type at substation as at sectionalizing points

1 = Single-element fuse
2 = Two-element fuse
3 = Three-element fuse

These curves represent conditions found on many rural circuits where the same type of protection is employed at the substation and out on the lines. A nonreclosing breaker could be substituted for the single-element fuse at the substation without changing these curves but, when substituted for the two- and three-element fuses, would raise these curves. The curves exceed the "yardstick" (100 per cent) because of the temporary faults causing outages. Observe three things:

1. The very large reduction in consumer minutes outage for "permanent faults alone" with line sectionalizing, but the much greater increase in this outage time caused by opening on temporary faults by sectionalizing fuses as compared with branch fuses, Figure 4

2. Single-element fusing provides an improvement (for all but one sectionalizing point at 85 per cent temporary faults) which with 65 per cent and lesser percentages of temporary faults is more than half of that obtainable

3. Two- and three-element fuses show much more benefit for sectionalizing than for branch protection

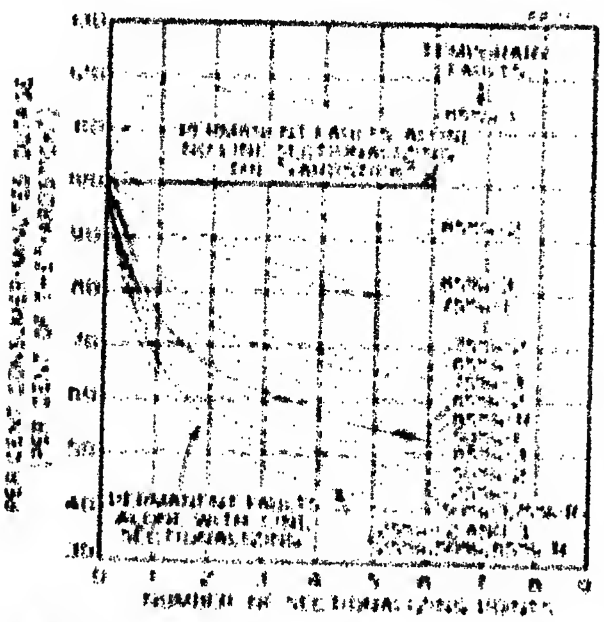

Figure 11. Line sectionalizing with reclosing breaker at substation

1 = Single-element fuse
2 = Two element fuse
3 = Three-element fuse
R = Resetting recloser

The curves exceed the "yardstick" (100 per cent) with 0 sectionalizing points due to the breaker locking out on some temporary faults (see Table IV in appendix). The reclosing breaker obviously reduces to a negligible value the outage-time when clearing temporary faults with no sectionalizing. Observe:

1. That this reduction is not so great with an increasing number of section points (as with branch protection, Figure 5), because line sectionalizing affords some of this reduction anyway, and because the benefit is restricted to the first section beyond the substation, which becomes shorter as the number of section points is increased

2. That single-element fusing provides almost an equal degree of improvement over the reclosing breaker alone as with a nonreclosing breaker, Figure 10

3. That resetting reclosers show a substantial improvement over three-element fuses with temporary faults exceeding 50 per cent

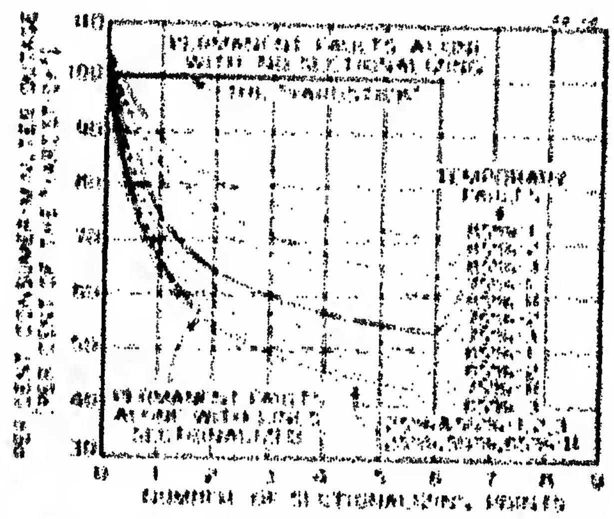

Figure 12. Line sectionalizing with reclosing substation breaker, set for instantaneous tripping on first opening, with all types of sectionalizing devices delayed to open only ahead of second opening

1 = Single-element fuse
2 = Two-element fuse
3 = Three-element fuse
R = Resetting recloser

It is assumed that all faults cause operation of the instantaneous trip, corresponding to ground relaying only. The improvement shown will be decreased approaching the corresponding curves of Figure 11, about proportionately to the percentage of faults that are line to line. Observe three things:

1. The major reduction in outage time with all types of sectionalizing equipments, because this overlapping protection is the equivalent to adding one automatic resetting reclosure to the device at each section point

2. The outage time is negligible due to fuse blowing or breaker opening on temporary faults even with single-element fuses at 65, and lesser percentages of temporary faults

3. Reclosing fuses or resetting reclosers at the section points become effective at 75 and higher percentages of temporary faults

ment that is likely to justify at least single-element fusing (see Figures 4, 5, and 6).

4. Individual protection should be applied to all the branches. Protecting only a portion of the branches affords less benefit, Figure 7, than protecting all the branches, Figure 4 (see also Figure 8).

5. Single-element fusing of branches provides approximately 85 to 95 per cent of the total improvement obtainable (see value worked out in example in Figure 3; see also Figures 4, 5, and 8).

6. Two-element reclosing fuse cutouts provide a slight additional improvement in service continuity (see Figures 7 and 8).

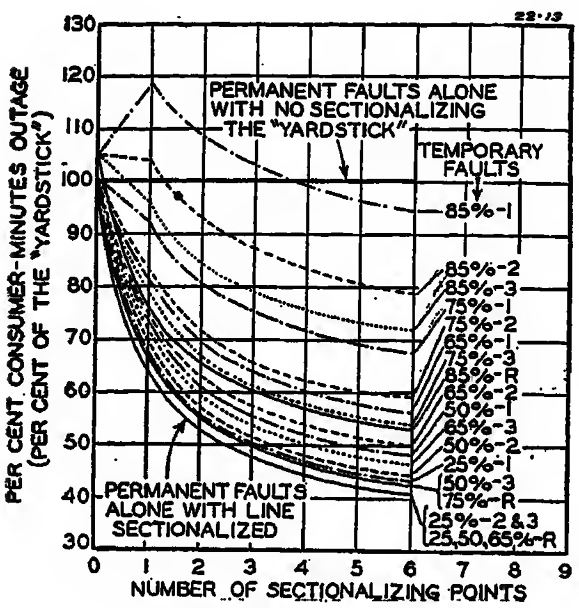

Figure 13. Line sectionalizing with reclosing substation breaker, set for instantaneous tripping on first opening, with all types of sectionalizing devices delayed to open only ahead of second opening of breaker. Breaker protection for only half of line

1 = Single-element fuse
2 = Two-element fuse
3 = Three-element fuse
R = Resetting recloser

Quite often the minimum obtainable pickup current setting of the relay only permits protecting part of the line or on delta circuits the overlapping protection only reaches out part way on the line. These curves show the effect of such relaying covering the first half of the 30-mile feeder. This does not overlap the sectionalizing device with just one point which is located at the center of the line so that the values under this condition are the same as in Figure 11. It should be noted that these curves are located about half way between the respective curves of Figures 11 and 12, or about proportionately to the section of the line on which the overlapping protection is provided

7. Three-element reclosing fuse cutouts afford so little benefit over the two-element reclosing fuse cutout that it raises the question as to the justification for the extra premium paid for the third fuseholder, Figures 7 and 8. (This is true even though the assumptions of Table IV in the appendix favor the three-element device.)

8. Reclosures which reset automatically after clearing a temporary fault provide only a slight additional improvement over that accomplished by reclosing cutouts, even when fuses are not renewed until an actual outage occurs (see Figure 9).

Of What Value Is Line Sectionalizing?

1. Sectionalizing the main feeder and long branches with protective devices connected in series generally affords additional improvement over the best service continuity that can be afforded by overcurrent protective equipment located at the substation.

2. Sectionalizing with single-element fuse cutouts is generally very effective. They

(*a*). Will afford the major portion of the total obtainable improvement at 65 or a lesser percentage of temporary faults with nonreclosing or reclosing substation breakers (see Figures 10 and 11).

(*b*). Will be more effective at 80 per cent temporary faults with the reclosing substation breaker which provides overlapping operation, that is,

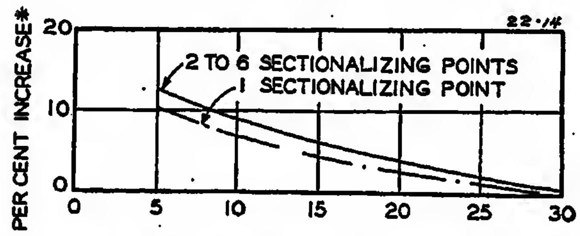

Figure 14. Line sectionalizing shorter lines

Same as on other curves so that these can be added directly to values in Figures 10, 11, 12, and 13

tripping ahead of all the fuses on the first operation, than three-element reclosing cutouts with a reclosing breaker but no overlapping protection—under similar conditions, at 65 or a lesser percentage of temporary faults will equal the best of reclosing equipment without overlapping protection (compare Figure 12 with 11).

(*c*). Require more than two points with a reclosing breaker or more than one point with a nonreclosing breaker in order to improve rather than impair service at 85 per cent temporary faults (see Figure 10).

3. Sectionalizing with two and three-element reclosing fuse cutouts is much more effective than the use of similar equipment for branch protection. Each affords respectively

(*a*). Some additional improvement over no sectionalizing at 85 per cent temporary faults with a reclosing cutout or breaker at the substation (see Figures 10 and 11).

(*b*). About 25 to 35 per cent additional improvement over the effective operation of the single-element fuse cutout at 75 per cent temporary faults with a reclosing cutout or breaker at the substation (see Figures 10 and 11).

(*c*). About 10 to 15 per cent additional improvement over the much greater effectiveness of the single-element cutout at 85 per cent temporary faults with overlapping reclosing breaker operation (see Figure 12).

The additional improvement referred to in (*a*), (*b*), and (*c*) above is in per cent of the ultimate obtainable between the curves for "permanent faults alone," with and without line sectionalizing. These percentages do not include any of the advantages possible from discovery and renewal of blown fuses with a service interruption (see Table V in the appendix).

4. Generally, two-element reclosing fuse cutouts are more effective than three-element designs because a greater number of the two-element cutouts can be connected in series and still provide selectivity of operation (see Table III). Figures 10 and 11 show this even with the more favorable assumptions for the three-element fuse of Table IV in the appendix.

5. Sectionalizing with reclosers, which reset automatically after clearing a fault, is most effective at the higher percentages of temporary faults where the resetting feature has a greater opportunity to decrease the number of outages of long duration caused by temporary faults, Figure 11.

(*a*). With 85 per cent temporary faults and a reclosing substation breaker, this amounts to 40 to 60 per cent additional improvement over three- and two-element cutouts respectively (see Figure 11).

(*b*). This additional improvement tapers down from about 25 and 35 per cent at 75 per cent temporary faults, to zero at 25 per cent (see Figure 10).

(*c*). With reclosing breakers at the substation which clear ahead of the protective devices on the first opening, the additional improvement is only about 15 to 25 per cent (see Figure 12).

The percentages of additional improvement (*a*), (*b*), and (*c*) above do not take into consideration any difference in the number of reclosers and cutouts that can be connected in series and provide proper co-ordination.

Should Branch Protection and Line Sectionalizing Be Combined?

1. There is a cumulative benefit obtainable by combining branch protection and line sectionalizing which cannot be provided by either one alone.

2. This cumulative benefit is obtainable, whether the system comprises one main feeder with a number of short branches, or two or more long branches with a short main feeder. (With the latter, the branches would be sectionalized with protective devices connected in series.)

3. The cumulative benefit does not increase directly with an increasing number of protected branches.

Should the Percentage of Temporary Faults Be Considered?

1. Any decrease obtainable in the percentage of temporary faults tends to permit securing an equal improvement in service continuity with lower cost overcurrent protective devices.

2. It might prove valuable to make a study in which the costs of improving line construction, tree trimming, and so on are compared with the savings in protective equipment which the improvements made possible.

Use of Curves for Specific Studies

It has been shown by this study that individual protection of branches and/or line sectionalizing can be combined effectively with the reclosing substation relay and breaker to reduce the consumer minutes outage on distribution systems. The data presented in the curves should facilitate the studying of specific problems.

This may make possible more efficient use of available equipment to meet the particular needs and justifiable economics of different circuits and systems.

Appendix. Assumptions Employed in Mathematical Study

1. *The Distribution Lines Studied (Length of Lines).*

(*a*). In one part of the study, one to six unprotected and protected branches, each one, five, or ten miles in length, were added at the mid-point of an unsectionalized 30-mile main feeder, increasing the total length of line, as in Figure 1. (The difference in total length might introduce a slight error in comparing the benefit provided with and without branch protection, but not in comparing the relative benefits afforded by the different equipments that might be employed.) Connecting the branches at the mid-point provided an average for an even spacing of the branches along the feeder.

(*b*). In the other part of the study, a 30-mile main feeder was broken up into from one to seven sections by zero to six overcurrent protective sectionalizing devices connected in series as in Figure 2. (The effect of the shorter, 5 to 30-mile feeders, was checked.)

2. *Equipment Employed.* Both studies included checking comparative results with overcurrent protection provided by:

(*a*). Substation breakers actuated by nonreclosing relays, automatic reclosing relays, and automatic reclosing relays which overlap all branch and line protective equipment, so that the breaker trips and recloses once without the branch or line devices opening, and then provides time delay before the second tripping of the relay on more persistent faults; each combined with

(*b*). Sectionalizing or branch-line single-element or two- and three-element reclosing fuse cutouts or reclosers which reset automatically after clearing a temporary fault.

3. *Number of Consumers.* Three per mile uniformly distributed. (Any other number per mile might have been used without affecting the percentages used for comparison.)

4. *Number and Type of Faults.* One per mile per year uniformly distributed with temporary faults equaling 25, 50, 65, 75, and 85 per cent of the total. (One per mile is probably somewhat high but any other value might have been used without changing the percentages used for comparison.)

5. *Attended Substation.* A period of five minutes was allowed after the fault occurred for notification and for the attendant to close the breaker, thus restoring service if a temporary fault had cleared itself after the breaker locked open. (Notification by an alarm system at the substation would lower the percentages used for comparison to the extent that the manual closing of the breaker approached that of a momentary outage. Conversely, any lengthening of the time, such as that required to get to an unattended station, would raise the percentages. In both cases, the degree of change would decrease slightly with an increasing number of protected branch or sectionalizing points.)

6. *Trouble Crew.* Always available at the substation to start instantly with no time allowed for notification or preparation. (More often the crew will be out on the system, sometimes closer to and sometimes farther from the fault location, so this assumption provided an average. If any longer time than the zero had been employed it would have indicated slightly greater benefits for branch protection, line sectionalizing, and single-element fusing.)

7. *Locating Fault and Restoring Service.* The trouble crew:

(*a*). Traveled 30 miles per hour to the sectionalizing point at which the protective device had opened. No time was allowed for examining sectionalizing or branch protective devices en route, as it was assumed these would have indicating features visible from the car.

(*b*). Spent five minutes to climb the pole and to restore service if a temporary fault had caused the outage at the sectionalizing or branch protection point.

(*c*). Traveled 15 miles per hour to the mid-point of the branch or section on which the fault persisted. The mid-point provided the average for the uniform spacing of faults.

(*d*). Spent 30 minutes repairing a permanent fault with the outage persisting on the entire faulted portion until the fault was repaired. (The inclusion of some sort of manual sectionalizing or cutting out of the faulted portion would have decreased the number of consumers affected, and thus decreased very slightly the improvement indicated, as resulting from line sectionalizing and branch protection. For example, if the permanent faults had been repaired in zero time for all consumers, the percentages used for comparison would have been raised only about five units.)

(*e*). After repairing the fault:

1. Either the substation attendant was notified instantly when he was required to close the breaker (although some time probably would be required for notification, which would have enhanced the value of line sectionalizing and branch protection).

2. Or the crew traveled 30 miles per hour to return to the sectionalizing or branch protective device to restore service.

Table IV. Assumptions and Operating Experience on Service Restoration

By Reclosing the Circuit	Service Restored Per Cent of Total Faults on Line♯	
	Values Used in Calculations (Per Cent)	Values From Operating Experience* (Per Cent)
Once	50	50 to 60
Twice	15 Additional	10 to 15 Additional
3 Times	5 Additional	5 Additional
4 Times	3 Additional	1 Additional

♯ If the percentage of temporary faults is less than these values, service is restored only up to the actual number of temporary faults. If greater than the sum of the percentages of restoration for that number of reclosures, it was assumed that the remaining temporary faults persisted longer than the lockout time of the protective device, causing a permanent outage until the substation breaker, line sectionalizing device, or branch protective device was closed manually. Thus perfect operation ("permanent faults alone" causing an outage) was assumed to be provided up to the sum of the 50+15+5 values or 70 per cent of the total number of faults for devices which reclose three times (50 per cent for those which reclose once, 65 per cent for those which reclose twice, and 73 per cent for combinations which reclose four times).

* See Table I in text and reference 3.

Maximum advantage was given to three-element reclosing fuses and other multireclosing devices as compared with two-element reclosing fuse cutouts, since the "values used in the calculations," Table IV, are low for the first reclosing, and high for the second as compared with the "values from operating experience." Some data show as high as 75 to 90 per cent restoration of service following the first reclosure. This would make all the curves for two-element reclosing fuses at branch or line sectionalizing points, as in Figures 7, 8, and 10 to 13 inclusive, approach more closely the curve for "permanent faults alone" for that setup. Of course, there would be a corresponding improvement with three-element fuses and resetting reclosers in approaching or equaling the curves for "permanent faults only."

8. *Service Restoration by 1st, 2d, 3d and 4th Reclosures* was assumed to be in accordance with the values in Table IV. Service restoration is expressed as a percentage of the total faults on the line.

9. *No Inspection With Reclosing Fuse Cutouts Was Assumed.* Because such inspection would have permitted re-fusing before an outage occurred, the data indicate only the minimum benefit for these devices. (This benefit would be increased to a degree approaching that of the device that resets automatically as such fuse renewal before the occurrence of an outage approaches 100 per cent. The percentage of such discovery and renewal is fairly high, because linemen and trouble crews are on the lookout for the indicating devices as they pursue their regular duties along the lines, Table V. Thus all reclosing fuse data are ultraconservative.)

10. *The Protective Orbit of the Substation Breaker* (which is determined by minimum pickup current of the relay) included the whole feeder and all of the branches. In many instances, distribution lines have outgrown this orbit. Consequently, the lower current individual protection of the branches and line sectionalizing on the otherwise unprotected portion may prevent burning down lines, annealing of the conductors, and loss of revenue, in addition to any advantages shown by the study. Conversely, this lower current protection will cause some outages (momentary or prolonged, depending on the type of equipment) for faults which would have burned clear. The combined effect of these few additional operations will balance off to the extent that faults which otherwise would have burned clear,

Table V. Operating Record of Two-Element Reclosing Cutouts on Line With Practically No Special Patrolling

Year	Total No. Faults	No. of Permanent Faults	Number of Temporary Faults Restored By Cutout: Discovered Without Outage	Not Discovered Before 2d Fuse Blew	Total Restored	Caused Outage	Total
1939	36	8	8	10	18	10	28
	100%	22.3%	22.3%	27.7%	50%	27.7%	77.7%
1940	59	15	14	15	29	15	44
	100%	25.5%	23.7%	25.4%	49.1%	25.4%	74.5%

Service was restored on 2/3 of the temporary faults, approximately 1/3 being made possible by discovering and renewing first fuse link before an outage occurred, and 1/3 by the reclosing operation of the cutout.

Current-Transformer Performance Based on Admittance-Vector Locus

A. C. SCHWAGER
MEMBER AIEE

Synopsis: In the past designers as well as users of current transformers have employed ratio error and phase-angle curves in which the abscissa represents primary or secondary current to a linear scale. Numerous curves were necessary both for obtaining a clear picture of the performance characteristics as well as for determining the errors for the multiplicity of possible secondary burdens. Part I of this paper shows that a more functional picture of current-transformer operation is obtained by replacing these commonly used curves by the admittance-vector locus of the secondary winding with the primary open circuited, the end point of the vector representing the independent variable in a curvilinear co-ordinate system. The numerous ratio and phase-angle curves resulting from various secondary burdens and, in case of multiratio transformers, from different numbers of turns, when referred to this new co-ordinate system revert to one single curve. Ratio error and phase angle for any burden at any power factor, turn ratio, and secondary current can be scaled or read directly from a chart using as a basis the admittance vector locus of the steel forming the magnetic circuit of the transformer. For designers as well as users it is often advantageous to be in possession of analytical expressions for ratio error and phase angle. In part II of the paper general formulas are set up which express the performance in terms of the various constants and variables of a transformer, making it unnecessary to refer to charts for the analysis of important design or performance factors.

Part I

BASED on the fundamental paper by P. G. Agnew[1] published in 1911, a practically standard procedure of computing current-transformer performance has been established in the past three decades[2] consisting of the following steps:

1. The transformer is most readily analyzed by introducing the 1/1 ratio type in which the number of primary turns is made equal to the number of secondary turns.

2. The above transformer can be represented by the equivalent circuit shown in Figure 1 and the corresponding vector diagram Figure 2 in which

$OA = I_2 =$ secondary current
$OB = I_e =$ exciting current
$OC = I_m =$ magnetizing-current component of I_e
$CB = I_w =$ watt-current component of I_e
$OD = I_2R_B =$ voltage drop across resistance of burden
$DE = I_2X_B =$ voltage drop across reactance of burden
$EF = I_2R_2 =$ voltage drop across resistance of secondary winding
$FG = I_2X_2 =$ voltage drop across leakage reactance of secondary winding
$OE = I_2Z_B = E_B =$ voltage drop across burden
$OG = I_2Z = E_2 =$ voltage drop across total secondary impedance
$\phi =$ phase-angle lag between E_2 and I_2
$\theta =$ deviation of phase angle between I_1 and I_2 from 180 degrees
$\phi_0 =$ phase-angle lag of exciting current referred to the reversed secondary voltage E_2

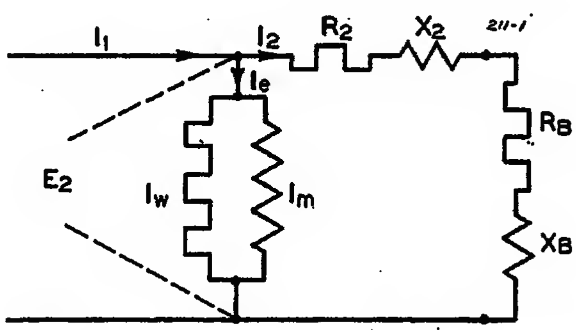

Figure 1. Equivalent circuit of a 1/1 ratio current transformer

3. Magnetizing and watt components of the exciting current are computed from charts showing watts, reactive volt-amperes, and volt-amperes per pound for the steel used in function of the flux density; see Figure 3. The conventional procedure consists of computing the voltage E_2 for the secondary current and burden for which the errors are to be determined, and calculating the flux density from

$$B = \frac{E_2 10^8}{ANf\ 4.44} \text{ gausses} \tag{1}$$

where

$A =$ cross section of core in square centimeters
$N =$ number of secondary turns
$f =$ frequency

and obtain I_m and I_w as follows:

$$I_w = W/E_2;\ I_m = RVA/E_2;\ I_e = VA/E_2 \tag{2}$$

The curves shown in Figure 3 apply to a conventional grade of silicon steel and will be used as a basis in the following. If a sample of the transformer to be investigated is on hand I_w, I_m, and I_e are available from the excitation curves of the secondary winding.[3]

4. Ratio and phase-angle can be computed by means of the following formulas:

$$R(1/1) = \frac{I_2 + I_m \sin\phi + I_w \cos\phi}{I_2 \cos\theta} \tag{3}$$

$$\tan\theta = \frac{I_m \cos\phi - I_w \sin\phi}{I_2 + I_m \sin\phi + I_w \cos\phi} \tag{4}$$

$$R(N) = \frac{N}{N_1} R(1/1) \tag{5}$$

where $N_1 =$ number of primary turns.

$$\text{Ratio error} = \Delta(1/1) = R(1/1) - 1 \tag{5a}$$

In order to obtain curves showing the errors over a current range, the above procedure must be repeated for numerous secondary-current values. In the following it will be shown that a clearer picture of current-transformer performance results if numerical calculations of ratio error and phase angle are not executed at such an early stage. The method used is similar to that of representing the per-

Paper 42-11, recommended by the AIEE committee on protective devices for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted October 20, 1941; made available for printing November 7, 1941.

A. C. SCHWAGER is vice-president, in charge of engineering, of Pacific Electric Manufacturing Corporation, San Francisco, Calif.

The author acknowledges the assistance given him in the preparation of charts and checking of the formulas by George Krumze of the test department of the corporation.

cause greater or lesser consumer minutes outage than faults for which additional protection is provided. No data are available on this relationship. However, they probably would have slight effect on the percentages used for comparison.

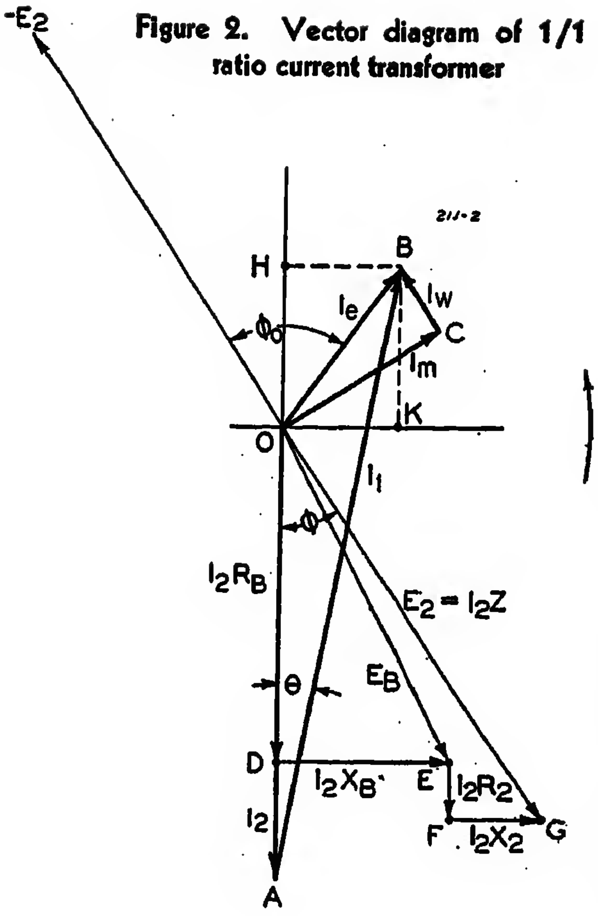

Figure 2. Vector diagram of 1/1 ratio current transformer

formance of power transformers and induction motors by means of circuit loci, or specifically by means of the circle diagram. Referring to Figure 2, extending calculations into the complex plane, the complex ratio $R(1/1)$ can be expressed as follows:

$$R(1/1)=\frac{I_1}{I_2}=\frac{-I_2+I_e}{I_2}=-1+\frac{I_e}{I_2} \qquad (6)$$

Since $I_2Z=E_2$, (6) can be written as follows:

$$R(1/1)=-1+\frac{I_e}{E_2}Z \qquad (7)$$

The vector I_e/E_2 can be recognized as the negative admittance vector of the secondary winding with the primary winding open circuited; denoting it with Y it follows:

$$R(1/1)=-1-YZ \qquad (8)$$

The ratio of a 1/1 transformer is equal to the negative real number one decreased by the product of the admittance vector and the total secondary impedance vector.

It is customary to represent the performance of transformers at various fixed secondary burdens Z_B. In bushing-type transformers with equally distributed secondary winding, the leakage reactance is negligible in comparison to the burden impedance and in wound-type transformers it can, in many cases, be considered constant over the normal metering range. Under these conditions Z remains constant when considering ratio error and phase-angle changes due to variations in the secondary current. The admittance vector becomes the basic current-transformer curve, curves for various burdens being similar. An investigation of the admittance-vector locus is therefore indicated.

The Admittance-Vector Locus

It appears advisable to refer to a specific transformer at this time. Due to its most frequent use a multiratio bushing transformer will be investigated, but none of the generalities of the study is thereby sacrificed. The transformer has N secondary turns equally distributed on a core of $17^1/_4$ inches inside diameter, $21^3/_4$ inches outside diameter, and $7^3/_4$ inches height, giving a cross section of 112.5 square centimeters and a weight of 265 pounds; it is used in conjunction with 115-kv oil circuit breakers. The admittance-vector locus is determined in accordance with the following procedure:

From formula 1 the flux densities B are determined for various assumed secondary voltages E_2; referring to chart, Figure 3, the corresponding VA/lb and W/lb values are determined. The power factor is computed for each voltage, and the total volt amperes are obtained by multiplying the VA/lb by the weight. The magnitude of the admittance vector is equal to

$$Y=VA/E_2 \qquad (9a)$$

If curves showing the exciting current and its components in relation to the secondary voltage are available,[3] the admittance vector and its components can be obtained as follows:

$$Y=I_e/E_2;\ \text{conductance}\ G=I_w/E_2;\ \text{susceptance}\ B=I_m/E_2 \qquad (9b)$$

For each voltage E_2 the calculated admittance vector is plotted. Due to its frequent use the admittance vector corresponding to one secondary turn has been computed and is shown in Figure 4. As can be seen, the locus has the shape of a hairpin, the admittance decreasing from 365 mhos for approximately 0.003 volt to 30 mhos for 1.5 volts and increasing again to large values for increasing voltage.

Similarly, the phase angle with respect to the secondary-voltage vector (positive real axis) decreases to a minimum with increasing voltage and increases with further increase in voltage. It is apparent that this curve is a function of the characteristics of the steel only; a more basic curve is shown in Figure 5, where the flux density is chosen as the independent variable. In the range shown the admittance decreases for flux-density values of from 10 to 5,000 gausses, where a minimum is reached, and increases thereafter with increasing flux density. Minimum admittance corresponds approximately to maximum permeability of the steel; the right-hand branch of the curve indicates the region below saturation, the left-hand branch the region in which saturation occurs. ϕ_0 is the phase angle of the exciting current of the steel. It is advantageous to refer to this basic curve, having B or a quantity directly proportional to B as independent variable. Obviously, the value of volts per turn E_2/N is such a quantity, having the advantage that it is related most directly to the important variables of the problem, namely applied voltage and secondary turn numbers. If the admittance vectors for a given core and varying turn numbers are compared at identical flux densities or volts-per-turn values,

Figure 3 (below). Volt-amperes, reactive volt-amperes, and watts for one pound of steel in relation to flux density

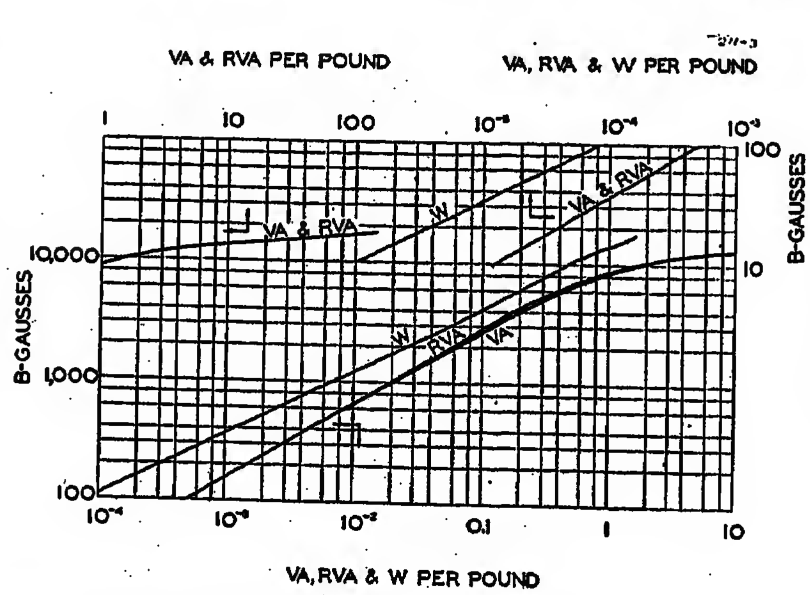

Figure 4 (right). Admittance vector Y_1 in mhos for one turn as function of volts per turn for 115-kv bushing transformer

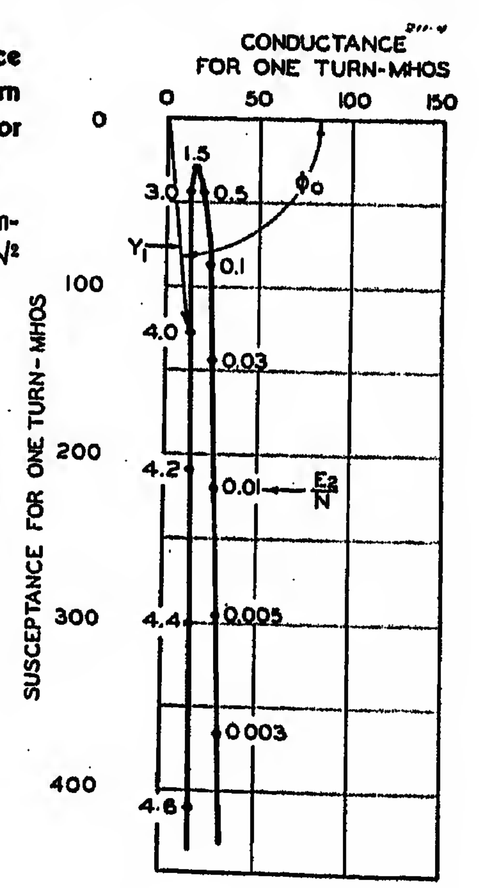
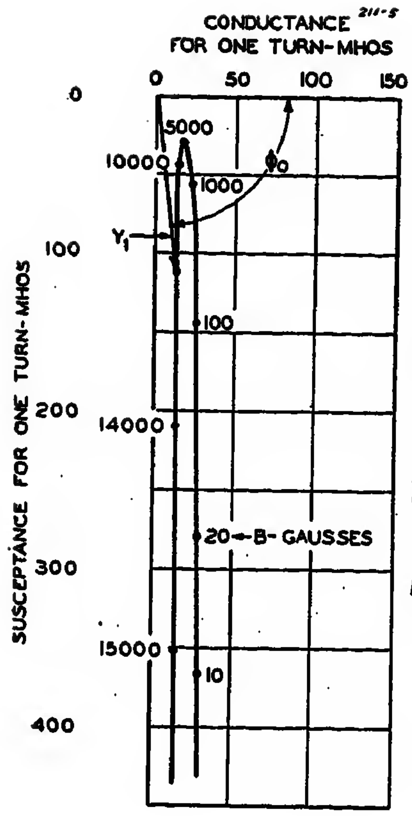
Admittance for N turns computed according to $Y_N=Y_1/N^2$





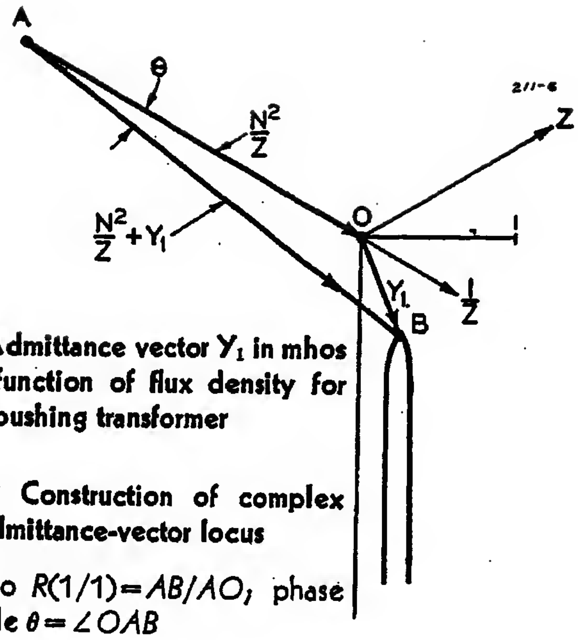


Figure 5 (left). Admittance vector Y_1 in mhos for one turn as function of flux density for 115-kv bushing transformer

Figure 6 (right). Construction of complex ratio from admittance-vector locus

Magnitude of ratio $R(1/1)=AB/AO$, phase angle $\theta=\angle OAB$

then the following well-known formula results:

$$Y_N(B)=Y_1(B)/N^2 \qquad (10)$$

This relation is indicated in Figure 4 showing Y_1, making it useful for determining the admittance for any number of turns. In order to profit by the application of this equation, volts-per-turn values are used as independent variable in the following.

Aside from its application in the following analysis, Figure 4 is valuable for determining the exciting-current vector in idle transformers in conjunction with multiple interconnected circuits, such as in bus-differential scheme protection.[4]

The use of this chart shall be shown in conjunction with an example:

Determine the exciting current of the above transformer for a voltage of 20 volts and 40 turns. E_2/N is computed to be 0.5 volt per turn. The resulting admittance Y_1 is 49 mhos; therefore

$$Y_{40}=49/40^2=0.031 \text{ mho}$$

and the exciting current $=0.031\times 20=0.62$ ampere; the phase angle amounts to 66 degrees.

The Universal Transformer-Ratio Chart

Referring to equation 8 and substituting $Y_N=Y_1/N^2$ in order to generalize for any number of secondary turns, it follows:

$$R(1/1)=-1-Y_1\frac{Z}{N^2} \qquad (11)$$

Except for constants defining the burden and turn number, the ratio is a function of the admittance vector Y_1 only.

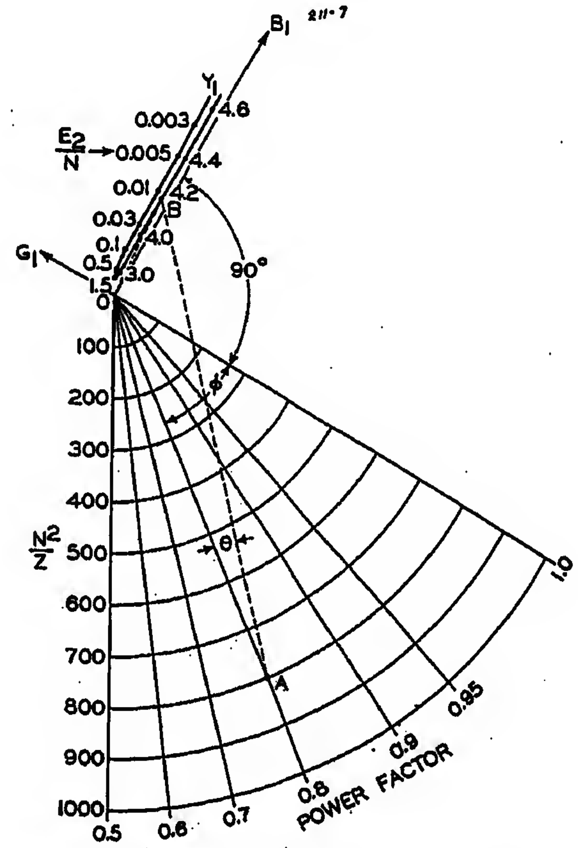

Figure 7. Chart for calculation of ratio and phase angle for any number of secondary turns N, any total burden Z at any power factor and any desired secondary current I_2, provided $N^2/Z<1{,}000$

Example: $N=40$, $Z=2$ ohms, pf$=0.8$, $I_2=84$ amperes. $E_2/N=I_2Z/N=4.2$ volts per turn, giving point B on locus. $N^2/Z=800$, giving point A on 0.8 pf line. Ratio $(1/1)=AB/AO=1.19$, $\theta=\angle OAB=9$ degrees 30 minutes

Equation 11 can also be written as

$$-R(1/1)=\frac{\dfrac{N^2}{Z}+Y_1}{\dfrac{N^2}{Z}} \qquad (12)$$

The construction of the complex ratio R in accordance with 12 is developed in Figure 6 where point O represents the origin of the Y_1 plane, B the end point of the admittance vector corresponding to a given value E_2/N, and AO the complex vector N^2/Z with its end point shifted to the beginning of the vector Y_1 in order to bring about the addition.

The absolute value of the ratio is equal to $R(1/1)=AB/AO$

The phase angle is equal to $\theta=\angle OAB$

If the transformer has a single turn primary, the ratio according to (5) is

$$R(N)=N\times R(1/1)$$

Using the construction shown in Figure 6, the chart in Figure 7 has been prepared from which ratio and phase angle for various burdens, secondary turns, and secondary currents can be quickly determined.

Assume a secondary current I_2, a secondary burden Z in ohms of power factor pf, and a given number of secondary turns N, the procedure followed is

1. Compute volts per turn$=I_2Z/N$ and mark point on locus Y_1 corresponding to this value as B.

2. Compute N^2/Z and mark corresponding point A at proper power factor resulting in
True ratio$=N\times AB/AO$
Phase angle$=\angle OAB$

Except for low ratio bushing-type transformers, Figure 7 can be modified so that the ratio error and phase angle can be read directly off scales. For bushing-type transformers with a large number of secondary turns and for wound-type transformers, the phase angle θ becomes so small that I_2 and I_1 can be considered parallel. Referring to Figure 2, the projection OH of OB upon the secondary-current axis divided by the secondary

6	θ(min)	$69{,}100(Z/N^2)\{(E_2/N)^{-0.4}-0.888\}$	$3.85(Z/N^2)\{(E_2/N)^8-11{,}370\}$

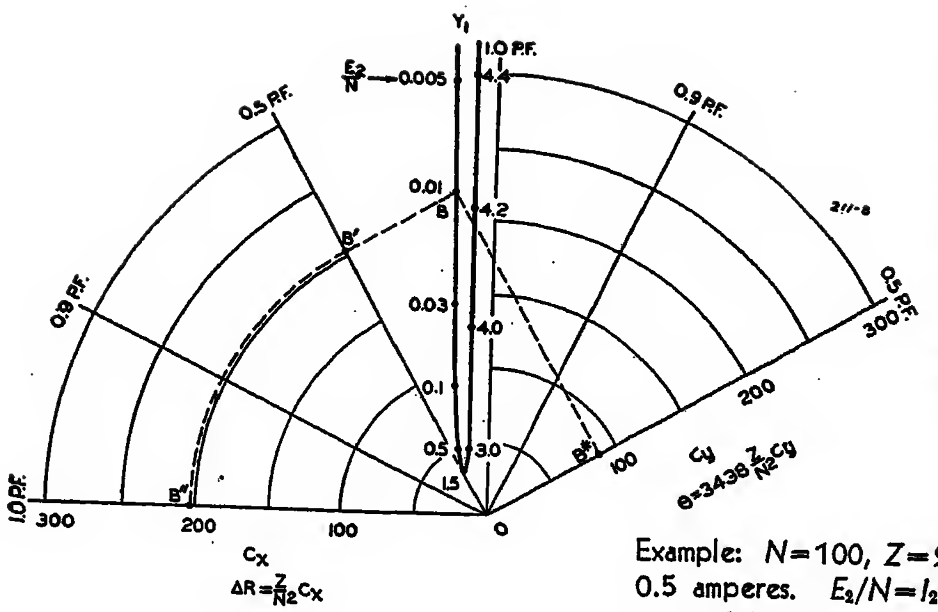

Figure 8 (left). Chart giving ratio error and phase angle for any number of secondary turns N, any total burden Z at power factors of 1.0, 0.9, and 0.5 and any desired secondary current I_2, provided $N^2/Z \gg 1{,}000$

Example: $N=100$, $Z=2$ ohms, pf$=0.5$, $I_2=0.5$ amperes. $E_2/N = I_2Z/N = 0.01$ volts per turn, giving point B on locus. Project B perpendicularly upon 0.5 pf line in left quadrant giving B'; follow B' along circle about O to B'' and read value $C_x = 203$, giving: $\Delta R = Z/N^2 \times 203 = 0.04$, resulting in $R(1/1) = 1.04$ and $R(N) = 104$

Project B perpendicularly upon 0.5 pf line in right quadrant giving B^*; read value $Cy = 88$, giving: $\theta = 3{,}438 \times Z/N^2 \times 88 = 60$ minutes

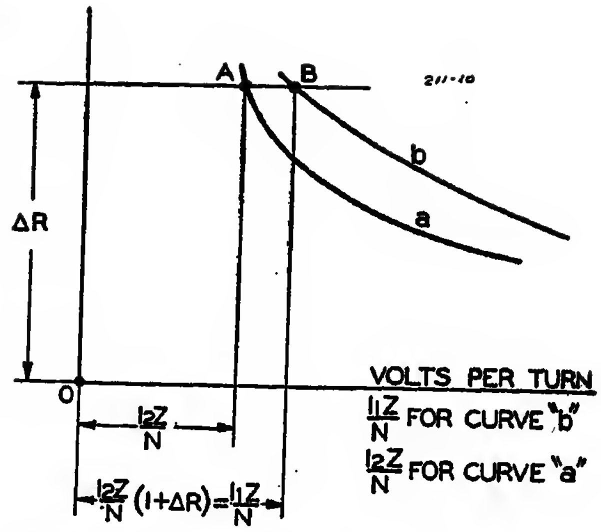

Figure 10. Transformation of I_2Z/N abscissa into I_1Z/N abscissa giving curve "b" from which ratio errors at given primary current can be read

current closely approximates the ratio error $\Delta R = R(1/1) - 1$. Similarly, the projection, OK of OB, is directly proportional to the phase-angle. Figure 8 shows the transformation of Figure 7 for the case of "small errors" for burden power factors of 0.5, 0.9, and 1.0. The readings obtained from the scales have to be multiplied by Z/N^2. Since Figures 4, 7, and 8 are based on the Y_1 curve, they can, if desired, be combined into one chart providing all the essential data required for the following calculations:

1. Exciting current of secondary winding.
2. Ratio error and phase angle for few secondary turns.
3. Ratio error and phase angle for a large number of turns.

It is believed that these charts give a more functional picture of the transformer performance than the large number of ratio and phase-angle curves previously required to serve the same purpose. Essentially there exists only one curve, the admittance-vector locus of the core into which all other curves revert by proper transformation. The practical advantage of the Figures 7 and 8 are numerous. In the past relay engineers, when determining errors for a certain burden were forced to interpolate from a large number of curves representing different burdens and power factors. The new methods give accurate values from one single curve which gives equal emphasis to the normal load and overload range. The problem of matching transformers becomes particularly simple; ideal matching requires point A on two transformers to slide simultaneously over identical E_2/N values.

In the case of bushing-type current transformers used for overcurrent relaying it is not important to know the phase angle. Figure 8 can, therefore, be changed to permit the use of a linear scale for E_2/N as shown in Figure 9, which indicates how the Y_1 curve is transformed into the conventional ratio-error curve "a." It follows that for transformers with "small errors" the ratio error ΔR for any number of turns and for any burden at a given power factor and any secondary current can be represented by a single curve in a rectangular co-ordinate system with linearly progressing secondary current scale.

It is often preferable to know the ratio error in terms of primary rather than secondary current. From curve "a" Figure 9, which shows the ratio error in function of secondary volts per turn, I_2Z/N, and therefore of I_2, another curve can be constructed which represents the error in function of the primary current. Since $I_1 = (1+\Delta R)I_2$, the following relation exists:

$$I_1Z/N = (1+\Delta R)I_2Z/N$$

Curve "b" in Figure 10 is obtained from curve "a" by determining I_1Z/N for various I_2Z/N values in accordance with

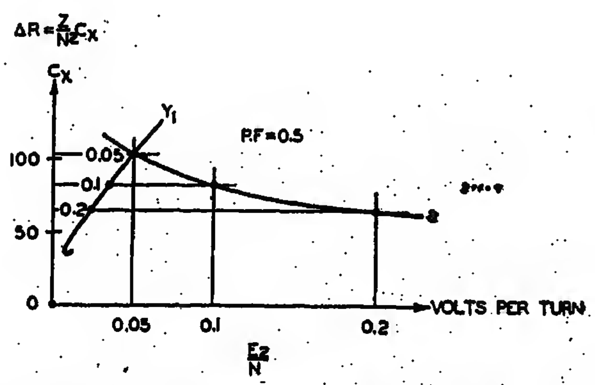

Figure 9. Transformation of Y_1 curve into conventional ratio-error curve "a", total burden power factor=0.5

the above relation and assigning to the I_1Z/N values so obtained ordinates equal to those corresponding to the respective I_2Z/N or E_2/N values.

Different curves result for differing Z/N^2 values; however, since, in standard multiratio transformers with burdens of 0.5, 1.0, and 2 ohms, several combinations of burdens and turns give identical Z/N^2 values, many of the curves coincide, resulting in a corresponding reduction in the total number of curves previously required.

In Figures 7 to 10, Z designates the total secondary impedance. However, since, in bushing-type transformers with equally distributed secondary winding, the leakage reactance is negligible and the resistance of the winding is small when compared to the resistance of the external burden, Z closely approximates the external-burden impedance.

The results obtained by the use of these charts are identical with those obtained by previous methods. For any current value, any secondary burden and secondary number of turns, ratio and phase-angle values calculated from these charts are identical with those obtained by the use of previous methods.[1–4]

Part II

Referring to Figure 5 it can be seen that the admittance-vector locus consists essentially of two straight lines which are parallel to the imaginary axis, indicating constant conductance for both low- and high-density range. It has been shown that the reactive volt-amperes in these two ranges can be closely approximated by formulas containing constant exponents for the flux density B.[5] Lines 1 and 2 in Table I, give the formulas for watts/pound and reactive volt-amperes/

pound applying to the steel represented by Figure 3. Lines 3 and 4 give the corresponding formulas for the conductance G_N and susceptance B_N respectively for N turns, for the particular bushing-type transformer described above. Formulas 3 and 4 can be modified to express ratio and phase angle in terms of the components of the admittance vector, and if the study is limited to small errors or $N^2/Z \gg 1{,}000$, result in

$$R(1/1) = 1 + Z(B_N \sin\phi + G_N \cos\phi) \quad (13)$$

$$\theta_{(\text{min.})} = 3{,}438Z(B_N \cos\phi - G_N \sin\phi) \quad (14)$$

Substituting for G_N and B_N the values from lines 3 and 4 of Table I into equations 13 and 14 and limiting the investigation to the commonly used power factor of 0.5, lines 5 and 6 result for ratio error and phase angle respectively. Although a wide range of flux density is omitted from formulation, it can be seen from Figure 5 that it represents a relatively small absolute range around the bend of the admittance-vector locus. A fair approximation can be obtained for this range by assigning it constant values corresponding to the values resulting from $B = 5{,}000$ in the low-flux density formulas of Table I, lines 3 to 6 inclusive. If the expression E_2/N is eliminated from formulas, lines 5 and 6, for either of the two flux-density ranges, linear equations result between ΔR and θ as previously pointed out for the low-flux-density range.[6]

Conclusions

From the foregoing analysis it can be seen that the admittance-vector locus is a useful means of representing current-transformer performance. It is advantageous to introduce volts per turn as independent variable. This procedure results in charts from which normal and overload performance of a particular transformer at any burden and turn ratio can be obtained from one single curve, the admittance-vector locus of the steel used in the core.

A considerable saving in drafting effort is accomplished in case of multiratio bushing-type transformers where heretofore a large number of curves was required. If desired, reference to charts can be avoided by the use of simple formulas giving ratio error and phase angle for the entire load range and for any desired turn ratio and secondary burden. This study is intended primarily to present a new method of approach for the representation of current-transformer performance. Numerous important factors, such as the modification of the vector locus due to wave distortion and methods used in measuring volt-amperes and core losses, have not been reported upon; it is hoped that they can be made the subject of a future publication.

Field Tests on High-Capacity Station Circuit Breakers

H. D. BRALEY
ASSOCIATE AIEE

Synopsis: The development of high-capacity air-blast breakers in this country has taken place without the background of operating experience which has attended the use of oil circuit breakers and has, therefore, emphasized the need for testing this equipment at levels comparable with the assigned interrupting ratings.

Although field short-circuit tests to verify circuit-breaker performance have been made on operating systems previously, they have been limited in most instances to moderate duty levels or, in the larger interrupting ratings, to the testing of high-voltage apparatus. Staging severe short-circuit tests at 15 kv introduces operating problems of greater significance since it virtually requires the application of the fault to the generating-station bus. This paper presents:

1. A résumé of the studies which indicated that it would be practicable to stage short-circuit tests ranging up to 2,000 megavolt-amperes directly on a particular generating-station bus.

2. A description of the physical plant equipment assembled for test purpose.

3. Operating experience during a series of 14 short circuits ranging from 200 to over 1,500 megavolt-amperes at 14.5 kv.

IN 1939 a trial installation of two 15-kv air-blast circuit breakers with a rated interrupting capacity of 500 megavolt-amperes was placed in service at the Waterside II station of the Consolidated Edison Company of New York, Inc. As a result of this operating experience a total of 24 15-kv air-blast circuit breakers ranging in rated interrupting capacity from 500 to 2,500 megavolt-amperes were purchased for installation in the Sherman Creek station.

The success with which the manufacturers of oil circuit breakers had been able to predict the performance of this equipment, as the result of field tests and extrapolation of laboratory tests at lower levels of duty, had been generally satisfactory, and there was, therefore, reasonable expectation that the same procedure could be extended to the air-blast design. However, the guide posts were not as well-marked as those in the oil-circuit-breaker field, and it seemed desirable to make tests up to the full rated interrupting capacity on one of the air-blast circuit breakers in the higher interrupting range.

When confronted with a serious proposal to stage not one but a series of major short-circuit field tests, it was only natural that the initial reaction of the more conservative minded should be one of considerable concern. The more progressive souls decreed that in addition to making an investigation of the feasibility of staging field short-circuit tests, consideration should also be given to the practicability of exposing the entire system to the short-circuit disturbance, on the hypothesis that it would be better to learn the effects under controlled conditions than possibly to be required to encounter a similar disturbance unexpectedly. The information obtained as a result of the field tests proved the wisdom of this course of action.

Preliminary Analysis

The first approach to this undertaking for making tests ranging up to 2,000 megavolt-amperes was to select the generating plant best adapted to the purpose with regard to capacity in generators, tie feeders, switching flexibility, space available for test apparatus, and facilities necessary to supply the required current and voltage. It was quickly ascertained that the Hell Gate station was outstanding in all the desired requirements by comparison with other stations in the system. Preliminary studies indicated that the mechanical stress imposed upon the windings of any generator would be not more than 50 to 60 per cent of that normally obtained with a short circuit on the generator terminals and should, therefore, be within safe limits if all winding insulation and bracing were in first-class condition. Furthermore, machines in this station had been subjected to short circuits in which the calculated mechanical stresses were of the same order as those expected in the proposed tests, and these had resulted in no apparent damage.

The second step involved short-circuit studies to determine the number of machines and tie feeders which would be necessary to furnish the required test current at each test level, making such allotment of generators and tie feeders as to expose each machine to a minimum number of short circuits. It was concluded that the three-phase short-circuit tests should be undertaken with the necessary generators isolated from the system load, except through such tie feeders as might be necessary for loading machines prior to the application of the fault and for providing the additional capacity to furnish the required fault current. This decision was based on two factors:

First, a three-phase fault directly on the Hell Gate load bus would result in a serious disturbance to the low-voltage network system served directly from that bus at generator voltage, and this procedure could not, therefore, be undertaken without annoyance to customers.

Second, the effect on the system would be greatly diminished by the cushioning impedance of the tie feeders. Moreover this would be a more severe test of the system performance than disturbances which had

Paper 42-12, recommended by the AIEE committees on power transmission and distribution and protective devices for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted October 25, 1941; made available for printing November 10, 1941.

H. D. BRALEY is division engineer in the electrical engineering department of Consolidated Edison Company of New York, New York, N. Y.

been encountered previously as a result of a three-phase operating failure just outside of a tie-feeder reactor and it would, therefore, afford a measure of system performance under severe fault conditions.

Since the maximum current tests were the determining factor governing the stresses on station equipment, the power requirements for this case were first determined. It was found that to attain the desired level of 2,000 megavolt-amperes, it would be necessary to raise the test voltage from the nominal operating value of 13.6 kv to 14.5 kv and to use all of the machines that could be spared from service while still maintaining the desired reserve. This required the use of a 60-megavolt-ampere tie feeder to Waterside Station II, a 100-megavolt-ampere tie feeder to the Niagara-Hudson system and three generator units of 43.75-, 62.5- and 188-megavolt-ampere capacity. In addition, it was found necessary to pretrip the test breaker in order to take advantage of the current asymmetry. The calculated currents together with the necessary facilities in machines and tie feeders for the various tests are shown in Table I.

A complete analysis of short-circuit forces was made on the connections and equipment of the feeder position supplying the test breaker. All calculations were based on the maximum peak value of current expected under the highest capacity test. Full offset at "zero" time was assumed and proper allowance made for the decay of both a-c and d-c components, resulting in a maximum instantaneous peak current, at the first half-cycle following the fault, of 200,000 amperes at 14.5 kv.

Since the station buses and feeder outlets are of isolated phase arrangement, forces arising from the interaction of phase currents are of little or no importance until the several phase conductors converge in the station cable vault. The arrangement of equipment grounding coppers within the isolated phase portion of the electrical galleries was such that any possible failure to ground would require ground-current flow at right angles to the phase conductors. This eliminated the necessity of considering interaction of phase and ground-fault current. Consequently, within the galleries, the actual forces considered were only those on the test-feeder circuit, arising from the current flow in the several sections of the phase conductor, as it looped, turned, and doubled back on itself, in passing through oil circuit breakers and the reactor of its own phase.

The maximum force concentration appeared as a cantilever load on the wall bushings entering the oil circuit breaker compartments. This amounted to approximately 5,000 pounds at the end of the bushing and normal to its axis. A greater force, 6,000 pounds, was found to act on the oil-circuit-breaker moving contact, tending to open the breaker against the restraint of its latching mechanism.

Since the wall bushing mentioned above was rated by its manufacturer as able to withstand only about 600 pounds at the end of the stud, it was decided to eliminate these forces by placing a short-circuiting strap across the external bushing studs, removing the circuit breakers and reactors of the feeder from the circuit, and thus eliminating virtually all cantilever loading on the wall bushings.

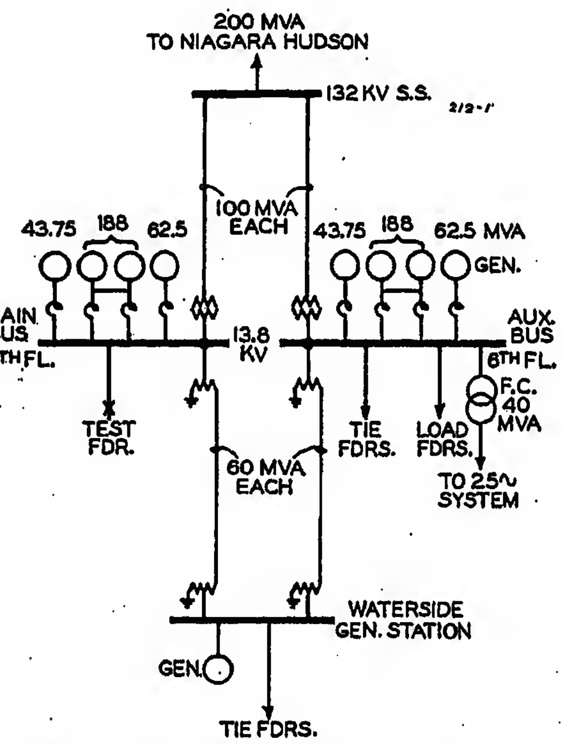

Figure 1. Simplified diagram of system connections to Hell Gate station in the maximum-capacity test

Within the station cable vault, where the separate phase conductors making their exit from conduit were racked in a parallel flat arrangement on the wall of the vault, maximum instantaneous forces of 3,700 pounds per foot were found. In regions where the cables converged to enter a joint with three-conductor cable, the sheaths were in contact, and the maximum instantaneous value of the forces tending to separate the cables was found to be 11,500 pounds per foot. Suitable wrapping and bracing were provided to hold these cables securely in place during the short circuit. Disconnecting switches in the test circuit, where rated below the expected test current, were removed and replaced by copper bus work.

Concurrently with the foregoing studies, an investigation was undertaken to determine the likelihood of instability between generators following clearance of the trouble. It was assumed here that the fault might have to be cleared by the backup protection, and that the total clearing time would be approximately 0.5 second. These calculations indicated that there would be no question whatever of stability, since no generator should swing from its initial position relative to the others by more than 10 degrees. Furthermore, the load readjustment throughout the system, after fault clearing, should not be sufficient to result in any material disturbance, even though the Waterside tie feeder should trip. The calculated voltage dips during the highest capacity fault were 18 per cent on the Hell Gate load busses, 15 per cent at Waterside II, 20 per cent at Sherman Creek, and 40 per cent at the Dunwoodie substation. A simplified one-line diagram of the 60-cycle system tie connections is shown in Figure 1.

Organization

A working committee was set up, comprising representatives of the production, system operation, construction, technical service, and electrical engineering departments of the company and also representatives of the General Electric Company. Schedules and dates were set up to cover:

A. Drawing and engineering information.

B. Construction dates and equipment deliveries.

C. Test procedure.

D. Personnel assignments.

To a key man in each group was delegated the responsibility of executing the work assigned by the chairman of the working committee. Through this organization it was possible to keep all work moving on schedule and settle all of the points, with a minimum of delay and with complete understanding as to the action to be taken by all concerned. This procedure was responsible for the success which was attained in completing all preparations on schedule and eliminating confusion as to procedures and responsibilities, during the actual carrying out of the test work.

Test Facilities

The breaker selected for test was a General Electric Company type *A R*-20-150 three-phase 60-cycle 1,200-ampere 15-kv unit with a rated interrupting capacity of 1,500 megavolt-amperes. The detailed description of this circuit breaker is covered in a companion paper,[1] and its

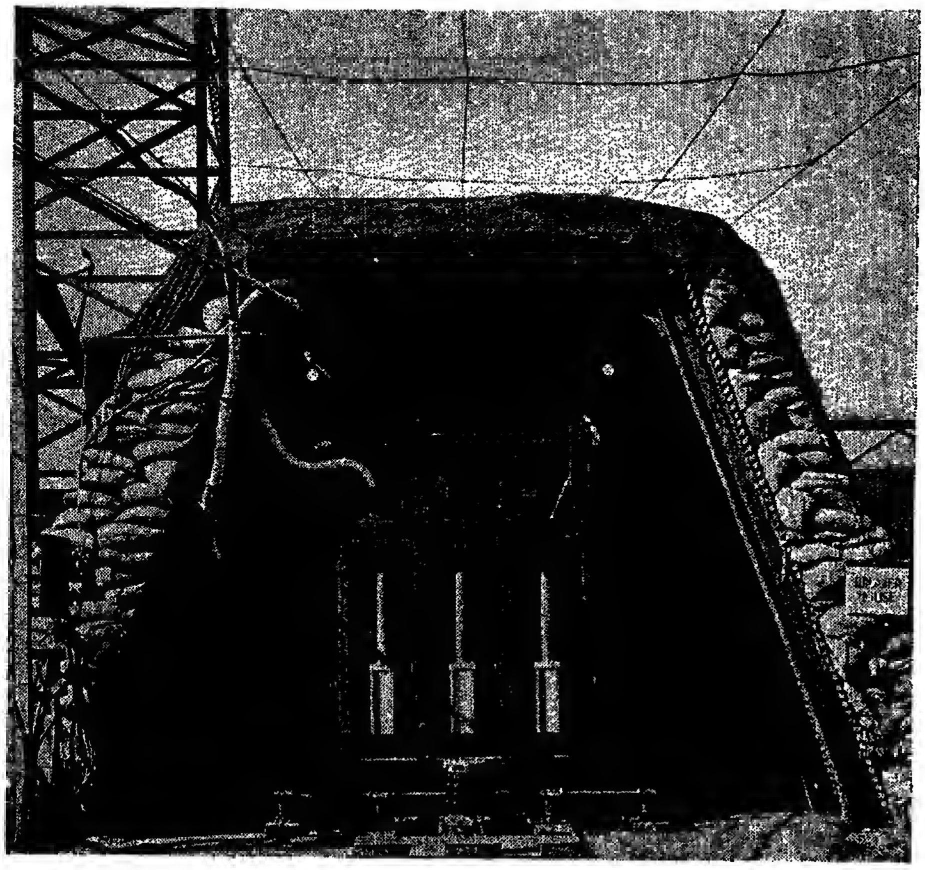

Figure 2 (left). Air-blast circuit breaker installed in structure

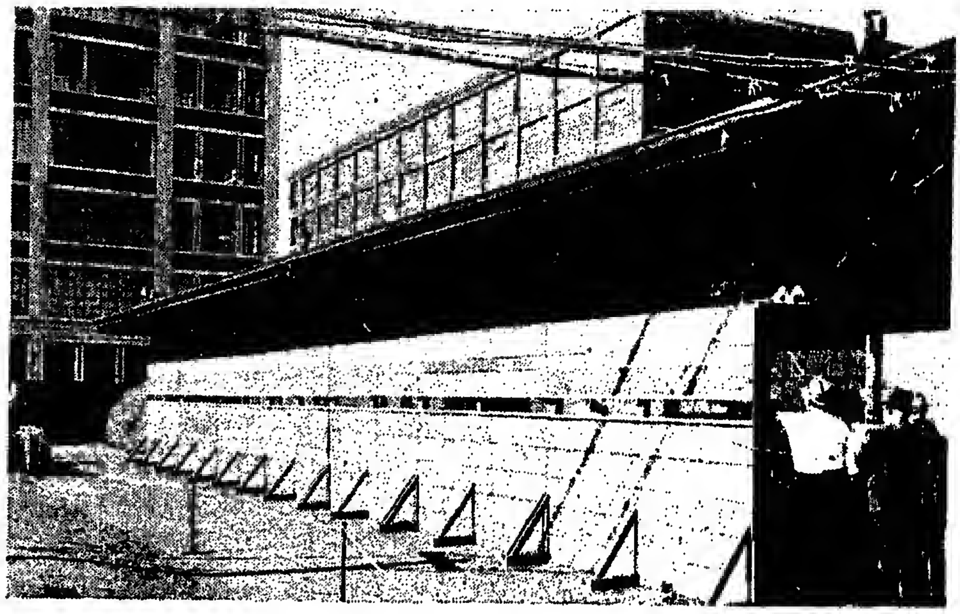
Control wiring and instrument wires to control station shown at upper left corner of structure

Figure 3 (below). View of observation barricade

Control cables from circuit breaker may be noted at the top



performance will be referred to here only insofar as it was concerned with the testing operations.

One of the type *H* circuit breakers used for closing duty in the testing station of the General Electric Company was used for the same duty in these tests. This breaker was installed in the breaker test house in close proximity to the air-blast breaker.

The clearance of material stored in the transformer and cable yard to make space available for the breaker test cubicle and other structures, at first appeared to present a task of gargantuan proportions, what with scores of cable reels, economizer tubes, grate bars, and an indescribable assortment of material accumulated by a decade of "string savers." At the very beginning, therefore, the test program began to pay dividends, to the delight of the station superintendent. It made necessary a general house cleaning of the storage yard, by transfer of some of the equipment to other locations, and a more orderly restacking of the remainder.

The breaker house structure, consisting of a steel framework closed on all three sides and the top with corrugated steel sheeting, was supported on a concrete mat. All enclosing sides and the top of the structure were covered with two layers of sandbags, as a protection to numerous transformers and other equipment against damage from possible fire and flying debris.

The open side of the structure was laid out to face a one-story brick storeroom structure. A barricade of two-inch thick lumber, erected in ten-foot sections for quick assembly and removal, for protection of the observers, was placed under the overhanging roof of the storeroom, directly facing and approximately 70 feet distant from the breaker house. A space in the storeroom, with a separate entrance door facing the breaker house, provided a convenient area for all of the magnetic oscillograph equipment required by the General Electric Company. The control station, for operation of the closing breaker and test breaker, as well as the communication facilities, with the generating station control room, was also located at this point. The remainder of the equipment required for the test included separate, standard wood construction shanties, such as were readily available in the market. Four such structures were used for housing the field construction office, dark room, air compressors, and cathode-ray oscillograph. Photographs of the breaker test house and the observation barricade are shown in Figures 2 and 3 respectively.

An independent three-point communication system was installed to provide communication between the test-control station in the yard, the generating-station control board, and the generating-station control-cable terminal room, where was located the Company's automatic recording instruments. A public address system was also installed, for information of the observers concerning safety regulations, announcement of test procedures, and the results of the various tests.

A standard feeder outlet position was used for the test outlet from the station bus, and the circuit from this point to the breaker test house consisted of two three-conductor 800,000-circular-mil lead-covered cables in parallel.

After careful consideration, the decision was reached that the station breakers should be used for backup protection against failure of the test air-blast breaker since there was some element of risk in using the control breaker in the breaker test house, due to its close physical proximity to the test breaker, and furthermore the control breaker might also fail as a result of its use in applying short circuits. The bus setup in the station could be arranged so that two 5,000-ampere, 1,500-megavolt-ampere bus-tie oil circuit breakers, in the section of bus to which the test feeder was connected, would divide the total test current, so that neither one would be subjected to a duty in excess of two-thirds of its rated interrupted capacity. Current transformers, installed on the bus section to which the test feeder was connected, were disconnected from the bus-differential relay circuit and connected, in such a manner as to totalize the total test current to a backup overcurrent induction relay, arranged to trip the two bus-tie oil circuit breakers. These connections are shown in Figure 4.

Operating Procedures

In order to maintain suitable safeguards and to avoid confusion and misunderstanding, the following operating procedure was established:

A. A production department representative with five assistants was stationed in the test area. The operator in charge of this group was responsible for the enforcement of safety regulations. He saw that the test area was cleared, protective barriers were in place, and so on, before each test. He also issued and cleared the necessary work per-

mits for inspection of the test breaker after each test and stationed his watchmen at various points in the test area before each test. This operator alone gave all of the orders to the high-voltage operator in the station for energizing and de-energizing the test feeder. Thus by delegating this authority to only one individual, any confliction of orders was avoided.

B. In the electrical galleries the doors between adjacent bus sections were blocked open, and qualified observers stationed in the gallery corridors on all floors had an unobstructed view of the gallery compartments during test periods. This procedure provided a means of detecting the nature and location of any trouble and also prevented the unauthorized access of other personnel.

C. A representative of the steam engineering department was stationed at the throttle of each turbine, and these men were under instructions as to the action that they should take in the event of trouble developing either on the turbine or the generator. The station electrical mechanics maintained a watch on the generator, and the generator cable ducts, and neutral cable duct runs, to watch for any indication of trouble in those areas.

D. A simple signal system was set up to warn all concerned that a test was about to take place. Signals were given throughout the generating station ten minutes in advance of each test. Each inspector or observer then reported by telephone to the high-voltage control board that he was in position. Five minutes before each test, a signal was given on the turbine-room call whistle and a "standby" signal put up on the signal stand on each turbine being used for the test. When all observers were reported as being in position, the production department representative in the test yard was notified and then proceeded to give the necessary switching instructions, relative to making the test feeder alive. One minute before each test communication was established between the production representative in the yard, the high-voltage operator, and the representatives in charge of the test instruments set up in the cable-terminal control room. Time was then counted off, and the test applied. Communication was maintained until all observers had reported to the high-voltage operator. At the high-voltage operating board an operator was stationed at the controls of each generator and was under instructions as to the steps which should be followed should trouble develop. Observers were also stationed at each street manhole through which the test feeder was carried, all manhole covers being removed during the test period.

F. An electrical construction crew was maintained in the station construction office for any necessary work which might develop as a result of unexpected trouble. For the same purposes a crew from the underground department was also maintained during the entire test period, to be available for any necessary repair work which might be required.

G. Beginning with the test at the 1,000-megavolt-ampere level and above, inspections were made of the equipment in the electrical galleries, the station cable bay, and

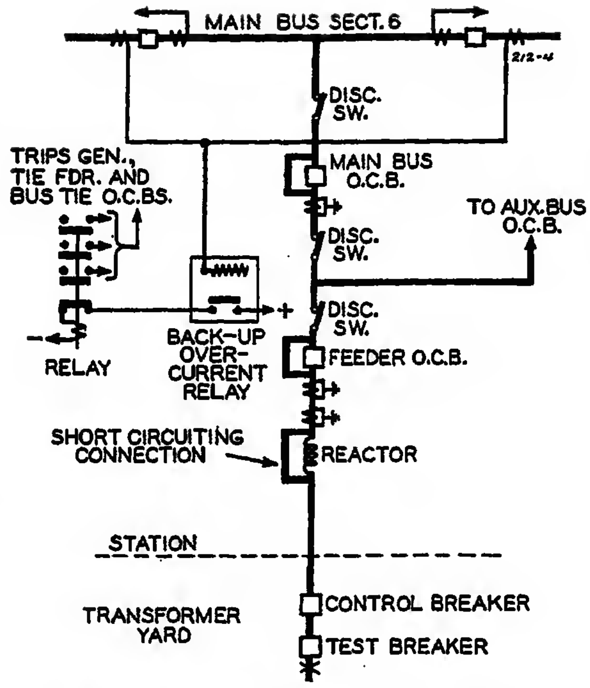


Figure 4. Diagram of relay connections for backup protection

the street manholes, for evidence of damage after the first test at each level.

1940 Tests

The first series of tests was undertaken Saturday, September 21, and the following Sunday, September 22, 1940. Test 1 at 200 megavolt-amperes was in the nature of a trial test shot for checking all of the equipment and the operating procedure. In this test the Waterside II tie feeder was tripped at Waterside number 2 by the directional impedance relays. This was the first of the unanticipated events. Later inspection of the oscillographic recording disclosed that the relay operation was undoubtedly due to the asymmetry of the current, which had the effect of increasing the operating range of the relay by some 40 per cent. This relay was blocked on subsequent tests, but protection was maintained by backup time delay over current relays.

On test 2 at 550 megavolt-amperes the same tie feeder was tripped again, but, on this occasion, by the directional impedance relay at the Hell Gate end of the feeder. This was unanticipated operation number 2. This relay was also blocked out for succeeding tests. Subsequent tests on this relay disclosed that there was excessive "wipe" in the contacts of the directional element. The incorrect operation was, therefore, attributed to failure of the directional contact to open before the impedance contacts closed. This may be better understood when it is noted that prior to the fault the power flow on the tie feeder was from Hell Gate towards Waterside, the tie feeder being used to load the generator prior to the test. The directional elements of the impedance relay were, therefore, closed under this condition, but when the fault was applied, the direction of power flow was reversed due to fault current being supplied from Waterside to Hell Gate. The tripping of the tie feeder, of course, caused a loss of load to the two generators after clearing the fault. The machines were, however, resynchronized to the station load bus without difficulty.

Test 2A at 550 megavolt-amperes was run off without undue incident.

In setting up the busses for the next test, a 160-megawatt unit, which had not been used in any of the tests up to that time, was placed on the test bus. One of the gallery observers heard a heavy static discharge, which appeared to come from the vicinity of the generator breaker compartment. This was unexpected event number 3. Although not directly related to the breaker test, this condition might have resulted in an operating failure if it had not been for the observers posted in the electrical galleries. The machine was immediately removed from service and testing of the circuit undertaken. It was ascertained that one of the stress cones at the termination of one of the cables was the seat of the trouble. The cable terminal was remade and gave no further trouble.

On test 3 at approximately 800 megavolt-amperes the air-blast breaker arced over on two phases and failed to clear the fault. The fault was cleared by the backup bus-tie breakers in the station in 29.5 cycles. Subsequent inspection of the bus-tie breakers disclosed that the 6-7 section bus-tie breaker had thrown some oil on the *B* phase pole unit. While the performance of the bus-tie breakers was not unusual in this respect, it was considered that a little more discretion might profitably be exercised, as means were available for so doing. The psychological effect of the flash and the accompanying sound effects, in connection with the arc to ground at the test breaker, undoubtedly lent some emphasis to the need for more caution. As a consequence, the backup relay in the generating station was arranged to trip all generators and tie feeders connected to the test bus, as well as the bus-tie breakers, since this would operate to distribute the duty among the various circuit breakers in the station somewhat more equitably.

It is well worthy of note that, although the air-blast breaker was subjected to severe arcing for nearly one-half second, there was no ensuing fire after arc extinction, no damage to any of the immediately adjacent apparatus in the breaker house, and the necessary servicing and adjustment were completed in

approximately two hours. This performance may be contrasted with that commonly experienced with oil-circuit-breaker failure of like nature.

After repairs and adjustments to the air-blast breaker, test 3 at approximately 860 megavolt-amperes and test 4 at approximately 1,000 megavolt-amperes were completed without undue incident.

On test *5B*, at approximately 1,500 megavolt-amperes, the air-blast breaker again failed to clear the fault, and it was cleared by the backup protection in 26 cycles. The damage to the air-blast circuit breaker was confined principally to the glaze of interphase brazing insulators and dislocation of some parts of the arc chute. As in test *3A*, there was no damage to adjacent equipment. There was no evidence of stress on any of the station circuit breakers except to a minor degree on the 6-7 bus-tie breakers. The voltage dip on the network distribution system ranged from 15 to 30 per cent in the Manhattan and Bronx districts, approximately 50 per cent at the Dunwoodie substation, and 10 to 20 per cent on the Niagara-Hudson system. A one-tenth cycle variation in frequency was recorded. A number of railroad synchronous converters in the Westchester area tripped out as a result of the disturbance. There were no operations of automatic network protector units noted at 24 key observation points. All generators and tie feeders were restored to the system within $4^1/_2$ minutes.

An examination of the end windings of all generators and equipment in the electrical galleries following these tests disclosed absolutely no evidence of any damage to the equipment.

1941 Tests

The second series of tests was made on Saturday, May 10, and Sunday, May 11, in 1941. The preparation was comparatively simple, since all the facilities had been retained from the previous year. A total of six three-phase short-circuit tests and one single-phase short-circuit test was scheduled. The three-phase tests consisted of one "*O*" and one "*CO*" test at approximately 600-, 1,200- and 1,500-megavolt-ampere levels.

The breaker tested in this series was the same as that used previously, except for modifications to increase the air pressure from 150 to 250 pounds per square inch, and certain modifications in the design of the arcing chamber and the exhaust stack. A special air-blast breaker designated as type *AR*-20-250*Y*, three-pole, 15-kv, was used for the closing control breaker in this series of tests, in lieu of type *H* breaker used previously. An additional cathode-ray oscillograph was provided for measurement of the voltages from the short-circuiting connection on the test breaker to ground.

All of the short-circuit tests were successfully interrupted by the air-blast breaker, and, as a consequence, all test work was completed very close to the schedule. During the tests at the higher levels of duty, there were several reports of flashes and sparks in the electrical galleries in the generating plant. These were, naturally, a matter of some concern, until a careful inspection disclosed only minor burns on the circuit-breaker operating rods at the clevis pins on the third floor and between a lighting-fixture outlet box and a ground bus on the second floor. As the short-circuit connection on the test breaker was ungrounded, and there was no indication of system ground current, it was evident that these manifestations in the galleries could have been caused only by induced voltages set up by the test current. Additional clearance was established at the points concerned and no further reports of sparks were received.

It is of interest to note that, on tests at the 1,500-megavolt-ampere level, the railroad synchronous converters in the Westchester area, which were subjected to a 50 per cent voltage dip, did not trip out as in the tests made the previous year. This very clearly indicates the benefits of high-speed fault clearing with respect to its effect on operating equipment.

In the "*O*" test "*5C*", it was hoped that, by setting the pretrip relay to operate 1.2 cycles after initiation of the fault, it might be possible to increase the test duty over that obtained in the previous year. For some unexplained reason, this was not entirely successful, although the pretripping time was checked by tests, before the test current was applied. The oscillographic record shows that arcing did not start until nearly three cycles after initiation of the fault, rather than 1.2 cycles as anticipated.

It may also be noted that the actual current obtained on tests was appreciably lower than the calculated values, particularly in the tests in excess of 1,000 megavolt-amperes.

This discrepancy may be attributed to two factors:

1. The reactance of the generator cables, busses, and test circuit within the station was not included in the calculations.

2. The subtransient and transient reactance constants of the large generator (188 megavolt-amperes) were probably higher than the calculated constants.

The line-to-ground test (*7D*) was made for the purpose of obtaining test data on the zero phase sequence reactance of the 188,000-megavolt-ampere unit and the station grounding system, rather than for testing the air-blast breaker. The 188-megavolt-ampere generator is composed of two 94-megavolt ampere generators driven by a cross compound turbine. The neutral of only one of the generators is grounded. In this test this generator unit and the tie to the Waterside II station were isolated from the rest of the system. The breaker tripping time was intentionally delayed in order to obtain a steady-state value of current. While the measured values were lower than those which had been calculated, this was attributed to the reactance introduced by the various multiple paths over which the ground current could flow between the generator neutral connection and the termination of the test cable in the electrical galleries. A recalculation of this circuit has shown that the difference between the actual test current and the calculated current would be accounted for by 0.05 ohm.

Conclusions

1. High-capacity short-circuit tests directly on the bus of a large power station may be made without unreasonable risk to the system and equipment, if the undertaking is preceded by careful planning, and if safeguards are established to protect against the abnormal conditions which customarily prevail as the result of short-circuit phenomena.

2. System tests under controlled conditions furnish valuable data on system and equipment performance. Such tests not only serve to check the performance of the apparatus ostensibly under test but also demonstrate the adequacy of other parts of the system, under the most severe conditions they are designed to meet.

3. Calculations of generating-station bus faults, in which the reactance of even very short runs of connections are neglected, apparently result in currents which are appreciably higher than actual values and are, therefore, on the conservative side in determining the interrupting duty of switching equipment.

4. Field testing tends to instill more confidence in the science of stability computations which has contributed so materially to the establishment of sound engineering principles in the design and operation of power systems.

5. It has been realistically demonstrated that the fire hazard inherent in the oil-circuit-breaker design is greatly minimized by the air-blast design.

Frequency-Modulated Carrier Telegraph System

F. B. BRAMHALL

J. E. BOUGHTWOOD
ASSOCIATE AIEE

Synopsis: Voice-frequency carrier-current telegraph systems used in this country and abroad have until now employed amplitude modulation, analogous to single current signalling in d-c telegraphy. A variety of so-called two-tone telegraph systems has been tried out by various workers, but none of these was adopted on a commercial scale because all required the employment of at least double the frequency spectrum space ordinarily assigned for amplitude modulation. The system described employs true frequency modulation to derive the advantages of polar current signalling, with the same spectrum efficiency as conventional amplitude systems, and secures at the same time freedom from attenuation change in the transmission medium and greater immunity to extraneous disturbing currents.

FREQUENCY-modulated systems for radiobroadcasting and facsimile transmission have been developed and placed in operation with remarkable success during the past few years. Publications covering practically all phases of this type of modulation, particularly with reference to its interference suppression qualities, have been legion. The fundamental principles have been soundly established and today are perhaps as thoroughly understood as those of amplitude modulation. Consequently, this paper will be confined to a brief outline of recent land-line voice-frequency telegraph-carrier developments culminating in the adaptation of frequency modulation.

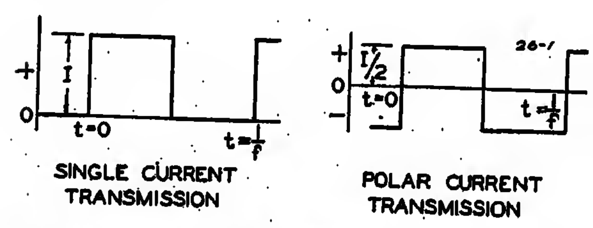

Figure 1. Relative current requirements in single- and polar-current systems for equal interference susceptibility

Theory

Virtually all telegraphic communication circuits fall under either of two basic types of operation:

(*a*). Single-current operation wherein transmission of current indicates a marking signal and absence of current a spacing signal.

(*b*). Polar operation wherein transmission of current of one sense or sign indicates a marking signal and current in the opposite sense or sign indicates a spacing signal.

Relative current requirements for equivalent interference susceptibility in single and polar operation are given in Figure 1. The resulting power relations are as follows:

$$\frac{\text{Power per cycle single operation}}{\text{Power per cycle polar operation}}=\frac{I^2R(t/2)}{(I/2)^2Rt}=2$$

$$\frac{\text{Peak power single operation}}{\text{Peak power polar operation}}=\frac{I^2R}{(I/2)^2R}=4$$

The two-to-one reduction in average power and the four-to-one reduction in peak power pertaining to the polar method constitutes a major reason for its adoption on all but relatively short d-c telegraph circuits. In addition, it is inherently immune to the bias losses experienced in single current operation as a result of variations in circuit transmission equivalent. Where peak current permissible is the limiting factor a two-to-one susceptibility gain is realized.

From their earliest inception down to the present time practically all telegraph carrier circuits have been founded on the basic form shown in Figure 2 wherein a carrier frequency is amplitude modulated, energy being transmitted on marking signals and interrupted on spacing signals in the usual single current mode of operation. The resulting square-topped wave trains existing at section *A* are modified by the restricted bandwidth of the channel tuners to the envelope form shown at section *B*. The envelope is then converted by a linear demodulator to a similarly shaped unidirectional pulsating current flowing through the receiving relay, as indicated by *C*. Faithful reproduction of the original modulation is secured by applying to the receiving relay a local bias of such magnitude as to produce equal marking and spacing intervals from the relay armature, curve *D*. It is self-evident from the sinusoidal nature of *C* that any alteration in its magnitude relative to the local operating bias—as, for example, might result from varying line attenuation—will destroy the equal time interval relationship between marking and spacing pulses introducing a loss in the form of biased relay action.

Inasmuch as the advantages of polar operation have always been clearly recognized, the development literature of the carrier telegraph has been replete with suggestions and schemes for its realization either in full or in part. To overcome bias susceptibility, for example, more or less complicated devices have been evolved which function either to maintain the demodulator input at a predetermined level or to regulate the receiving relay bias in accordance with received carrier level. Such artifices have been in use for a number of years with creditable results, their effectiveness being of the order indicated in Figure 3.

Of a more fundamental nature is the oft proposed "two-tone" polar carrier system involving two carrier sources of somewhat different frequency operating over separate channels and terminating differentially in a receiving relay as shown in Figure 4. Energy of frequency F_m is transmitted over one channel for a marking pulse and energy of frequency F_s over the other channel for a spacing pulse, thus closely approximating the requirements for polar transmission and providing the increased stability pertaining thereto. In theory, but not always in practice, both channels are similarly affected by variations in circuit attenuation, thus fulfilling the polar conditions for bias-free recep-

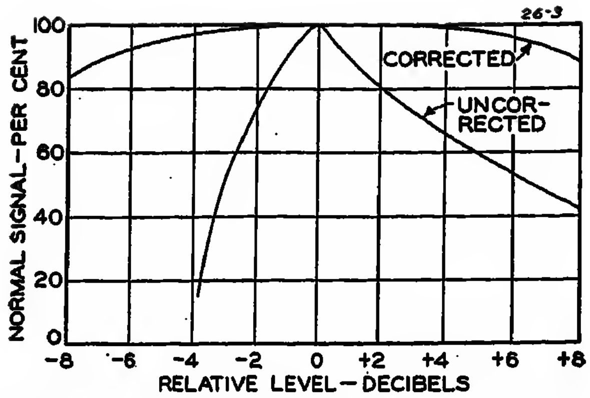

Figure 3. Effectiveness of automatic bias corrector

tion. From an operating aspect, however, this circuit is economically infeasible, requiring at least twice the frequency spectrum per telegraph channel as a single-current system. Suggestions for circumventing this obstacle usually involve a closer spacing of F_m and F_s so that both frequencies will be accepted by a tuner of the type normally provided for amplitude-modulation signalling. The fallacy herein can be seen by inspection of Figure 5, illustrating the distribution of carrier and sideband voltages in amplitude modulation of a carrier frequency.

In a single-current system (Figure 5a) the two intelligence-bearing sidebands created by the act of modulation and the carrier are symmetrically located with respect to, and lie entirely within the available band. The side bands, of course, are separated from the carrier by an interval equal to the modulating frequency. If an attempt is made to pass two carriers F_m and F_s representing marking and spacing frequencies through a similar band, the impossible conditions illustrated in Figure 5b obtain. Both carriers are amplitude modulated, each having an independent set of sidebands, the higher sideband of F_s and the lower of F_m lying outside the passband. The remaining components reaching the receiving demodulator will produce in its output not only a portion of the original modulation but also the beat between the two carriers and the two sidebands. The result will be severe distortion which can be eliminated only by sufficient separation and selection of F_m and F_s and their respective sidebands.

A mathematical analysis of carrier and sideband components resulting from the sine wave frequency modulation of a carrier F_o between the limits F_m and F_s at a rate equal to $(F_s-F_m)/2$ (unity modulation index) discloses the relative voltage relationships shown in Figure 6. A theoretically infinite number of sidebands are created symmetrically spaced with respect to the carrier and separated by intervals equal to the modulating frequency. Practically, however, the energy content of sideband components lying beyond the second is sufficiently minute to eliminate them from consideration. In addition, for telegraphic purposes, it has been found possible to further eliminate second-order sidebands without introducing serious distortion, leaving a spectrum during modulation similar to Figure 5a. The small distortion component can be eliminated by simple resistance-capacity shaping of the received signal if so desired. Under steady-state or d-c conditions the F_m or F_s frequency only is present, depending upon the transmitting relay position, and thus we have a method for deriving a "two-tone" polar system requiring no greater bandwidth than a conventional single-current amplitude-modulated carrier system. Except under certain critical conditions the F_m and F_s frequencies do not appear during modulation.

Description of System

The most obvious and practical method of frequency modulating a carrier in response to polar d-c telegraph signals is to vary the frequency of an oscillator by means of the transmitting relay. Figure 7 illustrates the method wherein the frequency determining circuit LC, tuned to mid-passband frequency F_o, is shunted by a control network comprising L_1 and L_2C_2 separately in series with rectifier elements A_1 and A_2. A cycle of operation, starting with the transmitting relay on spacing, connects positive battery to the control circuit establishing across R_1 a potential, positive with respect to ground, of magnitude slightly greater than the peak oscillating voltage existing across LC. Under this condition the impedance of rectifier A_2 approaches infinity, effectively isolating L_2C_2. Simultaneously rectifier A_1 becomes biased in the conducting direction, R_2 acting to limit the control current to a value slightly greater than the peak oscillating current flowing through A_1. As C_3 presents a low impedance to the carrier frequency, L_1 effectively parallels LC and the frequency approaches

$$\frac{1}{2\pi\sqrt{\frac{LL_1}{L+L_1}C}}=F_s$$

In like manner marking or negative battery applied by the transmitting relay isolates L_1, and L_2C_2 effectively parallels LC, the frequency approaching

$$\frac{1}{2\pi\sqrt{\frac{LL_2}{L+L_2}(C+C_2)}}=F_m$$

L_2 is necessary to provide a d-c path for the rectifier polarizing current similar to that provided by L_1. In practice, L_1, L_2, and C_2 are so proportioned that

$F_o-F_m=F_s-F_o=70$ cycles

The modulation index becomes equal to unity at a keying speed of 70 cycles per second, the nominal maximum of the system. The conditions set forth in Figure 6 are met by introducing a shaping network N to restrict the rate of change of control circuit voltage to an approximately sinusoidal shape at the maximum modulation frequency. Failure to provide this network introduces a distortion component of relatively small magnitude in the received signal. As might be surmised from Figure 7, the impedances of rectifiers A_1 and A_2, varying between maximum and minimum in inverse relationship, produce an amplitude factor in the modulated wave. This component is considerably smaller and, fortunately, inverse in phase to a similar component introduced by the curvature inherent in the attenuation characteristic of a normal carrier telegraph channel. Frequency

F_A = modulation frequency

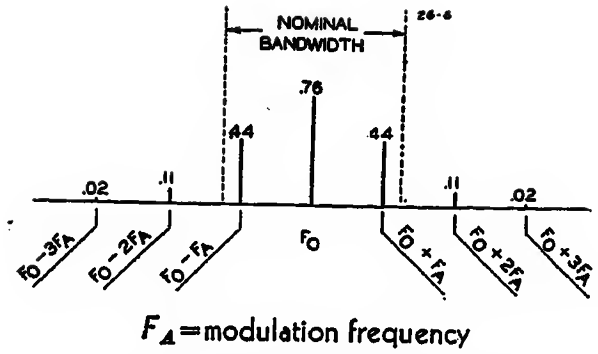

Figure 6. Carrier and side-band relationships in frequency modulation for unity modulation index

deviation accuracy of a high order is achieved as the percentage deviation is independent of voltage (above a certain critical minimum value) applied to the control circuit.

The receiving terminal employs a current limiter, converter, and differential detector as illustrated in Figure 8. The current limiter is perhaps unique in that regenerative action is utilized to secure the high order of sensitivity required on certain classes of systems where terminal repeaters are not justifiable. Regeneration is set to give stable limiting action down to minus 45 decibels, a gain in sensitivity of approximately 25 decibels over the unregenerative state. Thus a practically constant value of effective relay operating current is assured for all conditions conceivably encountered in commercial carrier practice. Conversion from frequency modulation to amplitude modulation prior to detection is effected by a discriminator comprising two parallel-tuned circuits L_1C_1 and L_2C_2 operating in series and tuned respectively to marking and spacing frequencies. The two discriminator output voltages, after being separately detected, are differentially added before being applied to a d-c power amplifier stage for operating the receiving relay. A differential biasing circuit is provided to compensate for slight circuit or relay misalignment. Figure 9 shows the mechanical arrangement employed in transmitter and receiver design, each unit occupying $3^1/_2$ inches of vertical rack space.

Comparative Test Results

A series of laboratory and field tests were made to determine the relative merits of frequency-modulated and conventional amplitude-modulated systems. The following data were taken at a line speed of 60 cycles per second under identical circuit conditions on a basis of equal peak carrier voltages as a criterion. A transmission testing machine was used to determine operating margins under any given set of conditions in terms of milliseconds loss, a method universally recognized for its accuracy in telegraph transmission studies.

A comparison of circuit susceptibility to single-frequency crosstalk (simulating severe unbalance in four-wire carrier systems as may be encountered under emergency conditions) is given in Figure 10. With amplitude modulation the signal loss is substantially proportional to the receiving tuner attenuation characteristic, becoming a maximum of 3.15 milliseconds for a 12 decibel peak ratio between signal and crosstalk at mid-band frequency. Conversely the frequency modulation characteristic displays the familiar double hump resulting from its triangular noise spectrum wherein the loss due to a single interfering frequency is proportional to its separation from the carrier frequency. As a deviation ratio of unity is employed, maximum loss occurs at a crosstalk frequency differing from the carrier by an interval equal to the deviation frequency. The signal loss at this point of greatest susceptibility is approximately 1.2 milliseconds, or a decrease of 8.3 decibels from the maximum loss with amplitude modulation for interference of this character.

A common form of undesirable noise encountered in telegraph carrier circuits is a random or fluctuating type produced by battery supplies, shot effect in amplifiers, etc. wherein the interference contains frequency components more or less uniformly distributed throughout the channel pass-band. Figure 11 is the average peak loss in milliseconds as measured at the receiving relay contacts for various values of fluctuating noise—a particularly difficult task to perform accurately owing to the probability factor inherent to random interference. A substantial improvement of roughly 9 decibels obtains to frequency modulation for large signal-to-noise ratios as compared with the theoretical value of $2\sqrt{3}\ F_d/F_a$ or 10.8 decibels.

A third form of interference to which open wire carrier circuits are particularly vulnerable is the impulsive type, usually attributable to lightning, wherein shock excitation of the receiving tuner by a steep wavefront produces in the terminal equipment an exponential wave train having a fundamental frequency in the neighborhood of the nominal carrier frequency. The ultimate signal loss is a function of both the amplitude and the phase of the transient relative to the instantaneous carrier, resulting in an interference fortuitous in nature. Peaks of maximum loss thus occur on a probability basis and must be given due consideration in the method of loss measurement. Figure 12 is a comparison of amplitude and frequency modulation under these conditions and closely resembles Figure 11 for fluctuation noise. A reduction of approximately 10.5 decibels in average peak loss is secured for large signal-to-noise ratios as compared to the theoretical improvement factor $4F_d/F_a$ or 12 decibels.

Operational Considerations

It is common practice in high-frequency carrier systems to employ group modula-

tion and demodulation for transferring the fundamental carrier channels to their assigned frequency band for transmission over the line. In the perfect case, channel frequencies leaving the receiving group demodulator are identical to those entering the transmitting group modulator. Practically, however, a frequency shift exists equal in magnitude to the instantaneous frequency difference in the carrier sources available for group modulation and demodulation which, by the very nature of frequency modulation, introduces a bias component in the received signal. It is required, therefore, that each frequency translating oscillator be a highly stable carrier source having an absolute frequency variation of less than plus or minus two cycles. Similarly, the tolerances on channel tuner stability are somewhat more stringent than for amplitude modulation but can be easily attained in production when proper precautions are observed. The difficulty of accurate level regulation on long carrier circuits is reduced to a problem of maintaining the aggregate repeater loads safely below the distortion point. This is easily accomplished by various well known techniques. Where higher grade carrier channels are required on an existing amplitude system, frequency-modulated channels can be directly substituted without disturbing the rest of the installation.

Evidence thus far presented would indicate a substantial improvement in carrier circuit performance wherever existing amplitude-modulated systems are converted to frequency modulation. This has been amply substantiated in practice during the past three years. Perhaps the outstanding advantage from a carrier attendant's viewpoint lies in the immunity of frequency modulation to received level variations. This feature provides greater flexibility as a channel group can be instantaneously swapped between routes having widely different equalization characteristics without readjusting individual channel levels for optimum performance; an important consideration where synchronism must be maintained on automatic telegraph circuits. In addition, detrimental effects of small instantaneous level fluctuations continually occurring on open wire carrier circuits are completely eliminated.

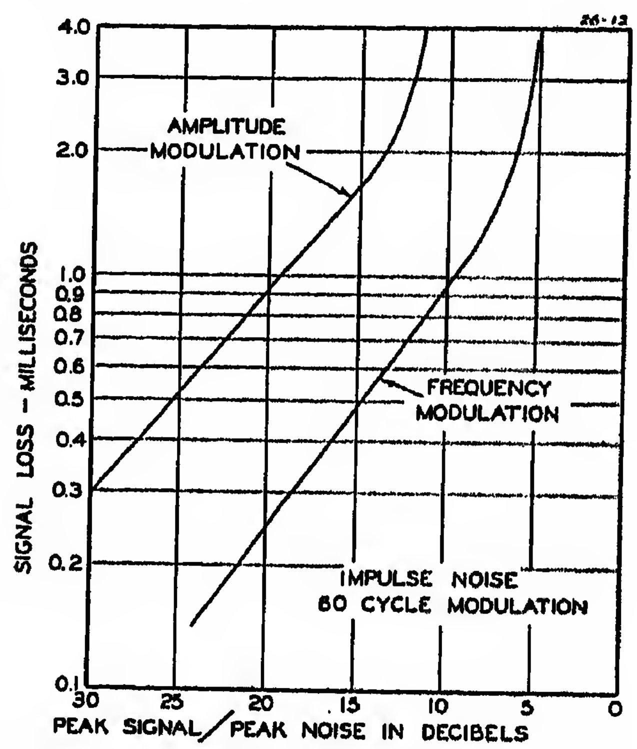

Figure 12. Effect of impulse noise on amplitude- and frequency-modulated systems

Polar operation and the triangular noise spectrum of frequency modulation combine to produce a real and substantial improvement in circuit interference susceptibility, reflected in greater operating margins and reduced testing and regulating work.

Performance of Ground-Relayed Distribution Circuits During Faults to Ground

Synopsis: An extensive oscillographic study has been made on power distribution feeders primarily to obtain data useful in the consideration of joint use of poles by power and telephone facilities. Some of the results, chiefly those obtained from three-phase, four-wire, multigrounded neutral feeders equipped with instantaneous ground relays and for immediate breaker reclosure, are believed to be of general interest and are presented herewith. Included are data on the performance of the protective devices utilized for clearing ground faults on the feeders included in the study, the effectiveness and certain limitations of these devices, and characteristics of the faults experienced.

STUDIES made by the Joint Subcommittee on Development and Research of the Edison Electric Institute and Bell Telephone System have shown that one of the important factors in promoting safety where power and telephone circuits are on jointly used poles is the prompt de-energization of the power circuit in the event of a contact with the telephone plant.[1] The Joint Subcommittee with the co-operation of a number of power companies, therefore, has made an extensive oscillographic study of the performance of protective devices utilized on power distribution feeders for clearing ground faults. Some of the feeders selected for study were of the three-phase, four-wire, multigrounded neutral type equipped with instantaneous ground relays and for immediate reclosure of the breaker. This paper deals primarily with the data obtained from this type of feeder regarding the performance of the protective equipment in clearing ground faults and the characteristics of the faults experienced which are thought to be of most general interest.

Since the oscillographs usually were arranged to record only residual currents in the power feeders, multiple-phase faults were recorded only when ground was also involved. As some disturbances were self-clearing and some were due to reclosures on or recurrences of sustained faults, somewhat special meanings have been attached herein to the terms "fault" and "disturbance."

"Fault" is considered to be any occurrence which caused a measurable oscillogram of power system current, which, in so far as could be established, was not from reclosure of a breaker or fuse on a previously existing trouble, from repeated oscillograph operations on a sustained case of trouble, or from load unbalance.

"Disturbance" is a fault as defined above, a reclosure on or recurrence of a previously established fault. In many instances a single oscillogram showed more than one disturbance due either to the fault re-establishing after being self-cleared or to reclosure of some protective equipment on sustained faults.

Extent of Data

The principal data presented in this paper concerning feeders equipped with instantaneous ground relays and for immediate breaker reclosure were obtained from feeders of four power companies. The extent of these observations is summarized in Table I. A total of 1,498 oscillograms, representing 1,279 separate faults and 1,758 disturbances, was obtained. The various feeders were under observation for periods ranging from about 4 to 48 months and had a total mileage of approximately 450 miles. Some data regarding tree-leakage currents and the performance of repeater-type fuses and pole-top reclosures were taken from observations on feeders equipped with inverse-time phase relays only or with inverse-time phase and ground relays. Details of these feeders are not given herein.

Table II gives the relay settings and reclosure practice applying to each feeder during the observations. The instantaneous ground relays locked out prior to first reclosure of the breaker on the feeders of companies *A*, *B*, and *C* but controlled the breaker for the first two openings in the case of company *D*. Following lockout of the instantaneous relays the feeders were protected by inverse-time phase and in some cases, ground relays.

Paper 42-8, recommended by the AIEE committees on protective devices and power transmission and distribution for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted August 8, 1941; made available for printing November 3, 1941.

C. L. Gilkeson, formerly with the Edison Electric Institute, New York, N. Y., is now with the Virginia Electric and Power Company, Richmond, Va. P. A. Jeanne and J. C. Davenport, Jr. are engineers with the Bell Telephone Laboratories, New York, N. Y.

Performance of Relays and Circuit Breakers

A. Manner of Fault Clearance and Automatic-Reclosure Performance

The manner of clearance of all faults, as deduced from the appearance of the oscillographic records in conjunction with the correlation data supplied by the power companies, is summarized in part *A*, Table III. The percentage of faults cleared by circuit-breaker operation ranged from 13 to 76 per cent. This wide spread in percentage is largely attributable to differences in fusing practice and to use of open-gap lightning protection on transformers of some feeders. The remainder of the faults in each case were either self-clearing or were cleared by other protection, such as transformer and branch-line fuses or pole-top reclosers located out on the feeder. No distinction has been made in tables and charts between these manners of fault clearance since the data were not sufficient, in most instances, for making such a classification. On one feeder (not otherwise considered in this paper) the observing equipment was arranged so that operations of pole-top reclosers, which protect most of the branches, could be identified. It was definitely established that they cleared 27 per cent of the faults. Undoubtedly other faults were also cleared in this manner but the data were not conclusive. The main breaker, which is controlled by inverse-time relays, cleared only about 22 per cent of the faults.

Part *B* of Table III was prepared to show the results of instantaneous relaying and immediate automatic reclosure. Under section *B*1 all initial breaker operations are considered, irrespective of whether the fault current persisted until the breaker opened; that is, included in this category are cases in which a fault initiated a breaker operation, but the current was interrupted by a fuse or otherwise before the breaker started to open. In section *B*2 of the table only those cases are included in which the fault current persisted until the breaker first opened, the breaker being responsible for initial interruption of the fault. This latter category would appear to be the better indication of the benefit that can be attributed directly to instantaneous relaying and rapid reclosure. The data indicate that from 50 to 100 per cent of faults falling in this category were clear on first reclosure, the average for all feeders being about 70 per cent.

There are, of course, a number of factors which affect the manner in which faults are cleared. One of these factors is

* All feeders are equipped with an instantaneous ground relay and for immediate reclosure of the breaker. Feeders of companies *A*, *C*, and *D* are three-phase, four-wire, multigrounded neutral feeders, while those of company *B* are three-phase, three-wire with the neutral grounded through a grounding transformer bank.

** Power system residual current was recorded in each instance.

§ These records are from accidental disturbances and do not include records from unbalanced load currents and staged tests. Where the oscillograph reoperated on a sustained fault the series of records obtained has been counted as one instance.

the nature of the fault itself, that is, it may be of very short duration, probably due to a momentary flashover which is self-clearing before a breaker or fuse has time to operate or it may be cleared by the operation of small transformer fuses. Where instantaneous ground relays are used it is intended that they operate to clear such faults before other protective equipment, excepting small fuses, can operate.

In the case of feeder *E*-1215 of company *A*, a cold cathode tube relay was used as the instantaneous ground relay for a portion of the observation period. At first it was used with no purposely introduced time delay; later, time delay of two cycles was introduced to prevent unnecessary tripping. Without time delay its operating time was approximately 0.007 second. As it has no inverse-time characteristic, operation is initiated practically as soon as the operating current is reached. This is an advantage if the fault is going to persist. However, if the fault consists solely of very short lived kicks, it is desirable to have a small delay in relay operation. A comparison of the operation of the tube-type relay with and without time delay of two cycles is given in Table *A*. From these data it is evident that slowing

down the relay saved a number of unnecessary trippings on very short duration disturbances.

B. Speed of Clearance and Reclosure

The recorded average time from initiation of fault to first breaker opening ranged from 7 to 15 cycles for the various feeders; the average time from initiation of fault to first immediate reclosure ranged from 34 to 57 cycles. In arriving at these times, one cycle has been added to the duration shown by the oscillograms to allow for the time it takes the oscillograph film to get in motion.

The oscillograms pictured in Figure 1 (A) and (B) illustrate faults which were breaker-cleared by operation of instantaneous ground relays which control the breaker for two openings. (Element 2, which indicates breaker operation, was controlled from a contact on the breaker whose opening lagged the actual breaker

openings and consequently closed slightly ahead of the breaker.) The first illustration also shows a typical transient following breaker reclosure and an instance in which the transient caused a false relay operation. These transients are discussed in the following section. The second illustration shows two operations in sequence of the breaker, both initiated by the instantaneous relay. In this latter case the fault was temporarily cleared but became reestablished about 40 cycles after first reclosure took place.

Observations on several feeders which were equipped near the substation with repeater-type fuses (three-shot), indicate an average reclosure time of the fuses of 32 cycles. Other observations indicate that pole-top reclosures, of the type used, operate in from two to four cycles and reclose in from two to four seconds.

The oscillograms pictured in Figure 1(C) and (D) illustrate operation in sequence of repeater-type fuses. The first illustration is for a one line-to-ground fault while the second illustration is for a line-to-line fault. Figure 1(E) illustrates the sequence of operation of a pole-top recloser.

C. Transients Following Breaker Reclosure

Reclosure of breakers on sound feeders usually produced residual current transients of fundamental frequency and nonsymmetrical wave form caused by the inrush of magnetizing current to distribution transformers connected between phase wires and neutral. The general nature of these transients is illustrated in Figure 1(A) which shows an oscillogram of a fault cleared by an instantaneous relay on a feeder equipped for immediate reclosure. In this instance the transient operated the instantaneous relay and retripped the breaker.

These transients have been studied with regard to their possible limitation on re-

Table A. Operation of Cold-Cathode-Tube Relay

\# One cycle added to allow for time required for oscillograph film to get in motion.

lay pickup current settings. It may be said, in general, that where instantaneous relays have control until after first reclosure (Halls feeder and feeder 7*M*35 utilize this condition) such transients may place a minimum limit on relay pickup current settings. However, this limit need not be the maximum value of the reclosure transient (except perhaps in the case of tube relays which have no purposely introduced time delay) because the maximum magnitude of the transient occurs only within the first half cycle, the transient attentuates rapidly and, due to the almost complete suppression of the upper (or lower) half of the wave, the effective value is much less than that of a sine wave of equivalent peak value. This is well illustrated by the fact that only eight cases of false relay operation were recorded on the Halls feeder from reclosure transients although the instantaneous ground relay was set to pick up on 25 amperes and the recorded maximum currents from reclosure transients ranged up to 125 amperes. The currents from this cause recorded on the other systems ranged up to 300 amperes but no relay operations could be definitely attributed to reclosure transients. Current values quoted for reclosure transients are peak amperes divided by $\sqrt{2}$.

D. Unbalanced Load Currents

A study of the oscillographic data was made to determine whether unbalanced load currents in four-wire, multigrounded neutral feeders might impose an important limitation on the pickup current settings of ground relays in the range from 50 to 100 amperes. The data obtained are summarized in Table *B*.

Unbalanced currents due to switching and temporary two-phase operation, as well as those due to normal load unbalance, have been included in this tabulation. The figures under the column headed "Total No." represent separate instances in which the unbalanced currents reached values sufficient to produce oscillograms. Momentary load surges sometimes tripped the oscillograph as is evinced by the fact that sustained currents lower than the oscillograph tripping currents were recorded. Only in the case of the four-kilovolt feeders of company *A* did the unbalanced load current exceed the relay pickup current, and the only instance of breaker operation due to unbalanced load current occurred on one of these feeders. The ground relays on these feeders were an experimental installation, and it seems to have been the practice to cut out these relays when, during emergency operation, a feeder was unbalanced by load being switched to or from another feeder. Most of the large unbalanced currents were recorded during such emergency operation.

These data are limited but indicate that ground relay settings of from 50 to 100 per cent of normal maximum load current but not less than 25 to 35 amperes would be realizable.

Table B. Data Regarding Unbalanced Local Currents

**Sustained current magnitudes. In a few instances the current magnitudes momentarily exceeded these values.

#No records of measurable magnitude were obtained from Feeder 7*M*35.

Effectiveness of Circuit Breakers and Fuses in Clearing Faults

In order to study the efficacy of relays, circuit breakers and fuses in clearing faulted lines, "shotgun" diagrams showing the magnitude and duration of all observed ground-fault currents having durations of one cycle or over were prepared for each feeder. On each of the diagrams the approximate relaying time-current characteristic curves also were plotted. Illustrations of this type of diagram are given in Figures 2 and 3 for feeder 3003 and the Hall's feeder respectively. In these figures the lines and curves coded as relay characteristics include relay plus breaker time. For instantaneous relays the time of operation, considered the same for all currents above pickup current, was taken as the average duration of instantaneously relayed faults, as determined from oscillographic records, plus one cycle to allow time for the oscillograph to get in operation. The plotted points represent the durations of the individual disturbances, as shown by the oscillograms, without any allowance for oscillograph starting time, a procedure followed to simplify handling the data. This, together with the fact that it is not always possible to determine accurately the duration from every record, accounts to some extent for the distribution of points above and below the instantaneous relay characteristic.

In general, the maximum current magnitude shown by each oscillographic record was used in plotting the points in the figures. Since most of the oscillograms showed a fairly uniform magnitude wave trace, the relays and fuses were usually subjected throughout the duration of the disturbance to currents of approximately the values plotted. A code is used to indicate the manner of clearance of the disturbances.

The results of these analyses, which were made for all feeders, indicate that the manner of fault clearance was consistent with what would be expected from the relay and fuse characteristic curves and other known circumstances at the times of the disturbances.

Performance of Fuses

In every case which could be used for this phase of the study, the fuse was found to have cleared within the time shown by its characteristic curve. In many instances where the clearing was apparently much faster than expected, the correlation data indicated that more than one phase conductor was involved in the fault. Some cases of damage to fuse holders were reported but there is no indication that the arc was sustained after the fuse blew.

Effectiveness of Fuse and Relay Co-ordination

Where high-speed (instantaneous) relaying and rapid reclosure are employed, the type of co-ordination sought is to protect, in so far as possible, feeder and

*Correlation data were most complete in the case of companies *A* and *B* and feeder *7M35* of company *D*.

§These data include some faults not recorded by the oscillograph but which were indicated by the correlation data.

Explanation of items used in classification:

Flashovers—only cases where no damage other than fuse operation was reported. While a flashover is not definitely known to have occurred, the presumption from the character of the disturbance, is that such was the case. Many faults of short duration fall in this category.

Conductors down—phase conductors, ground wires, etc.—no structures reported down.

Equipment failure—transformers, lightning arresters, etc.

Whipping conductors—contacts with other conductors, line structures, or structures adjacent to line.

Foreign objects—wires, trees, or limbs in line, automobiles striking poles, etc.

branch-line fuses during the first, and in some cases the second, tripout, so as to give faults, such as arc-overs due to lightning, an opportunity to clear before branch circuits or sections of the main feeder are interrupted and before permanent damage occurs. To provide against the contingency of permanent faults, the instantaneous relay is usually cut out prior to or in some cases following the first reclosure, and inverse-time relays are then depended upon for back-up protection of the circuit. The inverse-time relay in this case is set to allow branch-line fuses to clear before the breaker again operates. Thus, the objective is to prevent fuses from blowing by the use of instantaneous relays, while allowing them to blow before the inverse-time relay operates.

In the case of the 12-kv feeders of company *A* and the feeders of company *B*, branch-line fuses were co-ordinated with inverse-time relays and some benefit in the protection of these fuses apparently resulted from the use of instantaneous relays. However, with the speed of breaker operation utilized on feeders of the capacity of these it appears impracticable to protect branch-line fuses of about 40 amperes capacity or less, as these smaller rated fuses usually blew before the breaker, operated by an instantaneous relay, could clear the fault. Co-ordination between fuses and inverse-time relays is evidenced by the fact that the inverse-time relays were seldom called upon to clear a disturbance.

In the case of company *C*, it may be said that co-ordination appears to be good, since so many faults were cleared by the instantaneous relay and since so few of those which persisted beyond first reclosure were breaker-cleared.

The Halls feeder has relatively few fuses, the maximum size being 40 amperes. Since the feeder is fused near the substation, a fault at almost any location will have a fuse between it and the substation. Only 27 branch-fuse operations have been correlated with records of disturbances on this feeder and in each case they operated following lockout of the instantaneous relay but before the inverse-time relay contacts could close. Operations of the inverse-time relays occurred on other faults following lockout of instantaneous relays. In all but four cases the current magnitude, with respect to the duration shown on the oscillogram, was below that for which a 40-ampere fuse would co-ordinate with the inverse-time relays. In three of these four cases there was apparently no fuse between the fault and substation; in the other case the circumstances are not known. Thus, benefit apparently accrued from the protection of branch-line fuses by instantaneous relays. Also, the use of instantaneous relays may have prevented some cases of wire failure.

The data from the four-kilovolt feeders of company *A* and feeder *7M35* of company *D* are too meager to give much indication on this subject. However, it is probable that some benefit accrued from the protection of branch fuses by instantaneous relays.

Effect of Ground Relaying on Continuity of Power Supply

This study indicates that as compared with feeders utilizing inverse-time relays only, the use of instantaneous ground relays, while causing more frequent breaker operations, has increased the continuity of power supply, in that some branch-fuse

§25-Cycle feeders are carried on the same poles with feeder 20 at certain locations. Eight of the faults involving broken wires could be associated with contact or flashovers between the wires of these two feeders.

operations were prevented and probably some wire failures as well. Also, the instantaneous relays clear the fault much more quickly than do inverse-time relays. Thus, in the case of faults which were not permanent, momentary outages on the feeders were substituted for long time outages. Where instantaneous relays are set to pick up at much lower current than the inverse-time phase relays (see Figure 2) they furnish added assurance of positive disconnection in the fault current range between the two relay pickup current values, 40 to 320 amperes in this case. It should be pointed out that, except on feeders having limited fault current, instantaneous ground relays would not be expected to save branch-line fuses below 30 or 40-ampere rating.

Cause and Nature of Faults

As far as it has been practicable, all oscillographic records have been correlated with cause and nature of the trouble on the power feeders. In Table IV all faults are classified in accordance with the attributed primary cause and nature of the trouble. The lightning classification has been divided into two parts; one includes faults definitely correlated as due to lightning or to a storm during the lightning season; the other includes correlated plus uncorrelated faults whose causes and natures were unknown but which occurred during the lightning season (April 15–September 15). Experience indicates that these latter disturbances are, in most instances, due to electrical storms. The sum of these two is believed to represent more nearly the true effect of lightning. The data show that lightning has been the major cause of trouble, accounting in general for about 60 per cent of the total faults.

Trees have been reported as being responsible for only a small percentage of the faults and the trouble from them was largely due to limbs or trees falling into, or being blown or cut into the lines. The data from none of the systems gave evidence of intermittent or sustained leakage currents which might be a possible limitation to ground relaying. This has been substantiated by staged tests, conducted by two of the co-operating power companies, utilizing bare copper wires on 4 and 11-kv power circuits. The tests were made when the sap was in the trees and contact with the energized conductor was much better than would ordinarily occur with a wire in accidental contact with a tree limb. The maximum fault current of 10.5 amperes was recorded for a test in which the conductor was connected to a spike driven into a live willow tree trunk two feet above ground. The next highest current (nine amperes) was obtained from a test in which the conductor was wrapped several times around a dogwood tree trunk seven feet from the ground and pulled tight enough to break through the outer bark.

The above indicates that one or a few tree grounds are not likely to draw enough current to cause ground relay operation except where pickup currents are quite low, say below 25 amperes. It, therefore, appears likely that most tree trouble is due to branches getting across phase conductors, between phase conductors and neutral, or pushing the wires together, rather than to leakage through the trees to ground.

Faults Involving Broken and Burned-Down Wires*

All correlation data from each power system have been examined to determine, as far as practicable, those faults which apparently involved broken wires. The results as regards the causes of these faults are summarized in Table V. The major causes were wind and acts of man.

* In this section no distinction is made between broken and burned-down wires or between phase conductors and ground wires.

Although the data regarding the question of broken wires are, in some instances, rather meager, they indicate that of the total faults experienced on most of the feeders only a small percentage involved broken wires.

Magnitude and Duration of Recorded Residual Currents

Data obtained regarding the magnitude distribution of sustained fault currents (largest magnitude sustained for three cycles or more) are given by cumulative percentage curves in Figure 4. The ordinates of these curves indicate the percentage of faults in which the current magnitudes equalled or exceeded the corresponding abscissa. Since, in most instances, the wave traces are fairly uniform, the distribution of maximum current values would be essentially the same as is shown in Figure 4.

The duration distribution of the currents recorded on feeder K-1202 of company A are given by cumulative percentage curves in Figure 5. One curve is for the records obtained after the feeder was equipped with an instantaneous ground relay; the other curve is for the period when the feeder was equipped only with inverse-time relays and is included to show the effect of instantaneous relaying. The first mentioned curve is typical of the data from all of the instantaneously relayed feeders.

Summary

1. Oscillographic data obtained under operating conditions regarding the performance of feeders equipped for instantaneous ground relaying and immediate automatic reclosure are given. These data are presented as a matter of information and not in advocacy of any particular form of ground-fault protection.

2. The observations described herein, as well as others made during the same study, indicate that relays, fuses, and circuit interrupters operate consistently and reliably on currents at or above which they are set or designed to operate.

3. Considering only faults which persisted at least until initial breaker-opening, the percentage in which feeders were clear on first (immediate) reclosure ranged from 50 to 100 per cent, the average being about 70 per cent.

4. The average time from initiation of fault to first breaker-opening ranged from 7 to 15 cycles for the various feeders; average time from initiation of fault to first reclosure ranged from 34 to 57 cycles.

5. A main objective of instantaneous relaying and immediate reclosure is to substitute a brief outage on the whole feeder for a long time outage on a branch by preventing branch-line fuse outages on temporary faults such as flashovers. This was successfully accomplished in most instances for the feeders under observation except where fuses were less than 40 amperes rating on the higher capacity feeders.

6. On four-wire feeders, a transient caused by magnetizing current taken by distribution transformers on breaker reclosure may limit the pickup current for which instantaneous ground relays can be set if these relays retain control of the breaker for more than the first opening.

7. Data regarding the magnitude of unbalanced load current on the multigrounded neutral circuits were limited. However, it would appear that ground relay settings of from 50 to 100 per cent of normal maximum load current but not less than 25 to 35 amperes would be realizable.

8. Lightning was the major cause of trouble, accounting in general for about 60 per cent of the total faults.

9. Trees were responsible for only a small proportion of the total faults. Trouble from them was largely due to branches or trees falling into or being cut or blown into the lines. On no system was there evidence of intermittent or sustained tree leakage being a possible limitation to ground relaying with pickup currents of the order indicated in (7) above. This is further substantiated by staged tests in which the current drawn by well made tree grounds was measured.

High-Capacity Circuit-Breaker Testing Station

J. B. MacNEILL
MEMBER AIEE

W. B. BATTEN
ASSOCIATE AIEE

TEN years' experience with a high-power laboratory, giving approximately 1,100,000 three-phase initial symmetrical kilovolt-amperes on short circuit at the machine bus,[1] has defined its usefulness and limitations and has resulted in an addition to its installed equipment. By taking advantage of assymmetry this capacity has been sufficient to demonstrate ratings up to 1,500,000 kva, and the increased testing capacity is required to demonstrate interrupting ratings of 2,500,000 kva.

The previous equipment was capable of testing most circuit breakers up to their interrupting rating, but for the largest sizes special methods of testing had to be used to approximate the conditions at the breaker rating.

1. Single-phase testing on three-phase devices. This method is generally satisfactory providing the influence of adjacent phases on closing operation, speed of contact action, and restored voltage conditions are allowed for. It is particularly valuable on large designs with good phase isolation, but must be carefully supervised on compact designs where the influence of adjacent phases may be great.

2. Double-phase to ground on a single-pole,[2] with the contact cross bar grounded, was first used in Europe and is valuable on multiple-interrupter devices as it increases the total voltage on the pole unit for a given current and gives tank pressures corresponding to energy losses not otherwise obtainable. However, its use requires care, as the first interrupter to clear opens only 87 per cent of phase-to-phase voltage, and the voltage across the second interrupter is limited to the phase-to-phase value. Thus, a double 66-kv connection used to demonstrate 132-kv is limited in that the first interrupter opens 57.4-kv and the second opens 66-kv.

3. The use of high superposed voltage on a low-voltage circuit[3] has been advocated and discussed widely. Our experience with it indicates it is not sufficiently reliable for general use since the current wave form of the low-voltage circuit as it approaches final zero is affected, and leakage currents in the arc space around current zero are altered.

Paper 42-26, recommended by the AIEE committee on protective devices, for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 18, 1941; made available for printing December 8, 1941.

J. B. MacNeill is manager of the engineering switchgear division, and W. B. Batten an engineer, both with Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa. The authors wish to express their thanks to Mr. R. C. Van Sickle for his suggestions and assistance in preparing this paper.

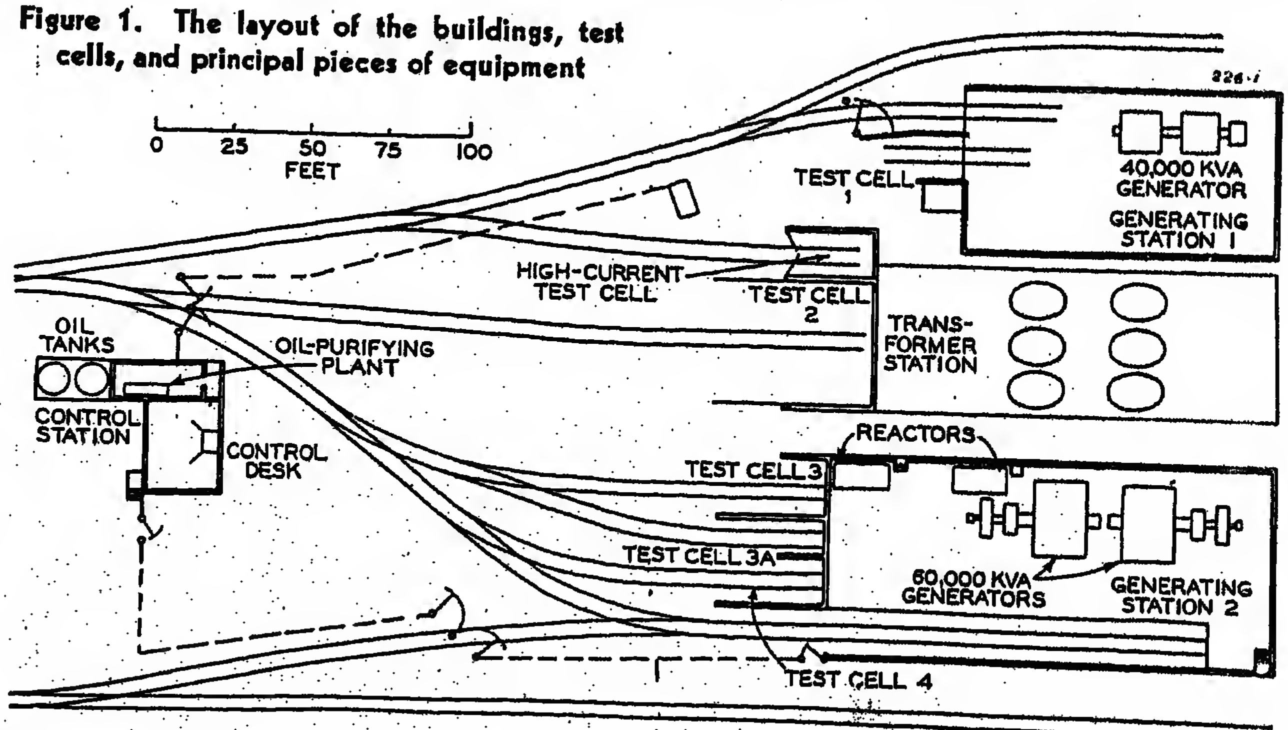
Because of these limitations in testing capacity, it has been desirable in some cases to design circuit breakers with multiple interrupters arranged for adequate distribution of voltage between them, each of which either singly or in groups can be adequately demonstrated for the maximum duty imposed on it. Eight and ten units per pole have been designed for very severe apparatus conditions and these designs have been presented to the Institute.[4] This practice, while giving satisfactory results in operation, requires a complication of design which should not be necessary in the future with the increased demand for high-power and high-speed switching.

On the other hand, when an attempt is made to simplify the structure of high-voltage and high-power interrupting devices, the need for increased testing capacity is evident, since the burden on the individual interrupter is increased and its reliability must also be above question. As an illustration, at the 1941 winter convention a single interrupter for 2,500,000-kva service at 132 kv was presented.[5] This trend, moreover, will be prominent in future design because of low arc energy, simplification of structure, and reduced cost.

Also, the use of compressed air for powerhouse installations is growing and 2,500,000-kva interrupting-capacity devices have been built and tested using a single break per pole. There are possibilities of space saving with this type, but such space reduction of three-pole devices increases the hazard of adjacent poles, and makes three-phase testing under full power and voltage conditions desirable. The results of such tests made in the laboratory here discussed are given in the paper by Ludwig, Wilcox, and Baker at this convention.

The laboratory described below is felt adequate for the future demands of American switchgear practice; in fact, its complete power is necessary for the largest

Figure 1. The layout of the buildings, test cells, and principal pieces of equipment



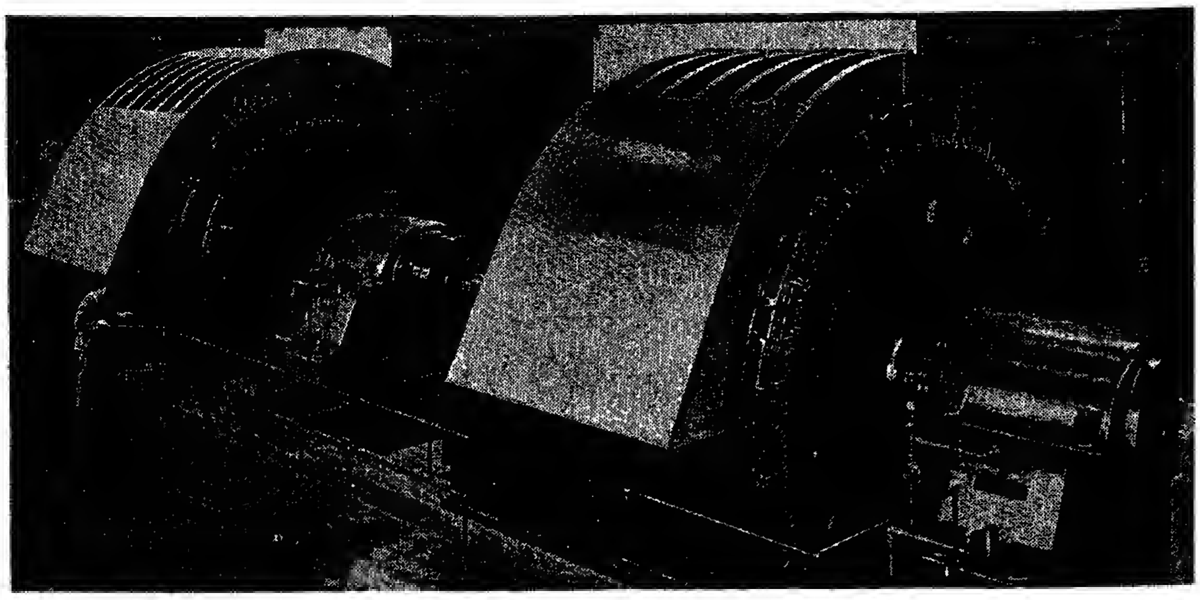


Figure 2. Station 2—a second generator doubles the short-circuit capacity

capacities only. However, it is in these large capacities that the major problems of switchgear design occur, including high-speed interruption, high-speed reclosing, and repetitive duty. These problems require continued activity, not only on existing types of apparatus, but especially on those newer forms now becoming active in this country, and on which a background of field experience at high power is lacking.

Development and Use of the Laboratories

The Westinghouse program of providing equipment for high-capacity short-circuit testing was inaugurated in 1925 when generating equipment capable of producing 400,000 initial three-phase symmetrical short-circuit kilovolt-amperes was installed. This was available at generator voltages only. Extensive use was made of this equipment, but transformers to extend the range of test voltages were needed. A bank of three 33,333-kva transformers together with a suitable high-voltage cell was put in service in 1928 to permit testing up to 230 kv. This transformer bank, which was larger than necessary at the time, was selected as the need for more generating capacity was already apparent. In 1930 the second generating station designed to house two 60,000-kva generators (nominal rating) was constructed, and one generator was installed. During the following ten years, this generator was used in making about 47,000 short-circuit tests. The need for more generating capacity became apparent late in this period and the second 60,000-kva unit was put in service in 1940. At this time a second bank of 33,333-kva transformers was installed to provide testing capacity at the higher voltages commensurate with the increased generating capacity.

To supplement this equipment, a high-current low-voltage transformer bank and a high-current test cell were added in 1940, and in 1941 a low-temperature test room was provided.

Since 1925 approximately 100,000 short-circuit tests (including both large and small generators) have been made in these laboratories. Although the greater part of this work has been for the purpose of determining interrupting ability of circuit breakers, many other types of equipment have been subjected to short-circuit tests. Included are:

1. Porcelain insulators—resistance to power arcs
2. Lightning arresters—power-follow tests
3. Power transformers—short-circuit tests
4. Current-limiting reactors
5. Current transformers
6. Fuses
7. Bus bar structures
8. High-voltage capacitors
9. Potential devices

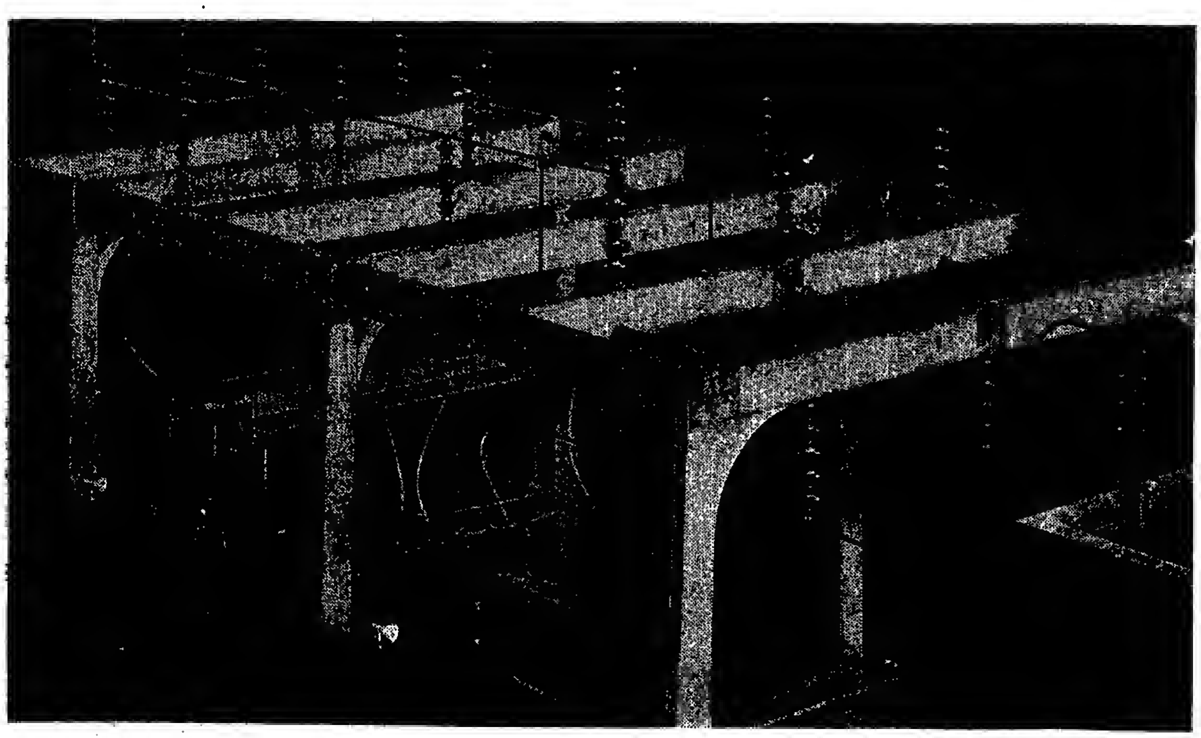

Figure 3. The new transformers and bus structure permit testing to 345 kv three phase

Generating Equipment

The physical arrangement of the essential parts of the Westinghouse Electric and Manufacturing Company's high-capacity testing plant is shown in Figure 1. In the original station 1 is located the 40,000-kva set which consists of two 20,000-kva generators driven by a 3,300-horsepower wound-rotor motor. Separately driven exciters are provided. Since the larger generators of station 2 were put in service, the 40,000-kva plant is used for smaller apparatus which it can test to full short-circuit rating. Also, for most of the work requiring the high-current low-voltage transformers, the 40,000-kva plant has adequate capacity. The generators in station 1 have an initial reactance of approximately 10 per cent, hence a short-circuit output of 400,000

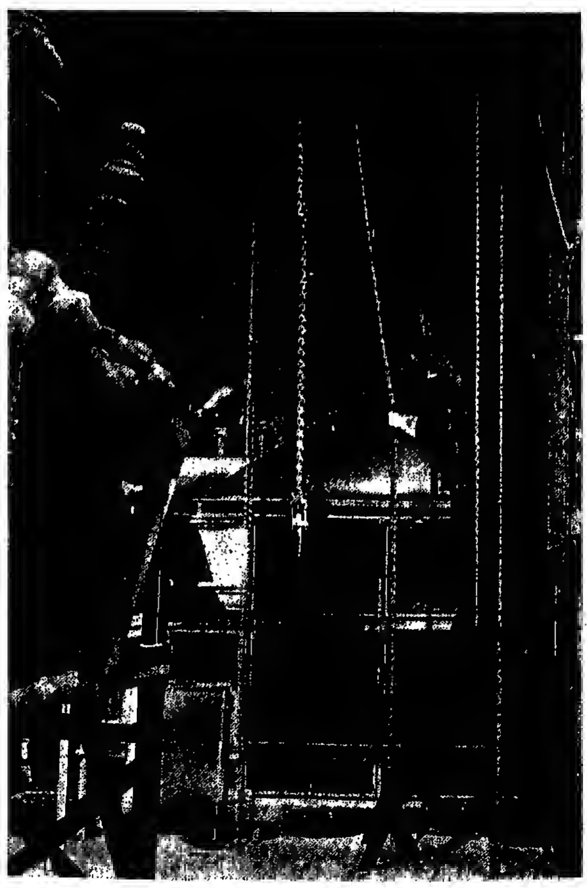

Figure 4. Inside the cold room with a sleet test in progress

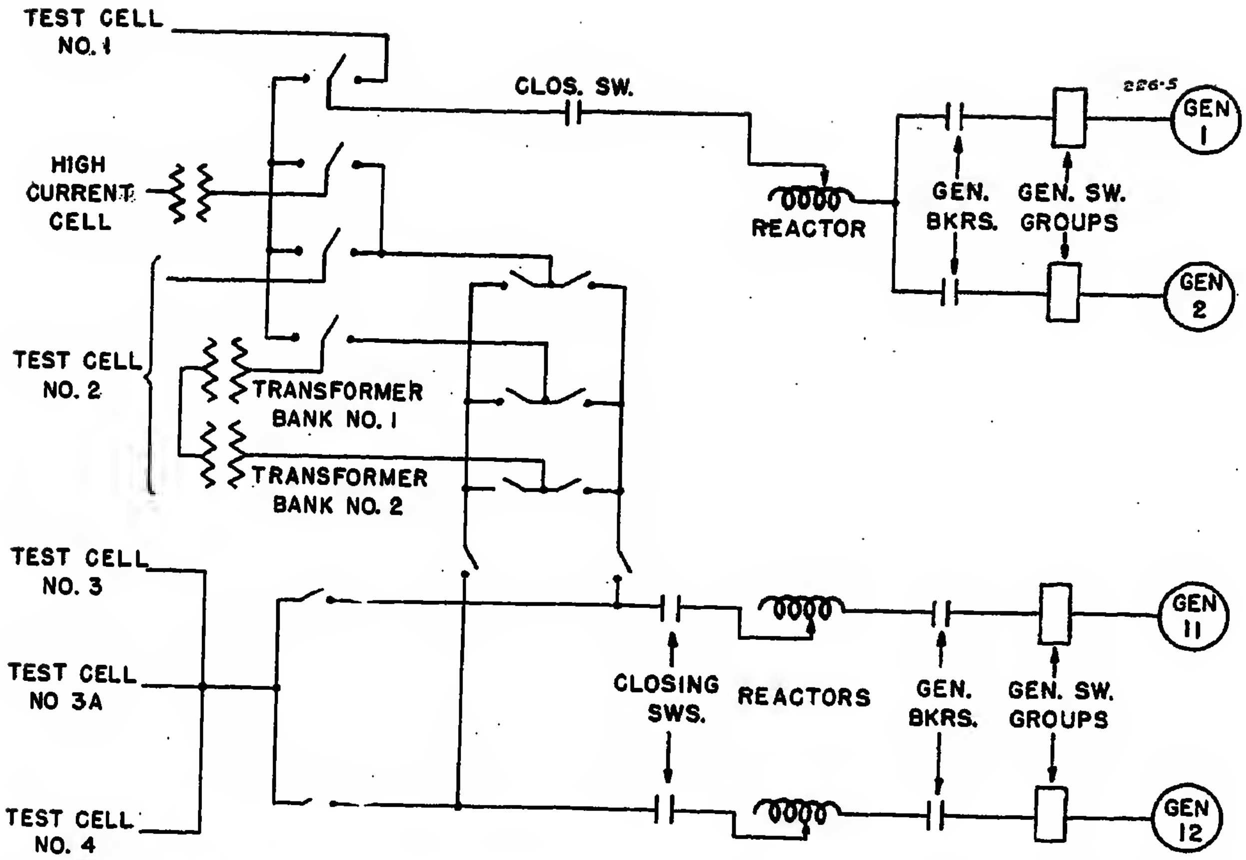

Figure 5. Power circuits combine simplicity and flexibility

initial three-phase symmetrical kilovolt-amperes may be obtained. By different generator coil arrangements full capacity of this plant may be obtained at 3.8, 6.6, 7.6 and 13.2 kv at 60 cycles. No provision is made to operate this plant in parallel with the larger generators in station 2.

In the newer station 2 are located two 60,000-kva (nominal rating) generator sets. These machines when operating in parallel can produce an initial three-phase symmetrical short circuit of approximately 2,000,000 kva at the 13.2-kv test cells. Each of these sets consists of its generator, a 6,000-horsepower wound-rotor driving motor, and a direct-connected exciter. The machines have 14 poles, hence they run at 514 rpm for 60-cycle operation and 219 rpm for 25-cycle operation. Since liquid rheostats are provided for starting, lower frequencies may be obtained by operating with resistance in the rotor circuits.

The two sets are mechanically independent, although provision has been made to couple them if it ever becomes desirable. Because of the 700-kw friction and windage loss of each set, an important saving in power is obtained by operating only one machine when it is adequate.

When parallel operation of the two generators is required, they are synchronized electrically, reactors being provided for this purpose. This operating arrangement has proved very satisfactory. The rotors of the two sets have the same inertia, and under the most severe short-circuit conditions, there is no tendency for the two sets to pull out of step.

From a casual observation (Figure 2) it would appear that the two generators are identical. However, the unit built in 1940 takes advantage of certain refinements in materials and incorporates some of the advances made in generator design. The total weight of each machine is 550 tons, being about equally divided between stator and rotor. The rotor diameter is 12 feet and has a peripheral speed of 22,000 feet per minute. The inertia of each rotor is 8,500,000 pound-feet^2. As is shown in Figure 2, the stators are spring-mounted to cushion the shock on the foundation at the time of short circuit.

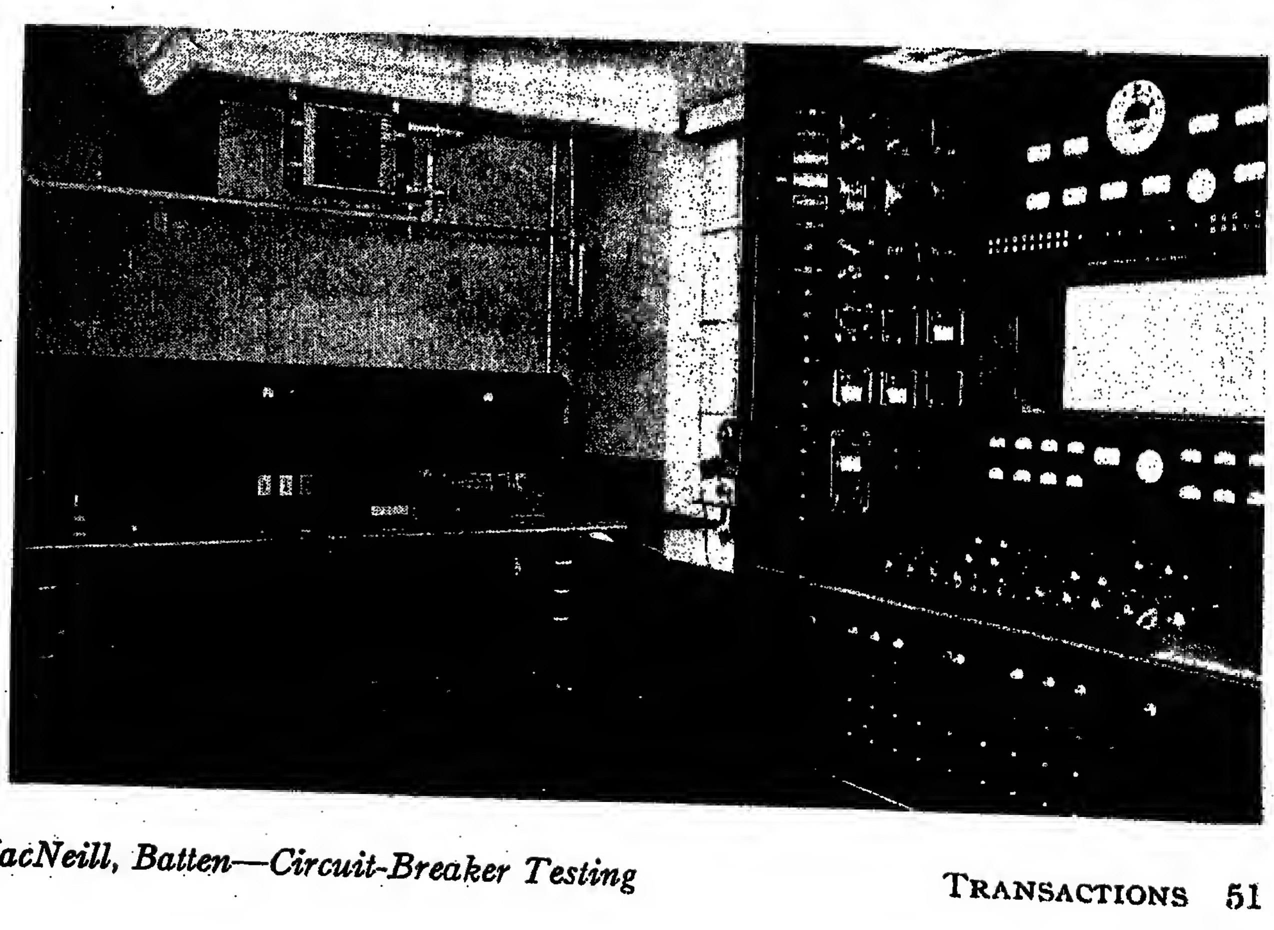
Full capacity may be obtained from these generators at 7.6 and 13.2 kv at 60 cycles and at 3.12, 5.5, 6.25 and 11 kv at 25 cycles.

The stored energy in the rotors of these sets is adequate to absorb the losses produced by short circuits, and it is unnecessary to disconnect the driving motors except in special cases where the short circuits are sustained for several seconds. This stored energy presents a problem when bringing the sets to a stop. With no braking, it takes two hours for the sets to come to a standstill. Provision is made to supply d-c to the driving-motor primaries and to let their secondaries feed energy into the liquid rheostats. In this way they can be brought to rest in about eight minutes.

High-Voltage Equipment

To provide for the testing of apparatus at voltages in excess of 13.2 kv, the transformer station is available (Figure 3). This installation includes six 33,333-kva single-phase transformers. They are supplied directly from the generators at 13.2 kv. The secondary of each unit consists of six 22-kv coils. Hence voltages of 22, 38, 44, 66, 76, 88, 115, 132, 152, and 230 kv are available with full capacity. The original three transformers are insulated for 132 kv-to-ground and the newer three for 196 kv-to-ground so that they may be connected in series to give higher voltages. It is, therefore, possible to obtain 345 kv, three-phase *L-L* with the neutral grounded and 396-kv single-phase with mid-point grounded. The 345-kv three-phase connection is made with one winding at 132 kv in series with another at 66 kv. Hence, due to differences in current carrying ability of the transformers, this connection is not suitable for the full capacity of the transformer bank. Various voltages other than those mentioned are

Figure 6. The station operator at the control desk has a direct view of all test cells



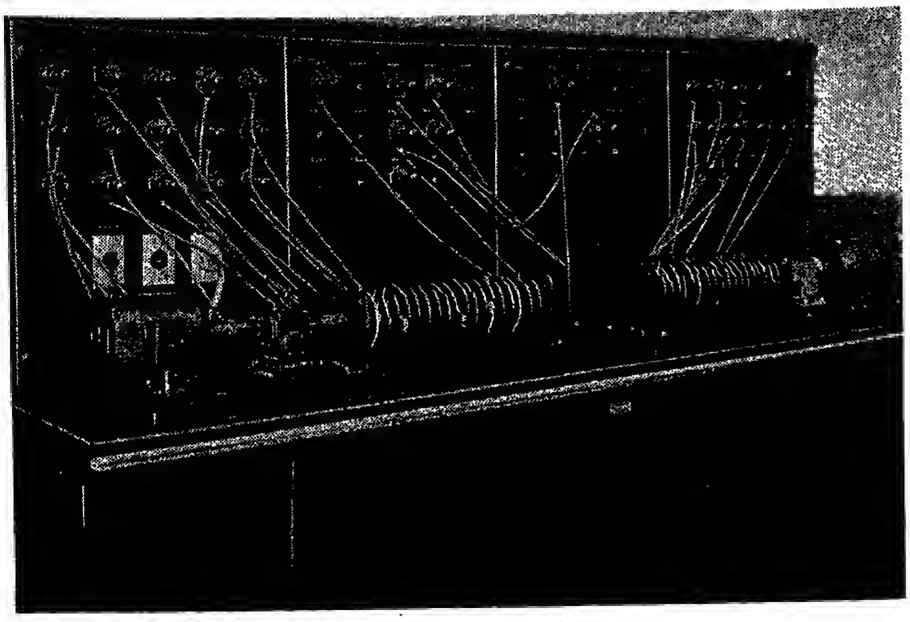


Figure 7. Duplicate sequence drums facilitate changes between tests and make possible simultaneous testing at both transformer and generator voltages

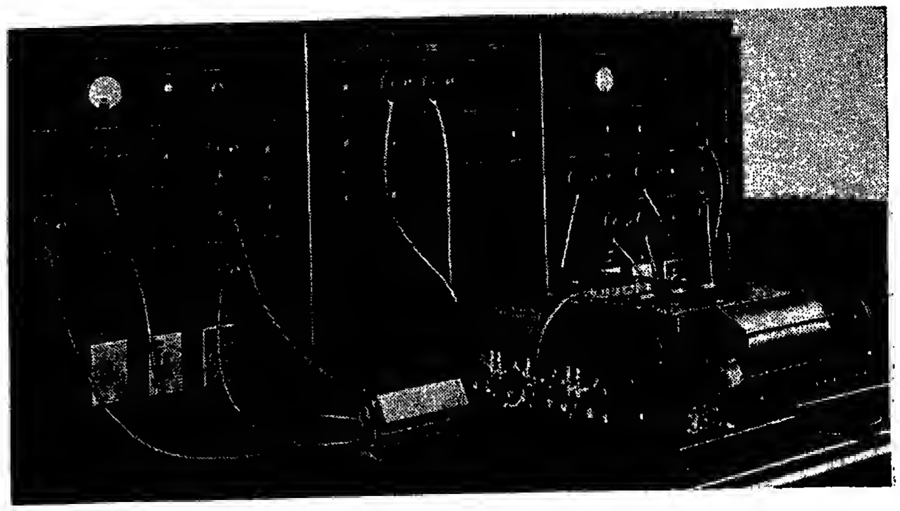

Figure 8. The oscillograph table and relay board

obtainable but in most cases not at full capacity as there are unequally loaded transformers involved. The reactance of the transformers is low so that their output, single-phase, is 75 per cent of the generator-bus kilovolt-amperes and on three-phase tests is 65 per cent. Six potential transformers, three insulated for 196 kv-to-ground, are provided for oscillographic recording of voltages.

Power from the transformers is fed to the test cell 2 where all testing at voltages above 13.2 kv is conducted. The only modification required as far as the test cell was concerned, when the second transformer bank was installed, was a new group of roof bushings adequate for 198 kv and a slight increase in the height of the cell to accommodate the larger bushings.

High-Current Transformers

To provide for momentary and five-second current-carrying tests, a bank of low-voltage high-current transformers has been provided. These transformers giving open-circuit voltages of 625, 1,250, 2,500, and 5,000 volts are located in an enclosure which forms a high-current test cell. On the 625-volt connection they are suitable for five-second tests at 200,000 amperes, three-phase or 345,000 amperes single-phase. At these currents the terminal voltage drops less than 50 per cent. These transformers are also useful for interrupting tests at low voltage.

Cold Room

When it was decided to provide a refrigerated room in which high-voltage breakers could be tested under severe sleet and temperature conditions, it became apparent that the high-current test cell could be used for this purpose. This room is about 25 feet long, 12 feet wide, and 25 feet high, hence has ample space for high-voltage breakers. It was insulated and an air-cooling and circulating unit was installed at the end away from the door. The compressor equipment was placed some distance away. Temperatures of −20 degrees Fahrenheit with outside temperature of 90 degrees Fahrenheit are easily obtained (Figure 4). A 110-kv bushing from this cell to the transformer yard provides for high-voltage interrupting tests. This test cell is, therefore, used for fuse testing, high-current testing, and low-temperature work.

Power Circuits

When the second 60,000-kva generator was installed, a number of changes was made in the bus system providing a more direct run to the test cells and the transformers. The arrangement of the power circuits (Figure 5) was made with the idea of flexibility as one of the principal considerations. Each generator has its own breaker, current-limiting reactor, and closing switch. Disconnecting switches are provided so that either or both 60,000-kva generators can supply power to the 13.2-kv test cells, either or both to either transformer bank, and either or both to the high-current low-voltage transformers, or directly to the high-voltage test cell 2. The two 20,000-kva units can supply power to cell 1, to the high-current transformers or the high-voltage cell, and to transformer bank 1.

The connections from the generator coils to the generator setup switches consist of flexible cable firmly cleated in place. From the setup switches to the closing switches, copper tubing covered with Micarta tubing is used. This assembly is supported by Micarta cleats spaced at short intervals. Beyond the closing switches, the bus carrying the output of both generators consists of a square tubular copper conductor similarly insulated with Micarta tubing and supported by Micarta cleats. In the test cells the same type of conductor is used but porcelain insulators are provided instead of Micarta tubes and cleats.

The two banks of current limiting reactors provide a wide range of flexibility. Each bank consists of 18 units (6 per phase). By means of disconnecting switches nearly 100 combinations are available, hence the reactance can be varied from its maximum of 5 ohms per phase to 0 in small steps.

It will be noted from Figure 5 that there is a total of six test cells available, thus making possible the assembling or dismantling of apparatus in some cells while tests are being conducted in others.

Control

The operation of the equipment in station 2 is controlled from a central control desk located in the control house (Figure 6), so arranged that the operator observes the equipment under test. This desk is very complete with indicating instruments, protective relays, annunciators, and buzzer for all protective devices and test jacks for checking all measuring and control circuits.

At various points about the laboratory and yard are located safety switches. Anyone working in the area covered by one of these switches moves the switch to the safe position and every switch must be restored to the operating position before voltage can be applied to the generators. Indicating lamps on the control desk show the position of these various switches. In addition, it is the operator's duty to see or otherwise account for all the individuals working around the yard before energizing the equipment.

The station is equipped with all the usual protective relays as well as photocells which clear the circuits and de-energize the generator fields in case of a power arc anywhere in the station. Furthermore, an observer is stationed in a

soundproofed booth in the generator room. He has control of an emergency switch which can be tripped in case of any trouble in the station. The observer also changes the reactor switches when changes in current are required, but, as was stated previously all control of the plant is located at the control desk.

Air-closing switches are used instead of breakers for initiating the short circuit, when opening tests on breakers are being made. These switches can start the short circuit at any desired point on the voltage wave, thus controlling the degree of current asymmetry on single-phase tests. As the closing time of these switches must remain constant, they are spring-closed and are operated by a solenoid mechanism which latches the switches in the open position. Synchronized closing is accomplished by tripping a grid-glow tube from a small impulse generator adjustably coupled to the main generator shaft. The grid-glow tube energizes the unlatching coil on the closing switch. As the operating time is constant within 0.0015 second, a close control of current asymmetry is possible.

In the control room are located (Figure 7) sequence drums which control the actual operations for a test, once the proper series reactance has been chosen and the generators excited to the proper voltage. In a normal opening test, the sequence drum starts the oscillograph, closes the closing switches, trips the test breaker, trips the generator backup breakers and trips the generator fields. In case of a close-open test, the operator closes the closing switches before starting the sequence drum and the drum closes and opens the test breaker.

Two sequence drums are provided, making it possible to test in two locations simultaneously. For instance, one generator may be used for a test in one of the 13.2-kv cells while the other is used for a test in the high-voltage cell. Adjustment of the time interval between the functioning of the various devices controlled by the sequence drums is accomplished by moving the cams with respect to each other. The cam-operated switches are connected to plugs as shown in Figure 7, and all essential controls are brought to jacks on the panels above the sequence drums. This arrangement provides great flexibility of control.

Measurements

Magnetic oscillograph records are almost invariably made of all tests. Figure 8 shows the oscillograph table (also located in the control room). Two multielement oscillographs are available and when desired, they can be operated as a single unit thus making available a total of 18 records. All potential and current transformer secondaries are brought to a plug board above the oscillograph table. Current transformers are used for all current measurements, specially designed units being provided to assure accurate current records. Potential transformers are located on the 13.2-kv bus supplying test cells 3, 3*A*, and 4. No potential transformers are supplied in the high-current cell. When required, portable units are used. Currents in the high-current transformers are measured on the primary or 13.2-kv side. Several relays are available from each test cell to the oscillograph table to take care of travel records, pressure indicators, and any other desired measurements.

A cathode-ray oscillograph of the cold-cathode type for measuring recovery-voltage transients is located on the second floor of the control house. An overhead transmission line provides the connection between the oscillograph and the test cells.

Transient Recovery Voltage

The severity of circuit-breaker testing depends not only on the voltage and current of the circuit but also on the rate at which the voltage appears across the breaker contacts during the recovery transient. The layout of the laboratory with the reactors close to the test cells makes it possible to obtain high natural frequencies, and values up to about 200,000 cycles per second have been recorded. Transients and breaker performance on these test circuits can be the equivalent of those obtained under severe service conditions.

Observation

A limited number of witnesses can be accommodated in the control room, but for the larger number of observers present for a demonstration test, a large room affording a good view of the test cells is provided on the second floor of the control house.

Operating Experience

The location of the high-capacity testing station within a manufacturing plant has been justified by sixteen years successful operation and the close effective cooperation thus obtained among the design, manufacturing, and test departments.

This high-capacity testing laboratory is in effect a power station capable of delivering, momentarily, a short-circuit output comparable with that obtainable on large power systems. In contrast, however, it carries no continuous load, and a short circuit is a normal instead of an abnormal condition. The flexibility of the testing station permits the duplicating of many voltages and currents corresponding to different service classes and ratings of equipment. Accurate control of the conditions and complete records of performance produce experimental data which, when properly used, result in circuit breakers and other equipment of adequate design and proven ratings.

Electrical Drives for Wide Speed Ranges

G. A. CALDWELL
ASSOCIATE AIEE

W. H. FORMHALS
ASSOCIATE AIEE

THE electrical drive for a wide speed range is obtained by the addition of a rotating regulator called a Rototrol to a conventional variable voltage system. This combination will give a speed range of 120 to 1 or more, and can be used effectively in many industries to simplify the mechanical design of the machine which it drives. Its use eliminates elaborate gear-change mechanism, clutches, and so forth, and at the same time gives a more flexible control scheme with the complete speed range under the control of the operator without leaving the work or stopping the machine.

The conventional variable voltage or Ward-Leonard scheme of control is the accepted method of obtaining speed ranges in excess of 6 to 1 with 20 to 1 about the maximum range. This range is obtained by combination of motor-field and generator-voltage control. The amount of field control is limited by motor stability, and the amount of voltage control is limited by speed regulation and maximum torque. The addition of regulating devices and other refinements to improve the characteristic of this scheme make it possible to extend the range into the field that can be defined as a wide speed range.

The increase in speed range has been accomplished by widening the range of voltage control, the range in field control remaining not more than 4 to 1 and preferably only 2 to 1. Therefore this type of drive is best suited to a load which has constant torque characteristics. The machine tool industry has many applications of this type, and it is here that the wide-speed-range drive has been applied. Feed drives on boring mills, milling machines, automatic screw machines, and so on, have constant torque characteristics as the load consists mostly of overcoming friction of the moving parts. Wide ranges of feed speed are required to satisfactorily machine the wide variety of sizes and kinds of metals. With the wide-speed-range drive, these speeds are always immediately available to the operator without the necessity of leaving the work and stopping the machine to change gears. Speed regulation is good, and when desired the rheostats can be calibrated to read feed speed directly.

To develop a satisfactory wide-range variable-voltage drive it has been necessary to compensate for certain characteristics at the low speed that are not important at high speeds. The two most important factors are the residual voltage of the generator and the *IR* drop of the system.

Most commercial generators have a residual voltage of between three and four per cent. This would mean that the no-load speed of a motor which is being driven from such a generator by variable-voltage control is limited to a no-load speed range of about 25 to 1, since the residual will not permit a voltage lower than itself to exist. If it is desirable to extend the range beyond 25 to 1, it becomes necessary to make some arrangement to overcome the residual voltage. Also, since the residual is a function of the previous magnetic history of the generator, it is necessary that the equipment used to overcome residual must be able to determine the actual conditions which exist.

The speed of the d-c motor will normally drop as load is applied due to the *IR* drop in the system. Since a feed mechanism must run at constant speed regardless of the load, it is necessary that the speed-torque characteristic of the motor driving the feed be practically flat. Since the normal drop on a d-c motor is due almost entirely to *IR* drop, some arrangement must be made to increase the applied voltage by the amount of the *IR* drop as the load is applied so that the induced voltage, and therefore the speed of the motor, will remain constant. These requirements would indicate that some means of regulation must be supplied in order to maintain the desired characteristics. It has been found by experience that a rotating regulator or regulating generator is satisfactory for this particular function and has been widely applied.

This type of rotating regulator was first developed for elevators and a large installation was made in Radio City in 1934. Since that time the Rototrol has been used in many industrial applications. It is the heart of the variable-voltage planer drive and has been proven in service over a period of several years. Other applications include paper mill drives, electric shovels, and skip hoists. In appearance it looks the same as a standard d-c generator and is usually mounted as a unit of the variable-voltage motor generator set.

In the use of any regulator which is to vary the voltage of a generator, it is possible to have the regulator take care of only the changes which are required, or to incorporate in it the total excitation of the machine to be regulated. Where very great voltage range is required and where the response should be quick and accurate, we have found it desirable to incorporate in the rotating regulator only the regulating functions which are desired and to supply the normal excitation from some other source. The most satisfactory method to supply the regulating current to the fields of the generator is by use of a Wheatstone bridge circuit in which the armature of the rotating regulator is placed where the galvanometer in the conventional bridge is located. This is shown in Figure 1.

In this circuit generator fields $GF1$ and $GF2$ are identical as are regulator fields $RF1$ and $RF2$. Resistors $R1$ and $R2$ are equal to each other and to the sum of the resistances of a regulator and a generator field. Thus all four legs of the bridge are of the same resistance, and a balanced bridge results.

It can be demonstrated that in a balanced-bridge circuit of the type described when a source of voltage is connected to points A and C, points B and D have the same potential, and consequently no current from said source tends to flow through any circuit connected between B and D such as the armature of the regulator. The converse is also true that a source of voltage applied to points B and D will not cause any current from said source to circulate in a circuit connected to points A and C such as the exciter circuit.

It can also be demonstrated that in a circuit as described, if the exciter voltage applied alone to points A and C circulates Ia amperes in each leg A-B and C-D (containing the variable-voltage generator and regulator-field windings) and if the regulator armature voltage applied alone to points B and D circulates Ib amperes in each leg A-B and C-D, then when the two voltages are applied together they will circulate in each leg A-B and C-D a current equal to the algebraic sum of Ia and Ib. Thus the use of a balanced-bridge circuit permits complete independence of

Paper 42-29, recommended by the AIEE committee on industrial power applications, for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 15, 1941; made available for printing December 8, 1941.

G. A. Caldwell is in the industry engineering department and W. H. Formhals in the motor engineering of Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

the excitation and regulating currents even though they have common paths in the field circuits of the generator.

Figure 1 shows a schematic diagram of the equipment required for a wide-speed-range feed equipment for a machine tool. For the purpose of simplicity many of the control elements such as operating coils for the various contactors, control stations, and so on, have been omitted as they are not required for this discussion. It can be seen that this circuit is basically the variable-voltage system except for the addition of the regulating generator and its associated circuits. These additions, however, extend the range of speed adjustment and give much better regulation than can be obtained with a straightforward variable-voltage system. The generator differential field *GF*3 and its contactor *BR* are a part of the variable-voltage scheme which prevents creeping in the off position and are not involved in obtaining the wide speed range.

If the generator-field rheostat be set at some position and the forward directional contactors *F* be closed, current will flow from the exciter through the two branches *ABC* and *ADC* of the bridge. This current, *Ia*, flowing through the generator fields *GF*1 and *GF*2 will cause the generator to produce a voltage across its armature and thus across the motor armature. Since the motor field is excited, the motor will run at the speed determined by its field strength and its applied armature voltage, assuming no load and thus no current and no *IR* drop in the armature circuit.

The current *Ia* flowing in the regulator fields *RF*1 and *RF*2 will set up a magnetomotive force in the regulator which will cause it to generate a voltage which will tend to circulate a current *Ib* in the direction so as to strengthen the fields of the generator and regulator in the bridge circuit.

This magnetomotive force is not permitted to act alone in the regulator but is balanced by the magnetomotive force of field *RF*3 which is connected so as to be differential to *RF*1 and *RF*2. Its strength is adjusted by resistor *R*5, so that at this condition of operation, its ampere-turns are equal in magnitude to the ampere-turns of *RF*1 and *RF*2. Thus the fields in the bridge circuit get a cue as to the value of voltage which is desired and the field across the armature circuit measures the actual voltage which is obtained. Since at no load the speed of the motor is determined by its applied voltage, we might consider these two regulator field circuits to compare actual speed with desired speed.

If the calibration of the fields has been made at the point being described then the resultant regulator magnetomotive force is zero and no voltage is present across its armature terminals and thus the regulating current *Ib* is zero.

Let it be assumed, however, that this condition of operation being described is not at the calibration point but at some other value of speed, and that, due to shape of the saturation curve or to effect of the hysteresis loop of the generator, the voltage generated is not as great as it should be to give the motor speed desired. Then the differential ampere-turns in *RF*3 are not so great as the cumulative ampere-turns in *RF*1 and *RF*2, leaving a resultant ampere-turns which cause the regulator to circulate current *Ib* in the direction shown in Figure 1. This current causes an increase in actual generator-field current, as shown earlier in this paper, and thus causes the generator voltage to increase to the value it should have.

To maintain this regulating current at the necessary value, the constants of the circuit consisting of the regulator armature, the resistances of the bridge circuit, and the regulator fields *RF*1 and *RF*2 must be such as to make the circuit self-energizing. This can be done by adjusting resistor *R*3 so that the field characteristic line of the combined effects of fields *RF*1 and *RF*2 will be coincident with the air-gap line of the no-load saturation curve of the regulator generator for those fields alone. Thus the regulator will force enough regulating current *Ib* through the generator fields until the proper operating point is reached. At this time the ampere-turns due to the

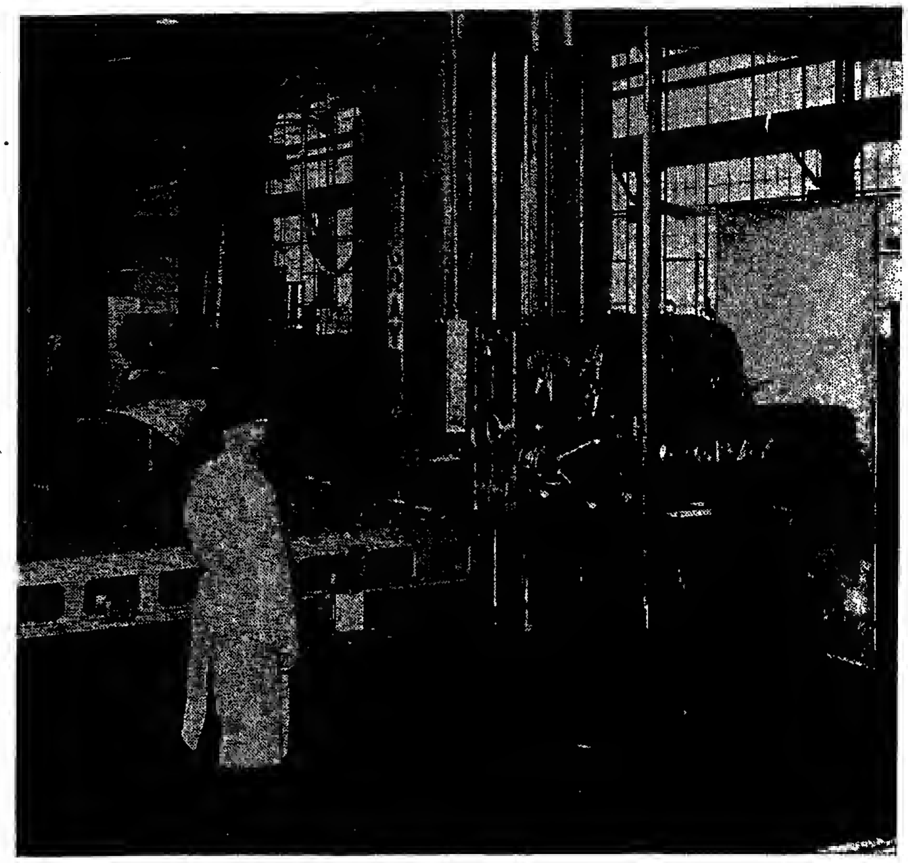
This is a four-unit set with a main generator, exciter, and regulating generator (on the right-hand side) driven by a squirrel-cage induction motor

Figure 4. This horizontal boring, milling, and drilling machine has an electrical feed drive with a speed range of 120 to 1

The electrical drive eliminates the use of change gears, clutches, and so on, and greatly simplifies both the construction and manipulation of the machine



current from the exciter Ia in the fields $RF1$ and $RF2$ will be balanced by the ampere-turns in field $RF3$ due to the proper voltage across the armature of the generator and the regulator current Ib through fields $RF1$ and $RF2$ will just maintain the current Ib.

It should be noted that if the regulating generator is not self-energizing that it would not be possible to get a correct operating point, since to have any corrective current circulated there would have to be some difference in the cumulative ampere-turns due to Ia and the differential ampere-turns due to voltage. In such a case the voltage would approach but never reach the correct value and the accuracy of regulation would be greatly decreased.

An ordinary generator when set up with a self-energizing field under the conditions above described would tend to build up to the point at which saturation begins to take place. In this regulating generator, however, this action is prevented since any charge from the correct operating point causes a corrective magnetomotive force, since the balance between cumulative ampere-turns and differential ampere-turns in the three regulator fields will be destroyed. Analysis shows that the difference which results will always cause the regulator output to return to the correct value.

From the foregoing it is evident that the no-load speed of the motor will always be made to agree with the value desired by the setting of the generator rheostat. If mechanical load is put on the motor, it will slow down, thus decreasing its counter electromotive force and thereby permitting a current to flow in the armature circuit of the two machines. A stable point of operation occurs when the drop in speed and counter electromotive force is just sufficient to make available enough of the generated voltage to circulate the current required.

To bring the speed back to the no-load speed necessitates the raising of the generator voltage by the amount of the IR drop. This is done by the regulator by adding on its magnetic structure another field $RF4$, which is connected in the armature circuit so as to produce cumulative ampere-turns. By proper adjustment of $R4$ this field can cause the regulator to correct almost perfectly for IR drop and armature distortion of the motor over a wide range of load thus giving a very flat speed-load curve.

Other conditions than load tending to change the speed of the motor might be thought of, but it will be found that the regulator generator will make appropriate corrections. Thus burning or shifting of the brushes of the generator often tends to cause stalling of the motor with the conventional variable-voltage drives. Also varying values of residual magnetism in the variable-voltage generator cause different voltages for the same rheostat setting. Such conditions however are corrected by the regulator.

In Figure 2 are shown the speed–load characteristics as obtained from actual tests on a $7^1/_2$-horsepower machine-tool feed equipment using a regulating generator such as just described. These curves show the regulation of the motor to double-full-load current over the range of from 15 rpm to 1,800 rpm or a speed range of 120 to 1. Of this range, speeds up to approximately 1,000 rpm are obtained by variable-voltage control and from 1,000 to 1,800 rpm by motor-field control.

It can be seen by reference to these curves that the change in speed due to application of load is so small as to be negligible, and there is no tendency for the motor to stall even when the speed has been reduced to $^1/_{60}$th by voltage control. It is to be noted that at light loads at this speed the voltage required is less than residual voltage of the generator. The regulator has, however, caused a reversal of current in the fields of the generator and thus bucked the voltage down to that required to get the speed called for.

From the results shown it is evident that the use of a regulator scheme such as indicated gives speed range far beyond the supposed limits of a few years ago without greatly complicating the electrical apparatus or going to laboratory-type equipment. The machine being driven can be a simpler, more flexible and more efficient machine tool.

Measurement of Maximum Demand

PAUL M. LINCOLN
FELLOW AIEE

Synopsis: "Maximum demand" has become an increasingly important item in rates for the sale of electric service since the appearance of Doctor John Hopkinson's notable paper, "Cost of Electricity Supply," in the year 1892—nearly 50 years ago. The writer estimates that the demand-measuring equipment which is now being used by the public utilities of the United States has a value of the order of $100,000,000. This is an index of its present importance. The object of the present paper is to describe in detail the thermal-storage method of measuring the maximum demand of a user of electric service. A comparison is made between this method, which at each instant of time indicates the logarithmic average load over some nominal time interval, and the commonly used "block-interval" method, which indicates the arithmetic average load over the same time interval. Also, the effect of using a modified design of thermal-demand meters is discussed. The writer has contributed a number of previous papers dealing with this same general subject, reference to which will be found at end of paper.

The Block-Interval Meter

As is well known, the commonly used block-interval demand meter measures the arithmetic average load over some definite interval of time. Its construction and operation are such that, at the end of the month, the maximum arithmetic average block of load over some definite time interval is indicated on the meter scale. The meter is then reset to zero so that the maximum arithmetic average load for the following month may be made available when the meter is again read and reset at the following month's end. As is well known, the commonly used "block-interval" demand meter measures this maximum arithmetic average load over some definite interval of time, such as 5 minutes, 10 minutes, 15 minutes, 30 minutes, and occasionally 60 minutes. Other time intervals have been proposed, even as low as one minute, but so far as the writer knows, no time intervals of less than 5 minutes nor more than 60 minutes are actually being used at the present time. The 15-minute time interval is the one most frequently used, followed by 30 minutes and 60 minutes. Knowlton, in his "Electric Power Metering," says, "A survey by the National Electric Light Association rate research committee in 1931 showed the 15-, 30-, and 60-minute intervals to be in vogue in the ratio of 40:8:1 respectively." Knowlton does not mention any time intervals shorter than 15 minutes, although to the writer's certain knowledge time intervals as short as one and two minutes have been used in the past. To the best of his knowledge the five-minute time interval is still being used to a limited extent.

Basic Weakness of Block-Interval Meter

As mentioned in the preceding paragraph, the "block-interval" demand meter measures the maximum arithmetic average load over some definite interval of time. The arithmetic average, as measured by the standard block-interval demand meter, is a discontinuous function of time. Any arithmetic average must necessarily be a discontinuous function of time, and, as such, be subject to a possible error of 50 per cent—a possibility which can become a certainty at the option of the service user. When it becomes necessary to use two or more block-interval demand meters on the same load, it is customary to synchronize the meters so that they reset at the same instant. This synchronization has no effect on the inherent inaccuracy of the block-interval demand meter, but it does prevent the utility and the utility's customers from becoming aware of the inaccuracy.

While we are considering possible inaccuracies of measurement when using the standard block-interval demand meter, a situation which recently came to the writer's knowledge may be of interest—a situation the possibility of which is mentioned in the preceding paragraph. This service user, as reported to the writer, is taking deliberate steps to "split peaks." His loading schedule is so timed that his demand meter resets, as closely as possible, midway during load applications. If this method of taking load is carried out to its possible extreme, the maximum demand measured and billed can be made one-half the actual arithmetic maximum demand. Such a method of taking service is, of course, open to any user of service whose maximum demand is measured by means of the standard block-interval demand meter. In the case of deliberate "peak splitting," the utility is always on the losing end.

Paper 42-15, recommended by the AIEE committee on instruments and measurements, for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted September 30, 1940; made available for printing November 19, 1941.

Paul M. Lincoln is president of Therm-Electric Meters Company, Inc., Ithaca, N. Y.

Maximum demand may be accurately measured only by a continuous function of time. Further, even if it were possible so to modify the demand attachment of the standard block-interval meter and thereby obtain a true and accurate arithmetic average, the maximum arithmetic average thereby obtained would still be defective. For instance the maximum arithmetic average—or logarithmic average—of a user of electric service who takes a perfectly steady load of 100 kw would, of course, be 100 kw, and his bill for service would be based on 100-kw demand. Another user whose maximum demand is measured by means of a standard 30-minute block-interval meter and who takes during each half hour 100,000 kw for 1.8 seconds, or 10,000 kw for 18 seconds, or 1,000 kw for 180 seconds (3 minutes), or 500 kw for 6 minutes, or 300 kw for 10 minutes, or 200 kw for 15 minutes, would have exactly the same arithmetic average as the first user—provided there were no "peak splittings." This latter group of cases certainly warrants a higher maximum-demand assessment than the first user. Also, the earlier mentioned members of this group warrant a higher maximum-demand assessment than the later mentioned members.

The Thermal-Meter Principle

On the other hand, the thermal wattmeter measures the logarithmic average of the load under measurement. (For a definition of the term "logarithmic average," see reference 1 at end of paper.) There is a basic difference between the logarithmic and arithmetic averages. The logarithmic average is a continuous function of time. That is, at each instant of time, it indicates the logarithmic average over the immediately preceding 15-minute, 30-minute, 60-minute, or other time interval. The length of this time interval is dictated by the value assigned to an adjustable constant k, the character of which is discussed later in this paper. The load taken by a user of electric service is continuous—but not necessarily steady—and its maximum demand can be consistently measured only by a continuous function of time. Even if it were possible to measure the maximum arithmetic average accurately—which is not the case with any of the existing types of block-interval meters—the thermal type would still be preferable, since the heating effect

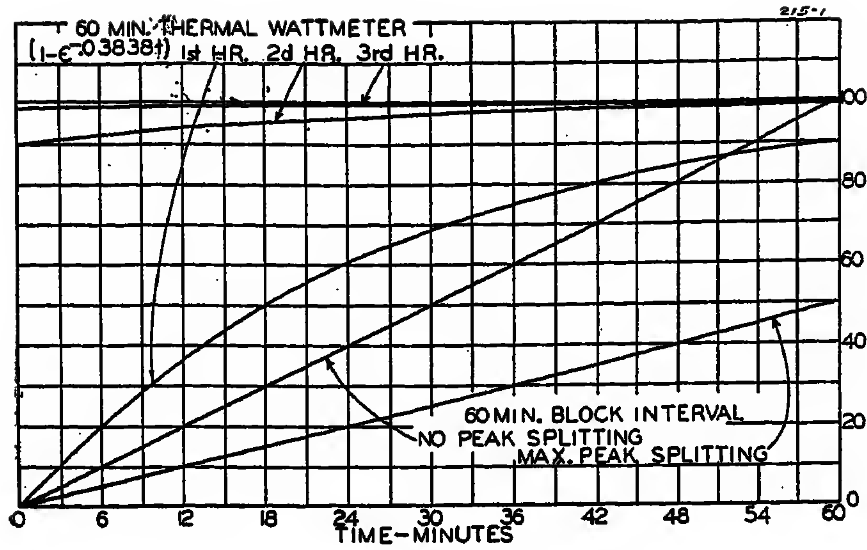


Figure 1

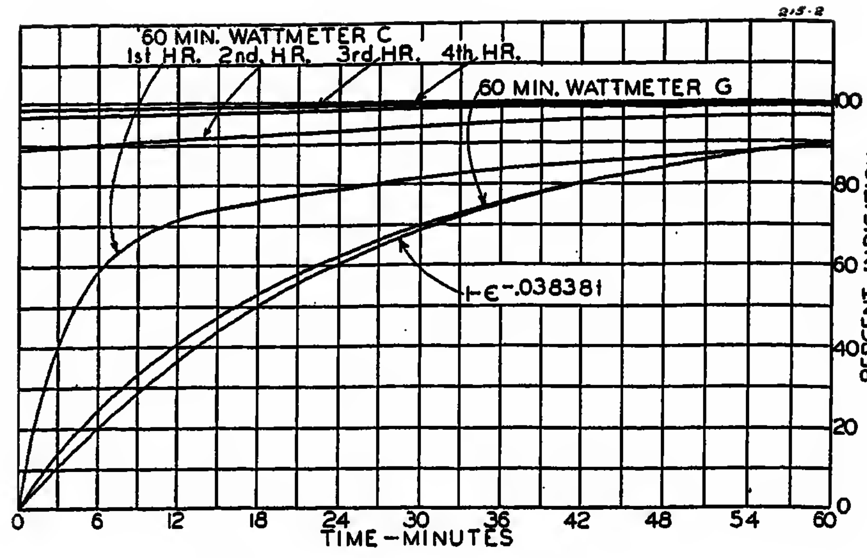

Figure 2

of any given load on the equipment serving the load is a logarithmic or exponential function of time and not an arithmetic function.

While the thermal wattmeter has been fully described in previous papers (see references 1 and 2), it might be well to give a brief description of its operation. A small transformer whose primary is connected across the supply voltage causes a current to circulate continuously through two equal resistances, which we will call r. Let us call this circulating current E, since its value is always proportional to voltage. The load current is caused to pass through these same resistances. Let us call this load current I. The load current is caused to pass through the resistances in such a manner that one-half its value adds to the circulating current in one resistance and subtracts from it in the other. The total current in one resistance is, therefore, $E+I/2$ and in the other $E-I/2$. The total heat applied to one resistance is, therefore $\left(E+\frac{I}{2}\right)^2 r$ and to the other $\left(E-\frac{I}{2}\right)^2 r$. The thermal wattmeter is so constructed that it constantly indicates the difference in temperature between two masses of matter which are being heated by these two currents. The difference in heat applied is obviously $2EIr$, a function which is always directly proportional to the watts entering the load. Since the masses of matter do not and cannot respond instantly to the heat applied, the result is a demand meter measuring the logarithmic average load.

Mathematical expressions for the indications of the two types may readily be obtained. For the arithmetic average (block-interval) meter, the mathematical expression for its indication is

$$\text{Meter indication} = \frac{1}{t_1-t_2}\int_{t_2}^{t_1} w\,dt \qquad (1)$$

The logarithmic average may be expressed mathematically as follows:

$$\text{Meter indication} = k\int_0^t w\epsilon^{-kt}dt \qquad (2)$$

In the above expressions

w = instantaneous value of watts
t = time
k = an adjustable constant
ϵ = base of Napierian logarithms
t_1-t_2 = time over which arithmetic average is measured

Figure 1 gives the solution of these two equations when the time interval for demand measurement is 60 minutes—the maximum time interval now being used. The relative indications of the two types for load durations up to 60 minutes may readily be seen from Figure 1.

As actually constructed, however, the relative indications of the thermal-demand meter may be made to depart radically from the purely theoretical ratios shown in Figure 1, or may be made to conform closely to it, depending on design. This comes about because the diffusion of the heat that necessarily enters or leaves the working parts of the thermal wattmeter during normal operation does not and cannot take place instantaneously. As is well known, heat does not and cannot diffuse instantly throughout any mass of matter that is being heated or cooled. The process of heat diffusion takes time. The values given in Figure 1 take no cognizance of this. Also, this factor depends to a marked extent on the design of the thermal wattmeter. This matter is treated further later in this paper.

Referring to mathematical expression 2, it might be pointed out that when the value of kt reaches 6.9078, ϵ^{-kt} becomes one-tenth of one per cent of what it is when $kt=0$. One-tenth of one per cent is as small a quantity as can be read accurately on the demand-meter scale. Therefore, while the integration of the thermal wattmeter extends from zero to infinity, the only significant part of this integration is that which takes place during the interval of one or two hours—or at most three hours—immediately preceding the instant of observation. This holds true when $kt=2.3026$, the value assigned to kt in the edition, 1941 Code for Electricity Meters, the code sponsored by the American Standards Association. This also assumes that the time interval for demand measurement shall not exceed one hour. If the time interval for demand measurement is 15 minutes, the time interval most frequently used in the United States, the only time interval of any significance is the 45 minutes immediately preceding the instant of observation.

Demand Measurement—a Problem in Transients

The measurement of maximum demand is a problem in transients unless the load during maximum is perfectly steady. If the loads taken by users of electric service were always steady, the standard block-interval demand meter would measure maximum demand with perfect accuracy. The arithmetic and logarithmic averages of a steady load are exactly the same. An unvarying load requires no demand meter. Under the conditions of the actual use of service, the only existing method of assuring accuracy of measurement is by the use of a continuous function of time. (The thermal wattmeter is an example.) Our usual conception of a transient is the phenomena that occur in a stroke of lightning or a power interruption. Anyone who dealt with the problem of transients is, of course, aware that time must appear as an exponential function, as it does in the thermal wattmeter. When dealing with thermal wattmeters, the time involved, instead of being of the order of microseconds, as in the usual type of transient, is now of the order of minutes, or even of hours.

Comparison of Block-Interval and Thermal-Demand Meters

Let us assume a case where a service user is taking a continuous steady load of such a value that it causes the demand meter to reach a value which we will call 100 per cent. Let us assume further that this load is being measured by a standard 60-minute block-interval demand meter and also by a 60-minute thermal-demand wattmeter. Let us assume further that the thermal wattmeter is the 60-minute wattmeter *G* which is described later in this paper. If this user's load is perfectly steady, both wattmeters will indicate 100 per cent demand. If however, business falls off to such an extent that it is necessary to use service only during alternate hours, Figure 6 shows the relative indications of the two demand meters. The data shown in Figure 6 are the results of a carefully made test. Inspection of Figure 6 shows that the indications of the thermal and block-interval types cross at approximately 52 minutes when there is no peak splitting. Therefore, if the time of load duration is less than approximately 86.5 per cent of the nominal time interval, the logarithmic average is always in excess of the arithmetic, whether peak splitting occurs or not. In this case, also, the utility using the block-interval meter is always on the losing end.

Ithaca Tests

In order to get some definite information on the question of how much difference might be expected in the indications of the two types of demand meters on actual loads, there has been conducted in the city of Ithaca, beginning in March 1939, and continuing for about 18 months, a series of tests which may be of interest. Ithaca, at that time, was using a 15-minute demand interval, since then increased to 30 minutes. For each of four customers, three demand meters were installed. These four customers were two garages, a beauty parlor, and a photographic studio. Number 1 meter was a 15-minute block-interval meter of standard make. Number 2 meter was an identical block-interval meter so adjusted that its time interval "broke joints" with number 1. That is, number 2 meter reset $7^1/_2$ minutes after number 1. Number 3 meter was a 15-minute thermal-demand wattmeter. For a time, there were two thermal wattmeters on some of the loads. This was done to show by direct experiment what theoretical considerations tell us; that is, that the logarithmic average, being a continuous function of time, must always be the same on any given load. In no case was any material difference found between the two thermal wattmeters.

Now, comparing the two block-interval meters, if we exclude one monthly reading, which for some unknown reason—presumably failure to reset—showed a higher difference than theory can account for (240 per cent), the maximum difference between the two was 27.3 per cent. From this, the difference ranged down to 0 per cent. In only six cases out of about 60 monthly readings did the two block-interval meters give the same indications. The average difference for the entire 60 monthly readings was 10.1 per cent. In some cases number 1 meter indicated the higher value, and in other cases number 2. This difference in indication is, of course, due to "peak splitting" either by number 1 or number 2 meter, or perhaps by both.

Now comparing the thermal-wattmeter readings with the two block-intervals, in only one case out of about 60 monthly readings did all three demand meters indicate the same values. In some cases, the thermal meter indicated higher than either block interval, in some cases, lower than either, and in still other cases, between the two block intervals. (For other comparisons between the two types see references 2, 4, and 6.)

When a public utility deals with its customers' pocketbooks, the degree of inconsistency shown by these Ithaca tests is, in the writer's opinion, intolerable. Accuracy in the measurement of kilowatt hours is and always has been extraordinarily high. Unfortunately, the same cannot be said of the measurement of maximum demand as evidenced by the Ithaca tests.

Advantage of Bourdon Tube Over Bimetal Strip

In the thermal wattmeter of the past, the means by which temperature difference has been indicated has been the bimetal strip. In the year 1924, Chester W. Rice of Schenectady contributed a paper to the AIEE entitled, "Free Convection of Heat in Gases and Liquids—II" (see reference 9). In this paper he showed that when the loss of heat from a hot body occurs by free convection, the rate of heat loss is not directly proportional to temperature elevation, but to the temperature elevation raised to 1.25 power. The writer did not become aware of this important contribution to our technical literature until about 1927. For many years previously, the writer had noted an error in the thermal wattmeter on low-power factors, for which he could give no satisfactory explanation. As soon as Mr. Rice's 1924 paper came to his attention, the reason for this error became obvious at once. In the bimetal-strip type of thermal wattmeter, practically all the heat escapes by free convection. The bimetal-strip type of construction does not lend itself to any means of heat escape except free convection. The only answer, therefore, seems to be to adopt some means of heat escape other than free convection. To accomplish this end, it was necessary to consider means of temperature detection other than the bimetal strip.

The writer therefore decided to try out the Bourdon tube. He had previously experimented with the Bourdon tube, but without success. Beginning about 1928, the writer began experimenting with Bourdon tubes in earnest. By about 1934, the Bourdon tube method of measuring maximum demand had arrived. A complete description of the Bourdon-tube demand wattmeter was contributed to the AIEE in 1935 (see reference 5).

The Constant k and Its Determination

Mathematical expression 2 given above brings into the picture of demand measurement the value of the adjustable constant k. There is a direct relationship between this matter of time interval and

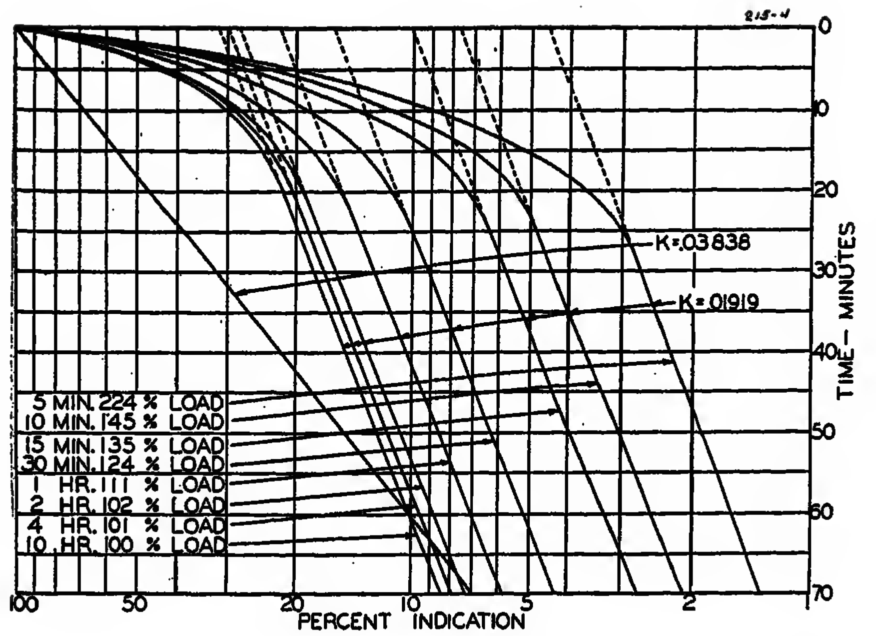

Figure 4. 60-minute thermal wattmeter C, zero-load performance

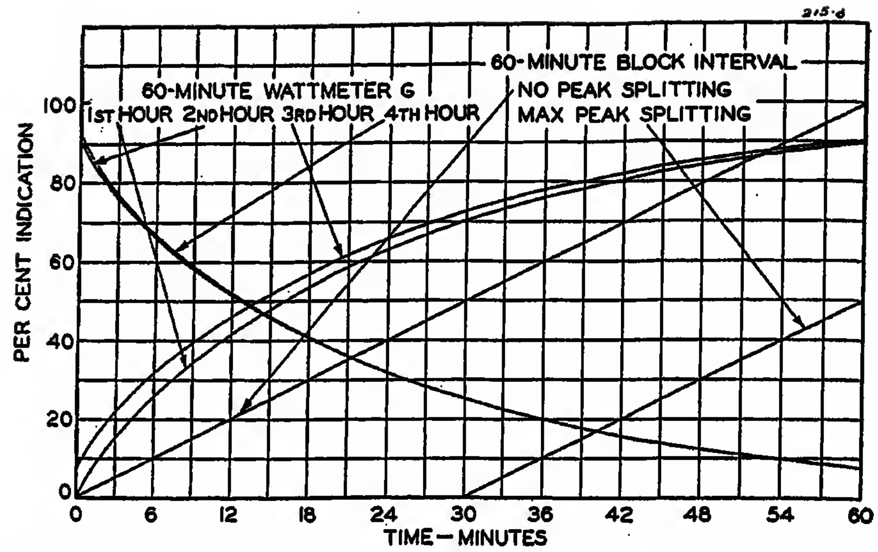

Figure 6. Comparison of 60-minute thermal and block-interval wattmeters

the value of this adjustable constant k appearing in mathematical expression 2. The existing Code for Electricity Meters fixes the time interval for thermal-demand meters as the "time required for the instrument to indicate 90 per cent of the full value of the steady load, which is thrown suddenly on it." This provision fixes the value of kt in equation 2 at $kt = 2.3026$. This, in turn, fixes the value of k at that value which is obtained by dividing 2.3026 by 5, 10, 15, 30, 60, or whatever value of time interval the utility has adopted. Table A gives these values.

Effect of Heat Diffusion on Constant k

When we apply a given constant value of watts w to a thermal wattmeter in accordance with the procedure specified in the Code for Electricity Meters and take readings at equal intervals of time, the function we observe is the function $w(1-\epsilon^{-kt})$. The response for the two thermal wattmeters C and G shown in Figure 2 were obtained in this manner. If, when the meter indication has reached some value w', we throw the load entirely off and observe meter indications as they approach zero, the function we observe is $w'\epsilon^{-kt}$. This, a pure exponential function, plots as a perfectly straight line on semi-log paper. However, when we plot these data from the thermal-demand meter, we find a departure from a straight line, the amount of this departure being controllable by design. Figure 4 shows the performance of 60-minute wattmeter C with zero load, and Figure 5 that of 60-minute wattmeter G. Examination of Figures 4 and 5 makes it obvious at once that the value of k is not constant, but can be made to vary over a very considerable range during the first few minutes of the application or absence of load.

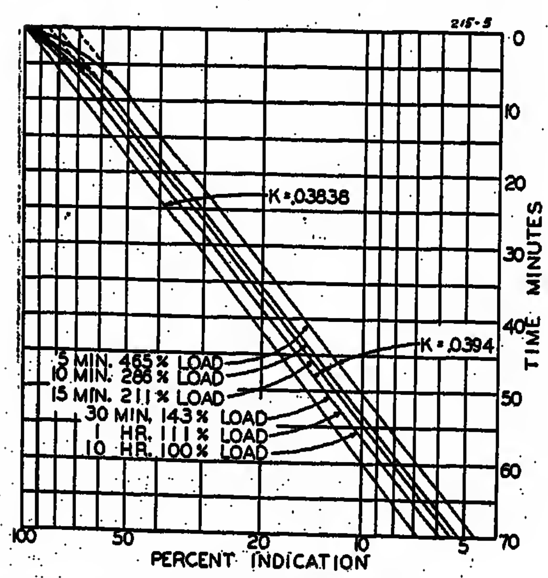

Figure 5. 60-minute thermal wattmeter G, zero-load performance

The reason for this anomaly of the variable constant is not far to seek and has already been intimated. Heat cannot be made to diffuse instantly throughout any mass of matter. In the thermal wattmeter, the source of heat is, of course, the heater shown in cross-section in Figure 3. In order to actuate the meter, the heat originating in the heater must reach the reservoirs shown in Figure 3. From the data given in Figures 4 and 5, the time required for the rate of heat flow to become constant varies over a very considerable range. From Figure 4, it is obvious that this rate of heat flow in wattmeter C does not become constant for some 20 to 30 minutes. From Figure 5, it is evident that the rate of heat flow for wattmeter G becomes constant in considerably less than 10 minutes. About five or six minutes would closely fit the experimental data seen in Figure 5. In other words, after a change in load occurs, k is not a constant, but a variable, and does not become a constant for some 5 to 30 minutes, the length of time being subject to meter design.

Table A

Time Interval	60	30	15	10	5
k	0.03838	0.07675	0.1535	0.23026	0.4605

Time Interval—How Long?

What is the proper time interval to use in the measurement of maximum demand? As indicated at the beginning of this paper, United States public utilities are using various time intervals in the measurement of maximum demand. It is obvious that the longer the time interval used in demand measurement, the less is the probability of a steady load during that time interval, and, therefore, the greater is the probability of a difference between the logarithmic and arithmetic averages. The 15-minute time interval is by far the most frequently used. The shorter time intervals have been brought about by the desire on the part of public utilities to obtain adequate compensation from those service users whose loads are inherently of the short-time, high-peak variety, such as welding, short-time heating, shovels for excavation purposes, and so on. It might be pointed out that the thermal-demand meter automatically recognizes the short-time, high-peak demands in this class of loads. Inspection of Figure 1 shows this clearly. The thermal-demand meter—even assuming instantaneous heat diffusion—gives higher demand indications on short-time loads, approximately 2.3 times that of a block interval of the same time rating. The phenomenon of heat diffusion increases this ratio still further.

Examination of the data in Figure 2 shows that if we use 60-minute wattmeter C, its indication on short time loads (load durations of a minute or two) is approximately equivalent to a five or six minute block interval. This ability of the 60-minute thermal-demand wattmeter to

read high on short-time loads may be still further emphasized by suitable design, if the users of demand meters so desire. It should be pointed out, however, that if the design be so altered as to make its short-time response equivalent to a two- or three-minute block interval, the rate of response for load durations of more than 90 minutes is so slow that it would require some 12 or 15 hours of perfectly steady road to cause the meter to reach 99.9 per cent of its final indication. In the writer's opinion, the modification of the 60-minute thermal wattmeter's design to the point where it is equivalent to a five- or six-minute block interval is as far as the modification should be carried. Even this modification has reduced the permanent value of the constant k to one-half that of the 60-minute thermal wattmeter when heat diffusion is assumed to be instantaneous—$1-\epsilon^{-0.03838t}$. Also, it is highly questionable in the writer's opinion, whether or not wattmeter C, while it meets the meter-code specifications, can honestly be called a 60-minute meter.

A 60-Minute Meter

On the assumption that if the time interval for demand measurement is ever standardized, such standardized time interval would not exceed the maximum time interval now used—60 minutes—the writer has been experimenting with 60-minute thermal wattmeters. The most obvious way of obtaining a 60-minute thermal meter is to add mass to the 15-minute meter, as shown in Figure 3, so that the time to heat this mass up to 90 per cent of its final temperature is increased from 15 minutes to 60 minutes. When a steady load was applied to this 60-minute meter, wattmeter C of Figure 2 shows the test results. It will be noted that when a steady load was applied to this 60-minute wattmeter C, it reached 50 per cent of final value in approximately 4 minutes, 60 per cent in approximately 6 minutes, 70 per cent in approximately 10 minutes, 80 per cent in approximately 26 minutes, and 90 per cent in approximately 60 minutes. The design of the meter was then modified so that the mass to heat and cool during normal operation was reduced to a small fraction of that necessary in meter C. Wattmeter G of Figure 2 shows the test results on this redesigned 60-minute meter. It will be noted that wattmeter G reaches 50 per cent of its final in approximately 17 minutes, 60 per cent in approximately 23 minutes, 70 per cent in approximately 30 minutes, 80 per cent in approximately 42 minutes, and 90 per cent in approximately 60 minutes.

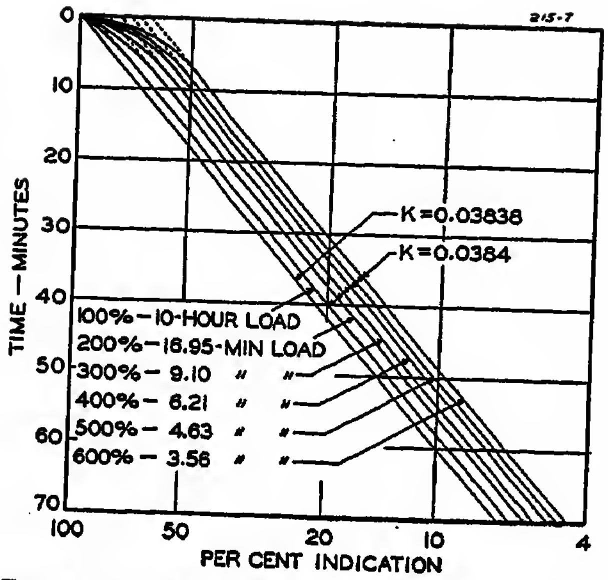

Figure 7. 60-minute thermal wattmeter I, zero-load performance

Let us examine this matter a little further from a purely theoretical standpoint. When we integrate mathematical expression 2 above, the result of this integration is, of course, meter indication $= w(1-\epsilon^{-kt})$. With large values of time (t), ϵ^{-kt} approaches zero and meter indication approaches w (watts). If $t=$ infinity (steady load), meter indication $= w$. If, however, t is of a small value making it necessary to use the limits of integration, meter indication $= \dfrac{w(1-\epsilon^{-kt})}{\text{per cent time}}$. In the foregoing sentence, the adjective "small" may be defined as any value of t (time in minutes) such that the product kt does not exceed 6.9078.

After a change in load occurs, wattmeter C acquires approximately 80 per cent of the value of this change during the 20 or 30 minutes k is a variable. The remaining 20 per cent requires approximately five hours additional time. Wattmeter G acquires approximately 20 per cent of final indication in the five or six minutes that k is a variable while the remaining 80 per cent requires approximately an additional three hours.

Now, examining 60-minute wattmeter G shown in Figure 2, it is obvious that its response is fairly close to the theoretical value given in equation 2. For very short time loads, its rate of response is some 30 per cent or 40 per cent higher than if heat diffusion could be made instantaneous, but this higher rate of response lasts for only five or six minutes. In this meter, the value of the adjustable constant k is close to the theoretical value of k for a 60-minute meter. Tests on a number of these redesigned 60-minute thermal wattmeters have shown a departure in the permanent value of k of not over two per cent or three per cent from the theoretical value—0.03838. Also, its temporary value is much less than in wattmeter C. On short-time loads, load durations of a minute or two, wattmeter G is equivalent to approximately a 20-minute block interval. The design of the 60-minute thermal wattmeter is capable of adjustment to almost anything the public utilities may desire between wattmeters C and G shown in Figure 2. The writer would appreciate an expression of opinion by those using demand meters as to which design shown in Figure 2 they would prefer. Or, perhaps some intermediate design between C and G would be preferable. It must be borne in mind, however, that wattmeter C can be made available for any time interval from 15 minutes up, while wattmeter G is available in 60-minute time interval only.

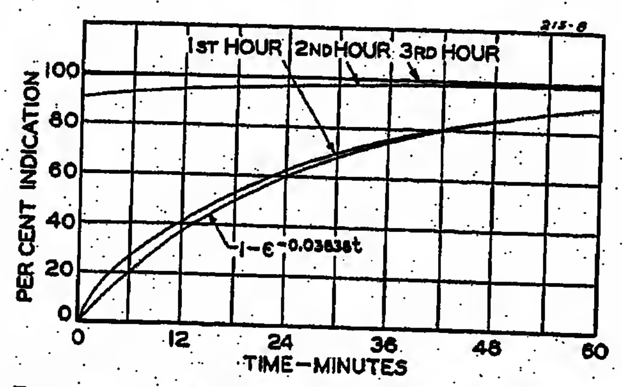

Figure 8. 60-minute thermal wattmeter, three-hour 100 per cent load applied

Statement Re Accuracy

The writer wishes to correct an impression which might be drawn from the preceding discussion. The accuracy of the standard block-interval demand meter in measuring an arithmetic average is as high as human ingenuity can attain, provided we limit this statement to the particular time interval which the meter happens to select. However, we must bear in mind that the particular time interval selected is only one out of an infinite number that might be selected. The writer does not wish his statement concerning the accuracy of the block-interval demand meter to be interpreted in any other manner.

New Data on 60-Minute Thermal Meters

Also, further experimental work has demonstrated that the time interval during which the constant k is a variable can be somewhat reduced below that shown in Figure 5. By taking all possible precautions to make the diffusion of heat as rapid as possible, Figure 7 shows the resulting zero load performance. The test results shown in Figure 7 indicate

that the constant k is a variable for a time interval but little over three minutes, even when the load applied is six times full load for 3.56 minutes. Figure 8 shows this meter's performance with full load applied for three hours. The constant k of 60-minute wattmeter I becomes 0.03838 when the two curves shown in Figure 8 become parallel; Figure 8 shows this to occur at approximately three minutes. Also, Figure 7 shows that the permanent value of the constant k departs from the theoretical value by only a negligible amount.

Ammeters Versus Wattmeters

There is one further point that should be considered. Thermal meters are available in both wattmeters and ammeters. These two instruments differ in at least one important respect. The wattmeter scale is uniform throughout its entire range, while the ammeter scale is inherently a scale of squares. Under the existing definition of time intervals, the time interval of both these instruments is defined as the "time required for the instrument to indicate 90 per cent of the full value of a steady load which is suddenly thrown on it." Since the ammeter scale is inherently a scale of squares, this means that the time interval of the thermal ammeter is approximately one-half that of the thermal wattmeter as time intervals are now defined. There are two ways to cure this defect:

1. The value of k for the ammeter may be fixed at one half that of the wattmeter.
2. The percentage of final indication for the ammeter may be fixed at the square root of that for the wattmeter.

If we adopt the first of the above, it means that ammeters and wattmeters will differ in construction, thereby increasing their cost. If we adopt the second, we must either make the wattmeter time interval the time to arrive at 90 per cent of final, as at present, and the ammeter time interval the time to arrive at 95 per cent of final, or we must make the ammeter time interval the time to arrive at 90 per cent of final, as at present, and the wattmeter time interval the time to arrive at 81 per cent of final. It is suggested that those who are responsible for the Code for Electricity Meters give careful attention to this matter and choose one of the above alternatives.

Conclusion

Summarizing, we must obtain the logarithmic average and not the arithmetic average if we would have consistency as well as adequacy in the measurement of maximum demand. Time must appear as an exponential function and not an arithmetic function, if the demand is to be metered in accord with the basic character of the quantity being measured. The writer would also urge that consideration be given to the matter of standardizing the time interval used in demand measurement.

A New Voltage-Regulating Relay Plus Line-Drop Compensator

H. J. CARLIN
ASSOCIATE AIEE

THERE are numerous applications where it is desired to measure a voltage at one point of a line or feeder by the use of an instrument placed at some other point. The instrument measures the voltage at the point of the line to which it is connected, and also measures the line drop to the remote point. These two measurements are combined so that the resultant indication is the voltage at the remote point of the feeder. If the instrument has contacts on it so that it may actuate control circuits, it is known as a voltage-regulating relay plus line-drop compensator. Such a device finds application to regulating equipment such as tap-changing transformers, capacitor-switching schemes for power-factor control, and the like.

Many of the applications for a voltage-regulating relay require a time delay. Usually such delay has been obtained by the use of timers which interpose a fixed lag between the operation of the relay and the device which is being controlled (for example a tap-changing regulator) independent of the magnitude or rate of voltage change. The relay described below eliminates the use of an external timer, since it has its own inherent time delay. In addition, this time delay is not a fixed quantity but varies inversely as the change in voltage. In this way the sensitivity of the regulating device is increased without introducing a large number of unnecessary operations.

The Voltage-Regulating Relay

An induction-type voltage relay with a permanent damping magnet inherently has an inverse time characteristic; hence, such a relay became the basis for design. Time curves for different voltage settings on an induction voltage relay with front and back contacts are shown in Figure 1.

The two major problems to be solved in the completed design were:

1. To make the temperature error negligible, for applications often call for outdoor installations where ambient temperature may vary over an extreme range of 0 to 110 degrees Fahrenheit.

2. To provide the relay with a self-contained line-drop compensator.

Starting with the final result, we may show how these two problems were solved.

Temperature Error

Figure 2 is a wiring diagram of the relay. Neglecting the compensator winding, the principle of operation of the relay is quite familiar.[1] When the potential winding is energized, the transformer winding on the lower pole feeds current to the upper-pole windings. This current induces an upper-pole flux which is out of phase with the potential flux, and a torque on the disk results which satisfies the equation:

$$T = K\Phi_1\Phi_2 \sin a \qquad (1)$$

where Φ_1 is the lower-pole flux, Φ_2 the upper-pole flux, and a the phase angle between them.

There are two sources of temperature error in such a relay:

1. For constant voltage across the relay, change in ambient temperature produces a change in the resistance of the upper-pole circuit. Hence, both the magnitude of upper-pole flux Φ_2 and the phase angle "a" will change. According to equation 1, the torque will, therefore, vary.

2. Change in ambient temperature may also produce variations in relay impedance so that the current in the potential circuit varies with the temperature even though the voltage remains constant.

In appendix I is a derivation which shows that when upper-pole reactance equals upper-pole resistance, temperature error due to variation of upper-pole impedance is a minimum. Accordingly, the upper-pole winding was designed to have a 45 degree impedance angle.

To correct for the second source of temperature error, a swamping reactor is placed in series with the potential coil. Hence, variations in relay burden have little effect on the total impedance of the voltage circuit, so that the current in the relay remains constant independent of temperature. Experimental tests made in a refrigerator and an oven over a range of temperatures from 0 to 110 degrees Fahrenheit showed an average temperature error of less than 0.018-volt per degree Fahrenheit. This ballast impedance method of correction was chosen so that the reactor could serve a dual purpose. Besides correcting for temperature error, it is an essential part of the line-drop compensator circuit. This function is described below.

The Line-Drop Compensator

The line-drop compensators in general use today employ what amounts to an artificial or replica line. That is, the compensator is a variable resistance and reactance which may be independently adjusted to suit a particular line impedance. These elements are placed in series with the voltage-regulating relay, and a current is fed to this compensator from current transformers in the main line, so that the drop across the resistor and reactor is proportional to the line drop and is subtracted from a voltage proportional to the sending-end potential. Thus, the voltage across the relay actually simulates the voltage at the load center, if the resistance and reactance of the compensator have been correctly adjusted.

The relay described in this paper has no such artificial line. Instead the equivalent of two separate torques is superimposed on the induction disk. One of these is proportional to the sending-end voltage, the other is proportional to the line drop, and the relay combines these so that the resultant torque is proportional to the receiving-end voltage. The former torque component is obtained by impressing on the relay-potential coil a voltage proportional to that at the sending end or regulator location. The torque component due to the line drop is obtained by means of a second upper-pole winding (see Figure 2). Current flowing in this winding from a current transformer in the line induces a flux, which reacts with the main-pole flux to produce a torque on the disk which opposes the main-relay torque.

If the relay is to perform correctly, the compensation torque must satisfy certain conditions which are a function of the electrical properties of the line, the magnitude of the load, and the power factor of the load. Consider a simple line, such as shown in Figure 3a. The vector diagram, Figure 3b, is drawn for a constant magnitude of load, I_L, and a varying load-power factor, θ. ϕ is the impedance angle of the line. This diagram shows clearly that the sending-end voltage, E_S, necessary to maintain constant receiving-end voltage, E_R, with varying power factor, has a maximum magnitude when δ, the angular

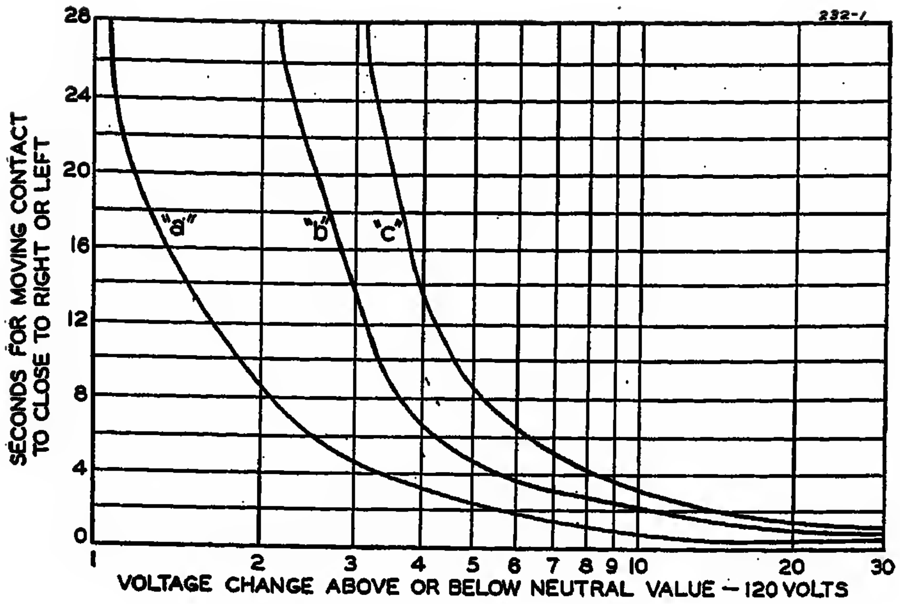

Figure 1. Voltage-regulating-relay time curves

(a). Right-hand contact set at 121 volts; left-hand contact set at 119 volts

(b). Right-hand contact set at 122 volts; left-hand contact set at 118 volts

(c). Right-hand contact set at 123 volts; left-hand contact set at 117 volts

shift between E_S and E_R is zero. This occurs when $\theta = \phi$. In order words, for any given load the relay must produce a maximum of compensation when the power factor of the load is equal to the impedance angle of the line.

What does this mean as far as the design of the relay is concerned? Referring to the general torque equation 1, it is seen that the compensator torque will be a maximum for any given load, when the angle between the compensator-winding flux and the potential-coil flux is 90 degrees. Therefore, a necessary condition for correct compensation is that when the load-power-factor angle equals the line-impedance angle, the compensator flux must be 90 degrees from the main-pole flux.

To see how this condition is translated into the actual structure of the relay, refer to the vector diagram, Figure 4.

Here E_1 is the voltage impressed across the relay terminals, and E_{1G} lags this somewhat due to the leakage drop in the potential coil. Φ_1, the main-pole flux lags E_{1G} by 90 degrees, and for maximum compensation torque Φ_C lags Φ_1 by 90 degrees. The compensator excitation which is proportional to the current in the compensator current transformer, leads ϕ_C by a

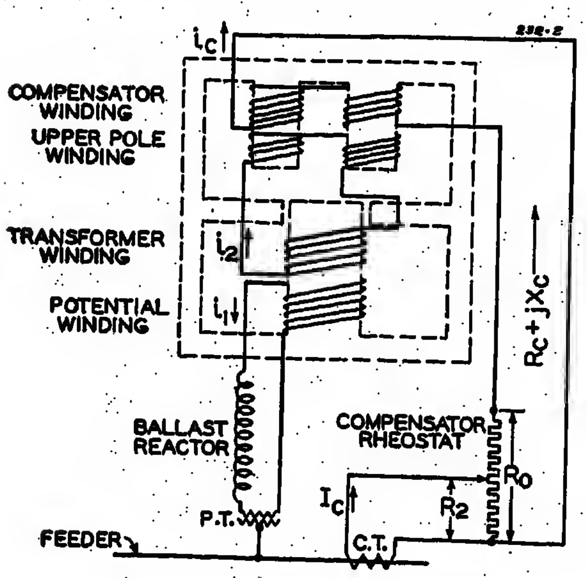

Figure 2. Schematic wiring diagram of voltage-regulating relay

small angle due to the eddy currents in the disk and the hysteresis loss in the upper-pole iron. Thus, the relay primary voltage, E_1, and the compensator current, i_c, will be very close to 180 degrees out of phase for maximum compensator torque. Actual measurements showed the angle to be 180 degrees ± 3 degrees.

As shown above, if the relay is to compensate correctly, maximum compensation torque must occur when E_S is in phase with E_R, and the load-power-factor angle is equal to the impedance angle of the line. Hence, in Figure 4, E_S is drawn at an angle $\theta = \phi$ ahead of I_L, or $180 - \phi$ behind i_c. Then, E_1 must lag E_S by the impedance angle of the line. This means that a phase shifting network must be placed between E_S, the sending voltage, and E_1, the relay primary voltage. If the effective shift of this network is equal to ϕ, the relay will compensate correctly.

In appendix II is an analytical derivation which corroborates the conclusions reached above. The voltage equation for a simple line is set up and compared with the torque equation of the relay, and it is shown mathematically that the necessary and sufficient conditions for correct compensation are that the compensator-winding excitation be proportional to the magnitude of line drop and that the relay primary voltage lag behind the sending voltage by an angle equal to the impedance angle of the line.

This will be clearer if we consider for a moment the line-drop compensators almost universally used at present. These devices must also satisfy two conditions if correct compensation is to result. The compensator-reactance drop must be proportional to the line-reactance drop and the compensator-resistance drop must be proportional to the line-resistance drop. To get this proportionality for different lines, the compensator has an adjustable resistor and an adjustable reactor. In the new relay we fit the two line constants by having one adjustment for the impedance of the line in ohms, and another for the phase angle of the line impedance. In other words, we compensate for Z/ϕ, instead of $R+jX$. In both cases there must be two variables of adjustment to match two line constants.

The phase-angle adjustment in this new relay is provided by a phase-shifting network. Theoretically, this should be adjustable to vary the phase position of the output voltage, while keeping the magnitude of output voltage constant. But to obtain such results requires relatively complex networks. However, as will be shown later, a great simplification in design is possible.

Figure 2 shows the circuit for obtaining magnitude adjustment. This consists of a potentiometer which is connected to the line current transformer and the compensator winding so that as the slide is moved, the magnitude of current in the compensator varies while the phase angle of the current stays constant. This is easily seen to be true, for if I_c is the current in the transformer secondary, then the compensator current is given by

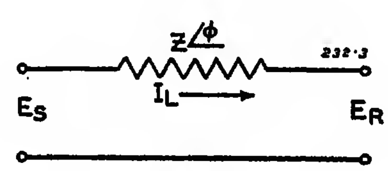
$$i_c = I_c \frac{R_2}{R_0 + R_c + jX_c} \tag{2}$$

in which the various quantities are as indicated on Figure 2. The denominator of equation 2 is a constant, hence only the magnitude of i_c varies with R_2.

The rheostat may be calibrated in line ohms, or volts line drop. The latter method is actually used on the relay.

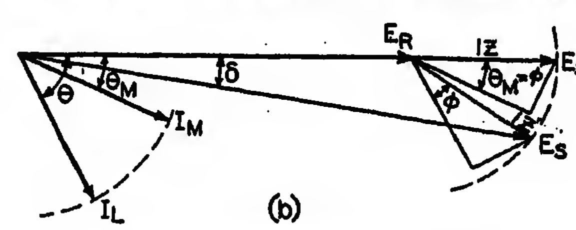
Settings

It is usually desirable that voltage-regulating relays be as inexpensive and simple in operation as possible, consistent with a minimum sacrifice in operating features. For this reason it is desirable to simplify the relay described in the pre-



(a)

Figure 3a. Schematic single-phase feeder



(b)

Figure 3b. Vector diagram of feeder

θ_M—Power factor for maximum line-drop compensation

I_M—Load current for maximum line-drop compensation

ceding paragraphs, even though this might mean some limitations in operating performance.

The part of the relay most susceptible to simplification is the phase-shifting network of the line-drop compensator. As shown above, this network should provide adjustable voltage phase-angle shift without affecting the magnitude of voltage. Circuits to operate in this manner can be constructed with inductors, resistors, and capacitors. The finer the adjustments, the larger the number of elements required and the more difficult the calibration. Such networks were experimentally constructed and they operated satisfactorily.

The simplified network consisted of the single reactor used also as ballast impedance for temperature correction. Obviously, once the reactor is chosen, the phase-angle adjustment is fixed, and the relay is theoretically adapted for only one line. Nevertheless, it is possible to take a relay so constructed and apply it to a wide range of lines without excessive error in voltage regulation. Suppose the reactor has been designed so that when placed in series with the potential coil of the relay the angle between the impressed voltage and the voltage across the relay is 40 degrees. This means that when used on a 40-degree line, the relay operates correctly for any load and any power factor, if the compensator-voltage scale is set for the true magnitude of full-load line drop. Now, suppose we place this 40-degree relay on a line whose impedance angle is 70 degrees. The relay would no longer give correct voltage indications if the compensator-voltage scale is set for the true magnitude of full-load line drop. However, for any given power factor, a setting of the voltage scale can be found which makes the relay operate correctly for any load *at that power factor*. This setting in volts will obviously not be equal to the true line drop. We define this compensator setting, in volts, divided by the true line drop, in volts, as the "compensator-correction factor." In effect, an intentional error in the compensator-voltage setting is introduced to correct for the error in the relay-phase-angle setting.

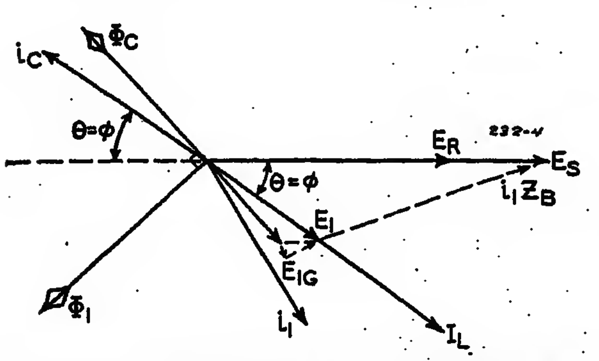


Figure 4. Vector diagram of voltage-regulating relay drawn for maximum compensation torque

Figure 5 is a family of curves to show how this factor varies as a function of load power factor when a 40-degree relay is used on various lines. Forty degrees was chosen because it is the impedance angle of the average low-capacity line.

The derivation of the correction factor curves is shown in appendix III. In order to verify these curves experimentally, apparatus was set up to simulate a line whose impedance angle could be varied, and a load whose power factor could be varied. Agreement between experimental and theoretical curves was very close.

A glance at the correction factor curves shows what errors may be expected in operating the relay on lines other than 40 degrees. Suppose we have a 60-degree line where the power factor varies from 80 to 90 per cent. The correction factor for 80 per cent is 0.91, for 90 per cent it is 0.85. The average setting would then be 0.88 and the variation plus or minus 0.03. Thus, if the line drop were 10 volts, the relay-compensator scale would be set at $0.88\times10=8.8$ volts and the maximum error plus or minus 0.3 volts. Obviously, the narrower the range of power factor, the smaller would be the relay-voltage errors. Also, the closer the line-impedance angle is to 40 degrees, the smaller is the error. As is the case with the compensators in use at present, calculated settings are only tentative, and final settings are usually chosen on the basis of field tests.

Conclusions

Due to the inverse time characteristic and integrating properties of the relay described above, circuits controlled by it are operated after a relatively short time delay when voltage conditions on the line require this. However, unnecessary operations are prevented when short-interval voltage surges occur. At the same time the relay is simplified to have only one adjustment for line-drop compensation without introducing excessive errors in indicated voltage.

Appendix II. Derivation for Minimum Temperature Error

By equation 1

$$T_S=K\Phi_1\Phi_2\sin a$$

Referring to Figure 6

$$\sin a=\sin(90-b)=\cos b$$

Therefore

$$T_S=K\Phi_1\Phi_2\cos b$$

$$=K\Phi_1\Phi_2\frac{R_2}{\sqrt{R_2^2+X_2^2}}$$

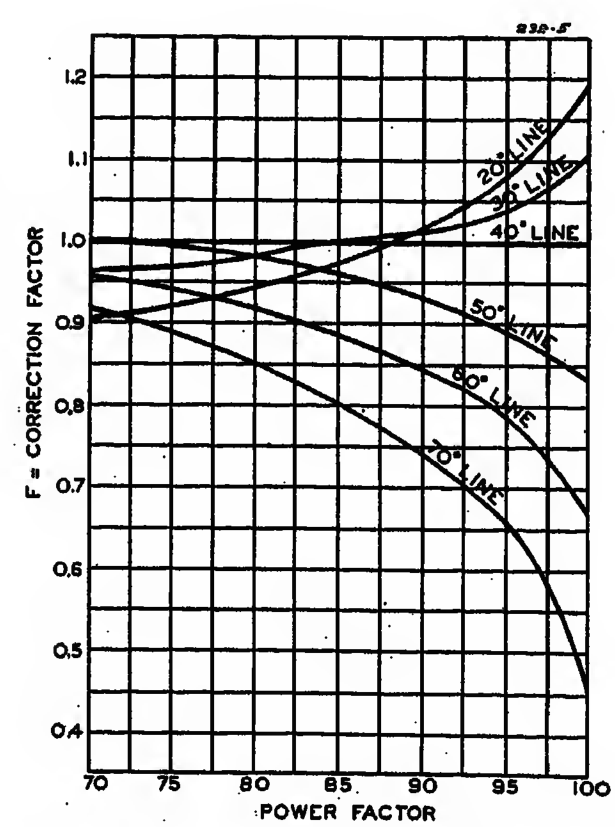

Figure 5. Correction-factor curves for 40-degree voltage-regulating relay. See appendix IV

Now

$$\Phi_2 = ci_2 = \frac{ce_2}{Z_2} = \frac{k}{\sqrt{R_2^2+X_2^2}}$$

where c and k are constants.
Or

$$T_S = \frac{kK\Phi_1R_2}{R_2^2+X_2^2} = \frac{AR_2}{R_2^2+X_2^2}$$

Differentiate this expression with respect to R_2 to find the value of R_2 which results in no change in T_S for small changes in R_2.

$$\frac{dT_S}{dR_2} = 0 = \frac{A}{R_2^2+X_2^2} - \frac{2AR_2R_2}{(R_2^2+X_2^2)^2}$$

where A is a constant.
Solving

$$R_2 = X_2$$

This is the condition for minimum temperature error.

Appendix III

Derivation to prove that the relay performs correctly if:

(*a*) The compensator-winding excitation is proportional to the magnitude of line drop.

(*b*). Maximum compensator torque occurs when the line-impedance angle ϕ, equals the power-factor angle θ. That is, β, the angle between Φ_c and Φ_1 shall be 90 degrees when $\theta = \phi$.

1. The Voltage Equation for the Line

Refer to Figure 3b and take E_S as reference vector.

$$E_R = E_S - I_LZ$$
$$= E_S\underline{/0} - I_L\underline{/\delta-\theta}\cdot Z\underline{/\phi}$$
$$= E_S\underline{/0} - I_LZ\underline{/\theta-\delta-\phi}$$

Let

$$\theta-\delta-\phi = \gamma$$

Then

$$E_R = E_S - I_LZ\cos\gamma + jI_LZ\sin\gamma$$

or

$$|E_R| = \sqrt{E_S^2 - 2I_LZE_S\cos\gamma + (I_LZ)^2} \quad (3)$$

2. The Torque Equation of the Relay

The two components of relay torque are T_S and T_c. The resultant relay torque is T.

$$T = T_S - T_c$$

$$T_S \propto \Phi_1\Phi_2 \sin a \propto \frac{N_1^2}{N_2}\cdot i_1^2 \cdot \sin a \propto \frac{N_1^2}{N_2}\cdot \sin a \cdot E_S$$

Since

$$i_1 \propto E_S$$

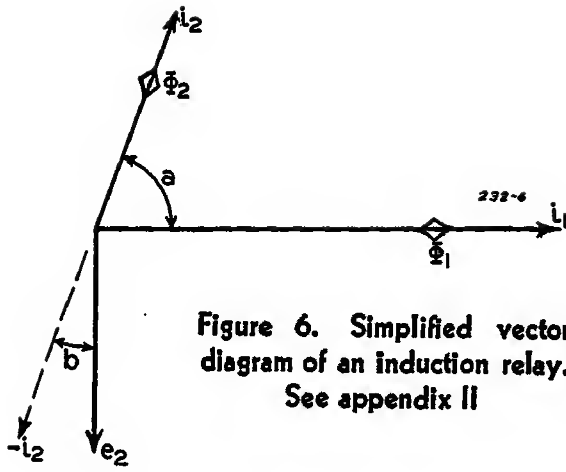

Figure 6. Simplified vector diagram of an induction relay. See appendix II

therefore

$$T_S = kE_S^2 \quad (4)$$

Since $(N_1^2/N_2)\sin a$ is a constant

$$T_c \propto \Phi_c\Phi_1 \sin\beta$$

$$T_c = CI_cE_S\cos(\beta-90)$$

where C is a constant
Since $I_c \propto \Phi_c$ and $\Phi_1 \propto E_S$, therefore

$$T = kE_S^2 - CI_cE_S\cos(\beta-90) \quad (5)$$

The relay is initially calibrated with the compensator scale set for zero volts compensation, so that if E_R' is the scale reading of the relay, equation 4 applies and we have

$$|E_R'| = \sqrt{T/k}$$

Substituting for T from equation 5

$$|E_R'| = \sqrt{E_S^2 - KI_cE_S\cos(\beta-90)} \quad (6)$$

Equations 6 and 3 are identical (if we neglect the term $(IZ)^2$ which is of the second order) when

(*a*). $KI_c = 2I_LZ$

(*b*). $(\beta-90) = \gamma = \theta-\delta-\phi$

That is, when $\theta = \phi$, and $\delta = 0$; $\beta = 90°$.

This is what we have set out to prove for (*a*) states that KI_c is proportional to the line drop, and (*b*) states that the angle between Φ_c and Φ_1 is 90 degrees when $\theta = \phi$.

Appendix IV. Derivation of Correction-Factor Curves

1. Assume the relay is adjusted to compensate for a line of impedance angle ϕ' and a voltage drop $(I_LZ)'$. The true line drop (I_LZ), and the true line angle is ϕ. Then, for a load power factor θ, the relay develops a torque in accordance with the voltage equation

$$E_S\underline{/\delta} = E_R\underline{/0} + (I_LZ)'\underline{/\phi'-\theta} \quad (7)$$

E_R is taken as reference vector, and is the required receiving-end voltage.

2. The true line angle is ϕ, and the true line drop I_LZ. Then, since E_S is the head-end voltage of the line determined by the relay, the voltage equation of the line is given by

$$E_S\underline{/\delta} = E_{R_0}\underline{/\alpha} + I_LZ\underline{/\phi-\theta} \quad (8)$$

Where E_{R_0} is the actual voltage at the end of the line.

In the equations below $(I_LZ)'$ is determined as a function of the line and relay constants so that $E_{R_0} = E_R$ = the required receiving end or load center voltage.

Equate (7) and (8)

$$E_R\underline{/0} + (I_LZ)'\underline{/\phi'-\theta} = E_R\underline{/\alpha} + (I_LZ)\underline{/\phi-\theta}$$

Solve for (I_LZ)

$$(I_LZ)'\underline{/\phi'-\theta} = E_R\underline{/\alpha} - E_R\underline{/0} + (I_LZ)\underline{/\phi-\theta}$$

$$(I_LZ)'\sin(\phi'-\theta) = E_R\sin\alpha + (I_LZ)\sin(\phi-\theta)$$

$$(I_LZ)'\cos(\phi'-\theta) = E_R\cos\alpha - E_R + (I_LZ)\cos(\phi-\theta)$$

Divide these equations to eliminate $(I_LZ)'$, simplify and solve for (I_LZ)

$$(I_LZ) = E_R\frac{\sin\alpha - [\tan(\phi'-\theta)\cdot(\cos\alpha-1)]}{\cos(\phi-\theta)\tan(\phi'-\theta) - \sin(\phi-\theta)}$$

Solve for $(I_LZ)'$

$$(I_LZ)\underline{/\phi-\theta} = E_R\underline{/0} + (I_LZ)'\underline{/\phi'-\theta} - E_R\underline{/\alpha}$$

$$(I_LZ)\sin(\phi-\theta) = (I_LZ)'\sin(\phi'-\theta) - E_R\sin\alpha$$

$$(I_LZ)\cos(\phi-\theta) = (I_LZ)'\cos(\phi'-\theta) - E_R\cos\alpha + E_R$$

Divide these equations to eliminate (I_LZ), simplify, and solve for $(I_LZ)'$

$$(I_LZ)' = \frac{E_R\cdot\tan(\phi-\theta)\cdot(\cos\alpha-1) - \sin\alpha}{\cos(\phi'-\theta)\tan(\phi-\theta) - \sin(\phi'-\theta)}$$

$$F = \frac{(I_LZ)'}{(I_LZ)} =$$

$$\frac{[\cos(\phi-\theta)\tan(\phi'-\theta) - \sin(\phi-\theta)]\cdot[\sin\alpha - \tan(\phi-\theta)(\cos\alpha-1)]}{[\cos(\phi'-\theta)\tan(\phi-\theta) - \sin(\phi'-\theta)]\cdot[\sin\alpha - \tan(\phi'-\theta)(\cos\alpha-1)]}$$

For line drops of the order of 10 per cent δ is very small and hence α must be even smaller.

Therefore

$$\sin\alpha = \alpha$$
$$\cos\alpha = 1$$

or

$$F = \frac{\cos(\phi-\theta)\tan(\phi'-\theta) - \sin(\phi-\theta)}{\cos(\phi'-\theta)\tan(\phi-\theta) - \sin(\phi'-\theta)}$$

The curves on Figure 5 are graphs of F versus θ for various line-impedance angles, ϕ. $\phi' = 40$ degrees.

A Static Voltage Regulator Insensitive to Load Power Factor

C. M. SUMMERS
MEMBER AIEE

T. T. SHORT
NONMEMBER AIEE

THE voltage regulator described in this paper is intended for those applications where the operating efficiency is of secondary importance to other requirements. Excluding the consideration of efficiency, the output voltage of an ideal voltage regulator should be of sinusoidal wave form and should remain constant with any variation in input voltage and frequency and any variation in load volt-amperes and power factor.

These are ideal requirements, and a regulator has not been designed which will fulfill them completely. Several types of static regulators have been available in recent years, but all of them have had one or more serious defects. The more serious of these defects are sensitivity to frequency and power-factor variations and slow speed of response. Since most voltage sources have good frequency regulation, the power-factor sensitivity has been the most prevalent defect in previous regulators. Because of this, a given regulator has had a limited flexibility in its application.

The voltage regulator described in this paper has the important distinction fundamentally of being independent of load power factor. It will meet all of the other requirements except frequency variations of an ideal regulator within limits of which can be summarized as follows:

The regulator can be designed to maintain an output voltage which will not vary more than $\pm 2^1/_2$ per cent for a simultaneous variation of 30 per cent in line voltage, 100 per cent in load, and any desired range of power factor. For fixed loads, the regulation can be held to less than ± 0.5 per cent for 30 per cent variation in line voltage. The regulator will re-establish the load voltage within three cycles after a sudden change of 30 per cent in line voltage or 100 per cent in load is imposed on it. A variation of one-half cycle above or below the rated frequency will change the level of output voltage but will not materially affect the regulation of the new frequency. The wave form at or near full load will have a maximum harmonic content of about 6 per cent, and at open circuit its harmonic content reaches a maximum of 20 per cent. The efficiency of a one-kilovolt-ampere regulator or larger is 90 per cent or higher at full load.

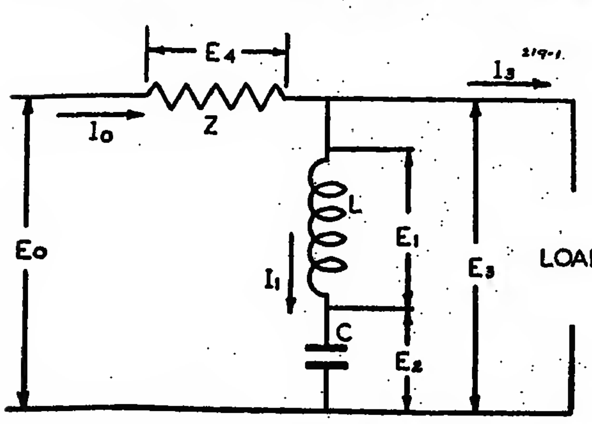

Figure 1. General circuit diagram for voltage regulator

Fundamental Circuit

The fundamental circuit employed in the regulator is simple and consists of a reactor and capacitor connected in series and shunted across the load as in Figure 1. The reactor has its individual characteristics, however, and these must be properly correlated with those of the capacitor. The reactor contains a special magnetic circuit[1] employing a bridge gap which will produce the volt-ampere curve E_1 in Figure 2. The capacitor is chosen so that its volt-ampere curve E_2 will be parallel to that of E_1. In an ideal circuit where L and C are pure inductance and capacitance, the voltage E_3 at the extreme terminals of the series circuit will be the numerical difference between the inductive and capacitive voltages. In Figure 2, therefore, the voltage E_3 can be represented by the vertical distance between the two volt-ampere curves, and this will remain constant between values of current represented by i_1 and i_1'. (In the following discussion capital letters are used to represent general values while lower-case letters represent minimum values and lower-case letters with primes [′] represent maximum values.) The permissible variation in series current is utilized in a series impedance Z in Figure 1 to compensate for changes in line voltage and load characteristics.

Assume, for example, an ideal circuit as in Figure 1 with the series impedance considered as pure resistance. Assume also that the circuit is operated at no load on a line voltage of some value which causes the minimum current of i_1 to flow through L and C. The vector diagram for this case is given in Figure 3 for which the following equations apply considering that $I_1 = I_0$.

$$e_0^2 = e_3^2 + (i_1 Z)^2 \quad (1)$$

$$(e_0')^2 = e_3^2 + (i'Z)^2 \quad (2)$$

Subtracting equation 1 from equation 2

$$(e_0')^2 - e_0^2 = (i_1'Z)^2 - (i_1 Z)^2 \quad (3)$$

Thus as the line voltage increases, I_1 increases to a value where the impedance drop E_4, $(i_1 Z)$, exactly compensates for the increase in line voltage. If the line voltage continues to increase, I_1 may exceed its limiting value of i_1' and the load voltage represented by the vertical distance between E_2 and E_3 in Figure 2 will decrease. This calls for a further increase in E_4 and a still higher value of I_1. Thus the load voltage drops very rapidly when the limits of I_1 are exceeded.

Now consider the same circuit operating on a constant line voltage and a variable resistance load. The vector diagram in Figure 4 shows the relation between I_1 and load current where it is important to note the minimum value of I_1 concurs with the maximum load current and that I_1 increases as the load decreases. The change in I_1 is dictated again by the amount of voltage drop in the series impedance Z necessary to compensate for the change in drop caused by the change in load current. In general the following vectorial equations apply:

$$E_0 = I_0 Z + E_3 = E_4 + E_3 \quad (4)$$

and

$$I_0 = I_1 + I_3 \quad (5)$$

The load current may have any value and phase angle with respect to E_3; and E_0 may fluctuate over any range, with the only restriction being that the limits of

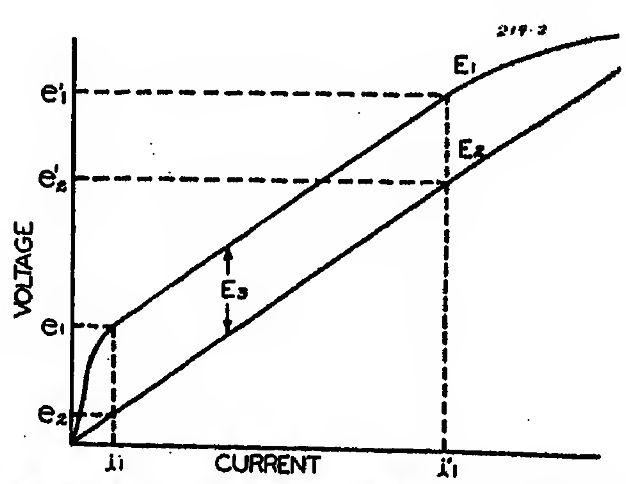

Figure 2. Volt-ampere curves of nonlinear reactor E_1 and associated capacitor E_2

Paper 42-19, recommended by the AIEE committee on industrial power applications, for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 6, 1941; made available for printing December 9, 1941.

C. M. SUMMERS is in the works laboratory of General Electric Company, and T. T. SHORT also is with General Electric Company, both in Fort Wayne, Ind.

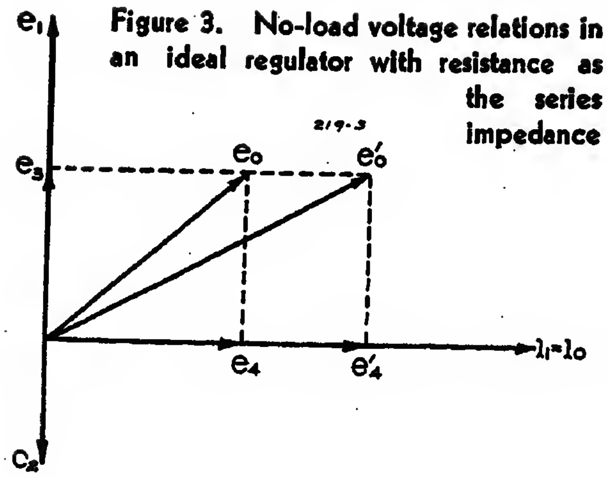

Figure 3. No-load voltage relations in an ideal regulator with resistance as the series impedance

I_1 are i_1 and i_1' as prescribed by Figure 2. If the load current becomes too high I_1 drops below the limiting value of i_1, and the voltage E_3 drops rapidly.

The characteristics of the series impedance Z materially affects the permissible range over which the various quantities are permitted to vary. A constant current type of series impedance shown in Figure 5 has several advantages. This circuit consists of a reactor and capacitor, connected in parallel, with volt-ampere relations similar to those of Figure 2. The line current is the difference between the capacitor and reactor currents at any value of their common voltage and can be represented by the horizontal distances between the two curves. It can be shown[1] that this circuit will maintain a constant current over a range of voltage from e_4 to e_4' which on Figure 2 would correspond to the voltages e_1 and e_1'. Thus another set of limits for correct operation must be added to those previously mentioned. The voltage drop E_4 across the parallel capacitor and reactor must remain within the limits of e_4 and e_4' over which there is a constant horizontal distance between the volt-ampere curves.

Analysis of the Practical Circuit

An accurate analysis of the regulator circuit must consider the actual power

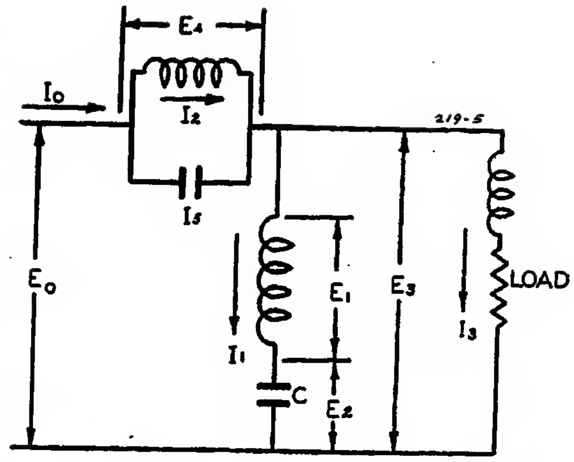

Figure 5. Complete circuit diagram of the preferred arrangement of the voltage regulator

factors of all of the reactors and capacitors in the circuit. A mathematical solution for the operating range can be established, but in practice, a graphical solution from a simplified vector diagram is quicker and accurate enough for design purposes. Hence a discussion of the vector diagram only will be attempted.

The complete diagram is given in Figure 6. In addition to equations 5 and 6, the following vectorial relations are needed.

$$I_0 = I_2 + I_5 \qquad (6)$$

$$E_3 = E_1 + E_2 \qquad (7)$$

The diagram shows all of the currents and voltages in their proper phase relations for a general load. The power factor of the reactors changes over their operating range which complicates an accurate vector analysis. However, experience has shown that average values of α and ϕ are accurate enough for the graphical calculations.

A simplified diagram may be constructed by using average values for α and ϕ. The vectors E_1, E_2, I_2, and I_5 may be omitted, and the voltage E_4 can be represented by a closing vector between E_3 and E_0. The diagram must include the range of the important variables if it is to be useful. Hence, it is convenient to represent the limits of E_4 by the arcs of two circles having the end of E_3 as their common center. The line-voltage vector will change in direction because I_1 has been taken as the reference axis, but its limits can be established by the arcs of two circles with their common centers at the origin. The locus of the constant line current is the arc of a circle, and the limits of I_1 can be indicated on the reference axis. A diagram incorporating these limits as well as variations in load is shown in Figure 7.

The actual design of a voltage regulator is based on a diagram similar to Figure 7. The variation in line voltage and the variation in load are prescribed by circumstances of the application. The limits of I_1 and E_4 are established by the parallelism of the volt-ampere curves and, under practical conditions, may cover ranges of 3 to 1 and 2 to 1 respectively. After a few adjustments of I_0, the values of I_1 and E_4 can be made to fall within their respective limits. Then, since the numerical values of line voltage and load current are known, all of the other currents and voltages can be scaled off of the diagram. A comparison between calculated and measured values of regulator currents and voltages is given in Table I.

Fundamentally, it is possible to design a regulator to operate any load over any range of power factor, leading or lagging; but, it is more economical to supply inductive power-factor correction for leading loads and limit the design of the

regulator to lagging loads. The reason for this is that an increase in power factor in a lagging direction reduces the value of current I_1, while an increase in a leading direction increases the value of I_1 beyond that required at no load. Thus, the capacity of every element of the circuit would have to be increased if the regulator were designed for both leading and lagging loads.

Characteristics

General

The equivalent characteristic of L and C in the series circuit is inductive, and the vector sum of its current I_1 and the load current must be constant. Therefore, I_1 will decrease for both an increase in load and an increase in lagging power factor.

The magnitudes of all quantities except E_4 in Figure 7 are independent of line voltage, but their phase angles with respect to the line voltage may change. Between full load and open circuit there is as much as a 90-degree phase shift between input and output voltage.

Stability

Stability of the regulator over its intended range of operation depends on the voltage relation between the series portion of the circuit and the line voltage, that is E_3 and E_0. If the vector E_3, in Figure 7, extends beyond the arc of minimum line voltage, the vector E_4 will intersect this arc at two points. Two values of E_4 will, therefore, satisfy the voltage triangle and the regulator may become unstable. Stable operation can be assured by establishing the value of E_3 somewhat less than the minimum value of line voltage.

Input Power Factor

The angle between E_0 and I_0 in Figures 6 and 7 is the power-factor angle on the line side of the regulator. This angle is leading for all values of load and line voltage. As the input current, I_0, is constant and independent of loading, the input volt-amperes will be proportional to the line voltage E_0. Therefore, as the load is decreased, the input power factor rapidly decreases until at no load the regulator becomes virtually a capacitor.

The input volt-amperes for a typical unit is approximately 150 per cent of the rated output at an average value of E_0.

Harmonic Content

The distortion of the output voltage wave shown in Figure 10a and b is caused primarily by a third harmonic. The analysis in Table II shows the comparison between input and output voltage for several harmonics. While the third harmonic is predominant, it reduces materially with load, whereas other harmonics are nearly independent of load.

Regulation

The curves in Figure 8 show the variation in load voltage for several conditions. This variation depends upon the accuracy of adjustment of the volt-ampere curves of the reactors. Since the curve E_1 is not a perfectly straight line between i_1 and i_1', the regulation is dependent also on the range over which I_1 is permitted to vary.

Table II. Harmonic Analysis of Regulator Voltage in Per Cent of Fundamental

		Regulator Output Voltage		
Order of Harmonic	Line Voltage	No Load	Full Load Unity Power Factor	Full Load 0.8 Power Factor
1	100	100	100	100
3	0.11	23.4	5.9	11.5
5	1.10	1.6	1.5	1.75
7	0.22	0.17	0.2	0.15
17	0.10	0.67	0.55	0.60
19	0.05	0.57	0.50	0.57

The effective value of output voltage is altered slightly by the change in wave form. It would change by three per cent from no load to full load on the basis of the harmonic content given in Table II. Thus considering the over-all regulation, the distortion does contribute an appreciable part.

The regulation can be improved by an adjustment in the volt-ampere curves of the parallel part of the circuit in Figure 5 so that I_0 decreases at the higher values of E_4.

Effects of Frequency

The effect of frequency on the operation of the regulator can be understood clearly by a reference to Figure 2. The volt-ampere curves are parallel for only one frequency, and, in general, the output voltage varies as the square of the frequency. In addition, the voltage regulation may be positive or negative depending on direction in which the frequency may change.

Efficiency

From the vector diagram in Figure 7 it can be seen that, as the load is decreased, the voltage increases across the various reactors and capacitors in the circuit. As a result, the losses are higher at no load than at full load, the no-load losses being approximately double the full-load losses. The general efficiency curves are shown in Figure 9.

Self-Protection

Mention has been made of the fact that as the load is increased above normal, the current I_1 in the series part of the regulator decreases. This is an important factor, because it guarantees that the regulator cannot be overloaded. When

the load current begins to exceed its maximum limit, I_1 drops below i_1, Figure 2, and the load voltage drops rapidly. A short circuit can be placed directly across the output terminals with no damaging effect whatever, as shown by the oscillogram in Figure 10c. In fact the losses in the regulator decrease under short circuit conditions because only the parallel portion of the circuit remains effective.

Speed of Response

The oscillograms in Figure 10 show how rapidly the regulator restores normal voltage when a sudden change in line voltage or load is imposed on the circuit. A transient of about three cycles occurs during which the load voltage may rise or fall about ten per cent.

Size

The size and equivalent kilovolt-amperes of the regulator depend on the range over which it has to operate. For a typical unit which operates over a range of 30 per cent variation in line voltage, 100 per cent variation in load kilovolt-amperes and from unity power factor to 80 per cent lagging power factor the size and equivalent kilovolt-amperes will be approximately seven times that of a standard transformer of the same rating. If the range is reduced to 20 per cent line-voltage variation 50 per cent variation in load kilovolt-amperes and from unity to 90 per cent power-factor variation, the size and equivalent kilovolt-amperes will be reduced to approximately four to one.

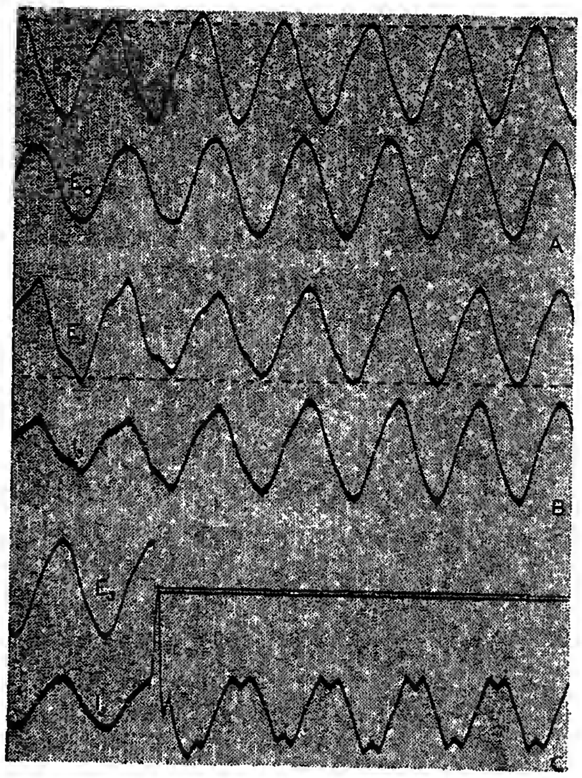

Figure 10. Voltage-regulator oscillogram

A—Transient in output voltage E_2 when line voltage E_0 is suddenly increased from 100 to 125 volts

B—Transient in output voltage E_2 when load current I_2 is suddenly increased from one-half load to full load

C—Transient in load current I_2 when a short circuit is placed on a regulator operating at full load

Conclusions

There has been presented in this paper a new form of static voltage regulator which can be separated into two parts. The first is a series circuit consisting of a capacitor and reactor which, over a predetermined range of current passing through it, will maintain a constant output voltage regardless of load or power factor. The second consists of a circuit containing a capacitor and reactor in parallel which, over a specified range of voltage drop, will maintain a constant current regardless of the line voltage. Thus, the two elements in conjunction convert variable potential to constant current, then to constant potential.

The regulator has many characteristics such as good voltage regulation, independent of load power factor, high speed of response and high efficiency at full load which makes it desirable for many applications. Its self protection against overloads makes it an ideal source of supply for filaments where the cold resistance approaches a short circuit.

In three-phase delta systems the regulator is unsatisfactory because the phase position of the output voltage depends on the load. However, in wye-connected systems three single-phase regulators can be used in each line to neutral.

The application of this regulator is necessarily limited by its size and cost. In general it will apply where some variation in load and power factor is expected and one or more of the following requirements are essential:

(*a*). High speed of response to eliminate the effect of transients.

(*b*). Very close regulation at any fixed load.

(*c*). Freedom from moving parts.

(*d*). Complete self-protection.

(*e*). Restricted overload capacity (maximum output current may be limited to as low as 125 per cent of rated current).

Sudden changes in line voltages of relatively short duration commonly occur on lines to which motors are connected, and these surges are passed through many types of voltage regulators. The three-cycle response speed of the regulator described above greatly attenuates these voltage fluctuations. This is an important factor in many applications for electronic devices and for testing purposes.

Multichannel Carrier-Current Facilities for a Power Line

P. N. SANDSTROM
ASSOCIATE AIEE

G. E. FOSTER
ASSOCIATE AIEE

Synopsis: A carrier-current system providing a relatively large number of channels is in service on a high-voltage power line. The facilities provide:

1. Transmission of signals both ways for the opening of the circuit breakers at the remote end by the operation of relays at the near end.

2. Two-way telephone service between any extension telephone at the remote generating station and any telephone connecting to the main telephone switchboard in the central office building.

3. Two-way telemetering (station generation one way and system total generation the other way).

4. Transmission from the system operator's office to the station of automatically generated load-control signals used to increase or decrease automatically the station generation.

5. Two channels in each direction for future requirements.

This paper describes the methods employed to obtain these channels over a single power line, including the special precautions taken with the high-speed transferred trip signals to prevent faulty tripping of the line due to external disturbances which might generate carrier-current tripping pulses.

The Carrier-Current Circuits

A carrier-current system providing 15 channels on a single high-voltage transmission line is now in service. The transmission line connects directly to the transformers at each end, and circuit breakers are provided only on the low-voltage sides of the transformers. The carrier-current channels are used for high-speed transferred tripping, telemetering, load control, and telephone.

Normally just a few carrier-current channels are required on a power line. If more than about four channels are required, many problems arise because of the need of guard bands, the practical limit of two-carrier frequencies per coupling capacitor, complexities of wave traps for separating frequencies, and so on.

The 15 channels are obtained as follows: One carrier frequency is used for single-frequency duplex telephone service since standard equipment is available to perform this function. Two carrier frequencies are established and kept in operation at all times, one in each direction over the line, for the signaling carrier system. These carriers are modulated with the requisite number of audio tones required for the other services. At the receiving point, the audio tones are separated and used to operate relays or other suitable devices. Figure 1 shows a photograph of the equipment required at one terminal for the telephone, eight audio channels transmitted and six audio channels received.

The above plan requires three carrier frequencies. The tuning and line circuits for these frequencies as well as the power frequency are shown in Figure 2.

One will notice that the circuit for each frequency consists of two phase conductors and a grounded center tapped output transformer. The path of the carrier current may be over the two phase conductors, or one phase may be opened or grounded and a path will then exist between the other phase conductor and ground. In this way work may be performed on the line without interrupting the carrier-current circuits. In addition, double-frequency wave traps are interposed between the line grounding switches and the coupling capacitors so that the line may be grounded without disturbing the carrier-current path.

Each coupling capacitor couples two frequencies to each phase conductor. In order to segregate frequencies, separate line-tuning coils and wave traps are provided. At each terminal each carrier frequency is selected by two line-tuning coils, two wave traps, and a matching transformer.

Relay or Signaling Carrier System

A block diagram of the equipment required for the signaling carrier system is shown in Figure 3. The upper portion of the diagram shows the transmission system and the lower portion the receiving system. Signaling circuits operate the audio-tone generators numbered 1 to 8. The signal may either start or stop the oscillator, as may be required. However, it requires about three milliseconds for the audio frequency to either build up or decay, and, therefore, this limits the speed with which the tone can be controlled. In Figure 4 is shown the circuit of one of these audio oscillators and its amplifier.

The frequency stability of the oscillator must be reasonably good. The oscillator is tuned to the desired frequency by means of small fixed condensers and a coil with a movable powdered iron core. The core is adjusted by means of a screw to give a fine control of the frequency.

The outputs of the various oscillators are added by connecting the output transformers in series with the modulator. This must always be borne in mind, since opening a circuit at one point or even removing an amplifier tube will remove all the audio frequencies. In setting the frequencies of these tone generators, the frequencies must not be harmonics of one another nor should they be within 30 per cent of one another. A study of these

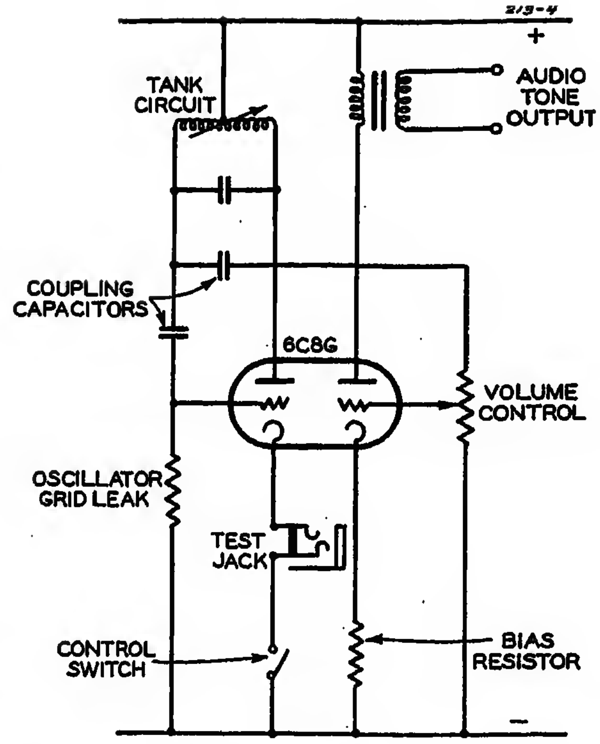

Figure 4. Simplified schematic diagram of audio oscillator and amplifier

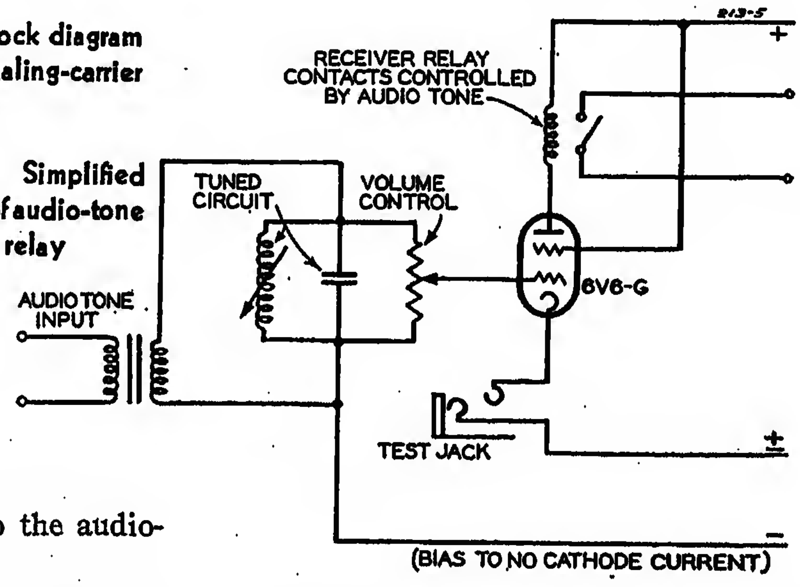

Figure 5 (right). Simplified schematic diagram of audio-tone receiver and relay

conditions shows that the frequency spectrum from 300 to 3,000 cycles will provide only about ten tones which will meet the above conditions. The equipment has been designed to accommodate a maximum of ten tones each way. The carrier frequency is supplied by a master oscillator which drives a power amplifier. This carrier frequency is always maintained so that a channel will be available for any audio tones which may be sent through. The power amplifier is plate modulated by the audio tones. From the power amplifier the carrier frequency is applied to the line tuning system shown in Figure 2.

At the far end of the line the carrier frequency is tuned by the proper line-tuning circuit and applied to a superheterodyne receiver. This receiver is equipped with both a squelch circuit, to prevent the reception of noise when no carrier frequency is present, and automatic volume control, to control the sensitivity to variations in carrier strengths. The output of the receiver is connected to an audio amplifier which provides about ten watts of power to the audio-tone filters.

The circuit of one of these audio filters is shown in Figure 5. The tuners are connected in series similar to the series connections in the transmitter. A parallel resonant circuit is tuned to each frequency which may be received by means of fixed capacitors and a coil with an adjustable powdered iron core. The voltage developed on the tuning circuit is applied to the grid of a detector tube which is biased to cut off when no signal is present. The arrival of signal of the frequency to which the circuit is tuned causes current to flow in the tube. This current normally passes through a relay which operates when the frequency is present.

The Transferred-Trip Circuit

One of the principal requirements of the signaling carrier system was to provide a high-speed transferred trip signal. The transformers on this line are not provided with circuit breakers on the line side. In case of a fault in a transformer, it is necessary to open the lower voltage breakers at both ends of the line in order to clear the transformer. The carrier is used to transmit the tripping signal to the far end of the line. Because of the large capacity of the transformers on this line, it was desirable that the time of transfer be as short as possible, and, at the same time, be completely reliable. In order to meet these conditions, it was decided to use three of the audio tones each way. These are arranged to provide the high-speed action desired together with automatic supervision and alarms.

The basic principle of the trip circuit is to have one of the audio frequencies, called a blocking frequency, always alive under normal conditions. This frequency upon reception, holds a relay contact open and prevents tripping. In order to trip, it is necessary to stop the blocking frequency and start another, called the tripping frequency. At the receiving point, a contact on the relay, associated with the tripping frequency, closes, and upon the closure of the contact associated with the blocking frequency, the trip circuit will be completed. Thus two things must oc-

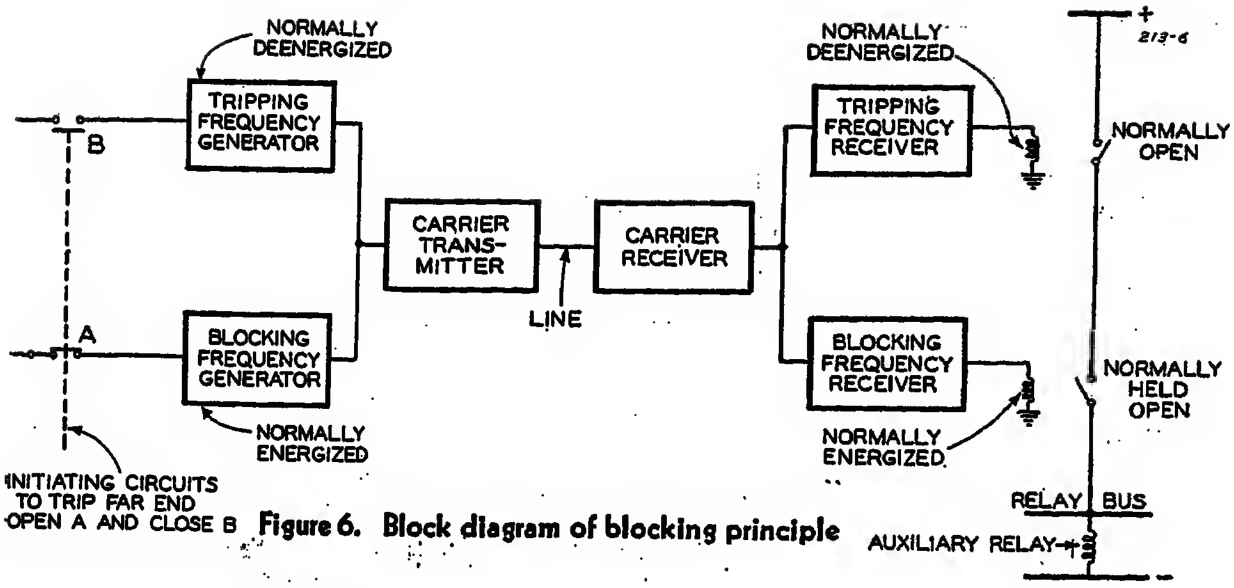

Figure 6. Block diagram of blocking principle

cur to cause a tripping action: First, the blocking frequency must be removed, and second, the tripping frequency must be started. As long as the blocking frequency is present, no tripping can occur even though the tripping-frequency relay might close from time to time, due to static, noise, and so on. Figure 6 shows this scheme in block diagram form.

The existence of the blocking frequency makes possible an interlocking supervising system. A block diagram of the circuit arrangement at the two terminals is shown in Figure 7. Frequencies $F1$ and $F2$ form one of the blocking loops. When the initiating switch 1 is in the normal position, it energizes the blocking oscillator $F1$. The blocking frequency $F1$ is transmitted and received; contacts 11 and 12 close and contact 13 opens. With the initiating switch 2 in the normal position, the closing of contact 11 causes the blocking oscillator to start, and the frequency $F2$ is in turn transmitted. At the other end of the line it is received. This causes contacts 21 and 22 to close and contact 23 to open. The closure of contact 21 lights a pilot lamp which shows that this blocking loop is complete and that the carrier equipment is normal, since any failure would result in the loss of the blocking frequency and the consequent extinction of pilot lamp.

A second blocking loop is provided by frequencies $F3$ and $F4$ in exactly the same way as the first blocking loop. This second loop causes contacts 31 and 32 to close and 33 to open at the remote terminal, and 41 and 42 to close and 43 to open at the supervising terminal. The condition of this blocking loop is shown by pilot lamp B.

These have been called blocking loops because they prevent tripping. This action occurs because contacts 13 and 33 are open at one end and, therefore, no feed is provided for the auxiliary relays; contacts 23 and 43 at the supervising end are open, also preventing tripping of this end.

The operation of either initiating switch 1 or 2, will trip the opposite end of the line. Operation of switch 1 removes the feed to the blocking oscillators ($F1$ and $F3$) and puts feed on the tripping oscillator ($F5$). At the far end of the line contacts 13 and 33 close due to the loss of the blocking frequencies, and contact 53 closes because the tripping-frequency receiver is energized. This provides feed to the auxiliary relay and trip circuits. Likewise operation of switch 2 will complete the circuit through contacts 23, 43, and 63, for tripping in the opposite direction.

Supervision of the carrier is obtained by other contacts on the relays. When a blocking loop is closed the push button receives feed through the corresponding contact 22 or 42. This push button tests the tripping frequency by means of a third loop. The test can only be made if one of the blocking loops is complete. Since there is no way of knowing whether the ($F5$) tripping-frequency oscillator or receiver, or the other ($F6$) tripping-frequency oscillator or receiver is in working condition, this test is necessary. Operation of the test push button closes contact 51 which in turn starts the tripping oscillator ($F6$) and closes the contact 61, indicated by the lighting of pilot lamp C. Pilot lamp C will light only when all the elements of the trip circuit are in operating condition. By connecting an alarm relay as shown in Figure 7, an alarm will be given whenever both blocking loops are lost. This occurs when something has become defective in the carrier circuit. To further aid in preventing trouble, due to the possible loss of carrier blocking coincident with the reception of undesired signals, the tripping-frequency receiver is set about one half as sensitive as the blocking-frequency receivers.

Initiating Circuits

In Figure 7 the initiating circuits are indicated as switches 1 and 2. In actual practice no switches are used for this purpose. The blocking frequencies are removed and the tripping frequency started directly from the closure of the primary relay contacts. Figure 8 shows schematically the essential features for transmission and reception, keeping the notation of Figure 7 as much as possible.

Two separate sets of contacts are provided on the primary relays, for two separate auxiliary relays. The carrier trip circuit must also feed from the same circuits as the auxiliary relays. Tubes $V1$ and $V2$ are provided as insulation between the two relay busses. Since only one carrier trip circuit is provided, the two relay busses must be paralleled, and yet back feeds from one bus to the other must be prevented. Tubes $V1$ and $V2$

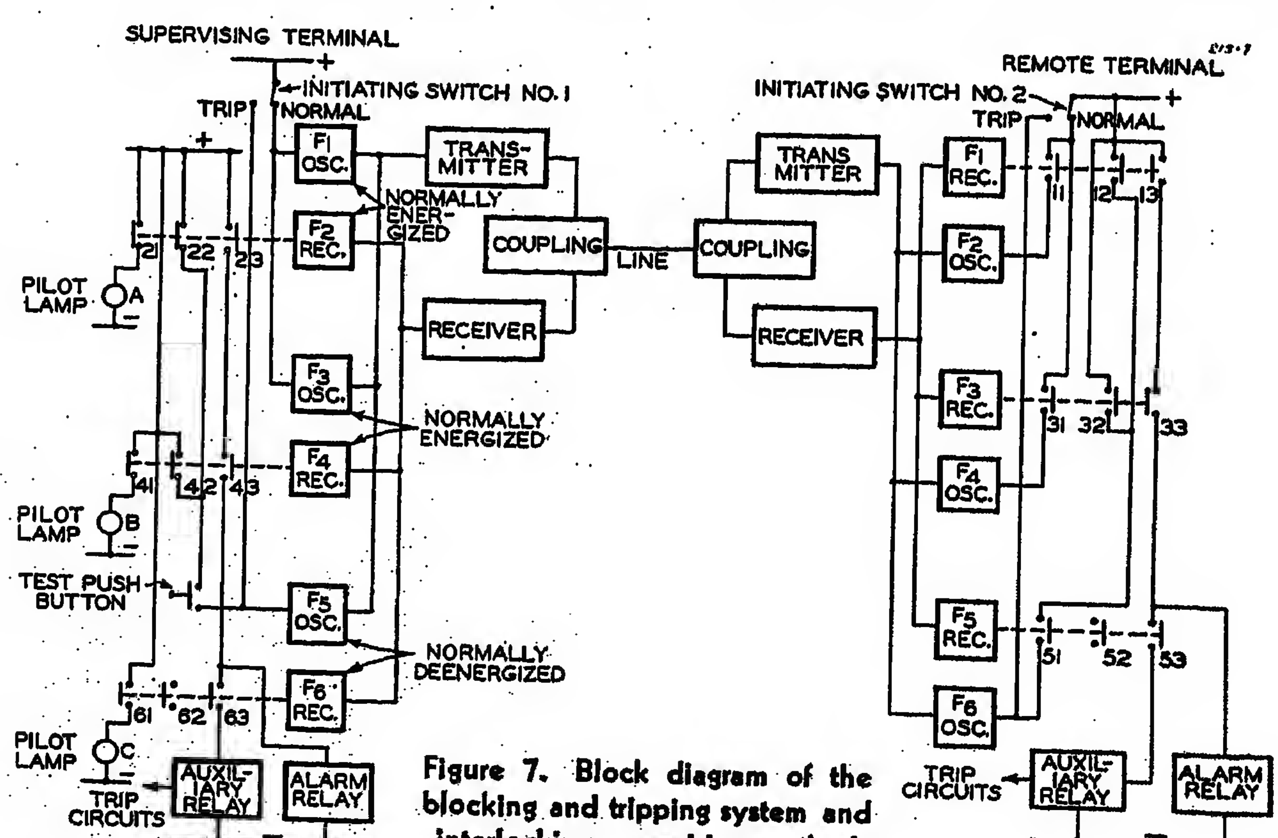

Figure 7. Block diagram of the blocking and tripping system and interlocking-supervision method

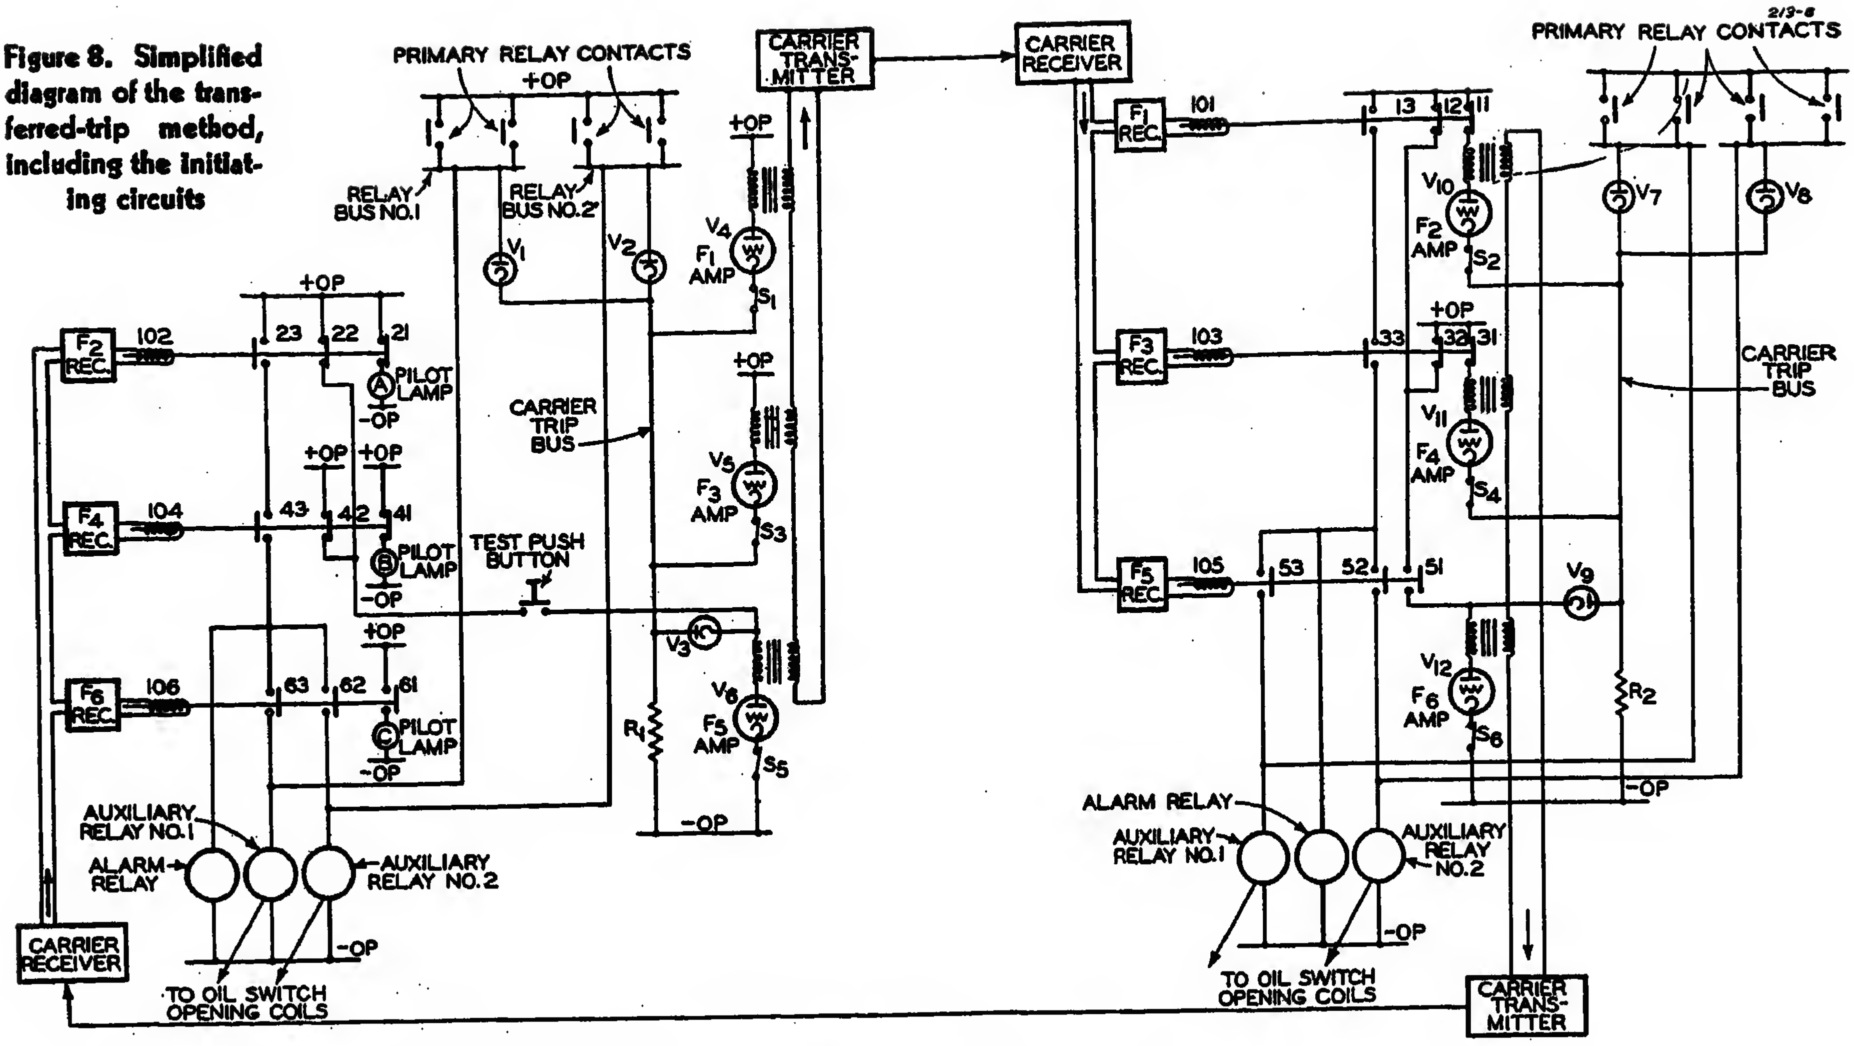

Figure 8. Simplified diagram of the transferred-trip method, including the initiating circuits

make this possible since they carry current in only one direction.

When the primary relay contacts are open, tubes *V*1 and *V*2 are nonconducting. Tubes *V*4 and *V*5 are amplifiers in the blocking loops. Under normal conditions they will have their starting switches closed and be in a condition to amplify. Their cathode current flows through resistor *R*1 and causes a voltage drop of about 15 volts on this resistor. This voltage is so small that the current through *V*3 and *V*6 is insufficient to amplify the tripping frequencies. The blocking frequencies (*F*1 and *F*3) are transmitted, and the tripping frequency (*F*5) is not.

At the remote end of the line closure of contacts 11 and 31 provides feed for the blocking amplifiers (*V*10 and *V*11), provided no primary relay contacts are closed. It will be noticed that a circuit exists here similar to that at the supervising end through the tubes *V*7 and *V*8 and resistor *R*2. Hence, the blocking frequencies (*F*2 and *F*4) are transmitted, and at the supervising end of the line, reception of these frequencies causes the pilot lamps *A* and *B* to be lighted and feed to be provided for the test push button. Likewise the tripping circuits are opened as previously discussed.

Upon closure of the primary relay contacts at either end of the line, either tubes *V*1, *V*2, *V*7, or *V*8 will become conducting, and practically full operating bus potential will be developed across either resistor *R*1 or *R*2. This action removes the voltage from the blocking amplifiers and causes either tube *V*3 or *V*9 to become conducting and provide feed for the tripping-frequency amplifier. This, of course, closes the trip circuit at the other end of the line as discussed previously. Tubes *V*3 and *V*9 are provided so that when the test push button is closed, the tripping amplifier can be energized without removing the voltage to the blocking amplifiers. Whenever the test push button is closed all six audio frequencies are present on the line. The alarm relays are also provided as described previously. The pilot lights and test push button are extended to the control room so that the condition of the carrier equipment can always be observed by the operators.

General Comments

This transferred tripping circuit was designed to provide as high a transfer speed as possible. Oscillograms were made on a test setup of the equipment, two of these being shown in Figure 9, one for each direction. It will be seen that the time required for tripping is less than 0.015 second. It will be borne in mind that this transfer circuit effectively parallels the trip busses at both ends of the line and that the time occupied in transferring the signal is the only delay in the simultaneous opening at both ends. The opening of one end of the line should always open the other end. The primary relays have preference over the push button circuit.

As the circuit has been explained, the tripping connection would seal itself in. To prevent this, back contacts were placed in the auxiliary relays at one end which would break the circuit as soon as these auxiliaries have operated.

Telemetering and Load Control

An impulse method of telemetering is used over the carrier-current circuit. The starting of the audio frequency used for telemetering indicates one impulse, and the stopping indicates a second impulse. In this way, the control of the audio oscillator is very simple. Load control signals of the time-duration type are also transmitted. These are based on the premise that the more the load is to be changed, the longer the pulse lasts. The starting and stopping of the audio frequencies, associated with the load control transmission, is rapid enough to cause inconsequential change in this timing.

Experiences With Equipment

As will be noted from Figure 2, the line-tuning system is quite complex, and it was considered too difficult to check the frequency response of the line using the actual equipment. A simple method was used for this measurement. Three resistors arranged in a star and grounded at the mid-point were connected at each end of the line. Drain coils were also connected across each resistor. A vari-

The oscillograms were made during tests on the equipment. Test I is one direction and test II the opposite direction

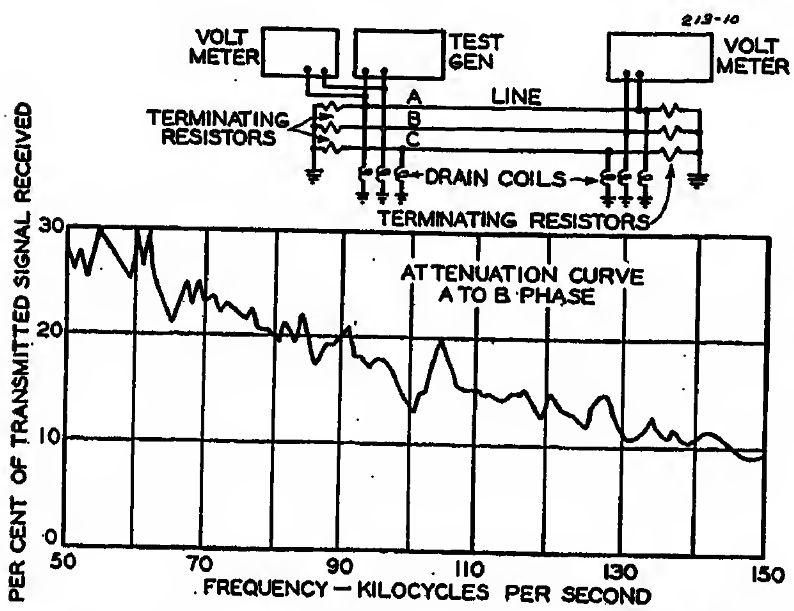

Figure 10 (above left). Circuit diagram of test method and curve of attenuation for the frequency range of 50 to 150 kilocycles

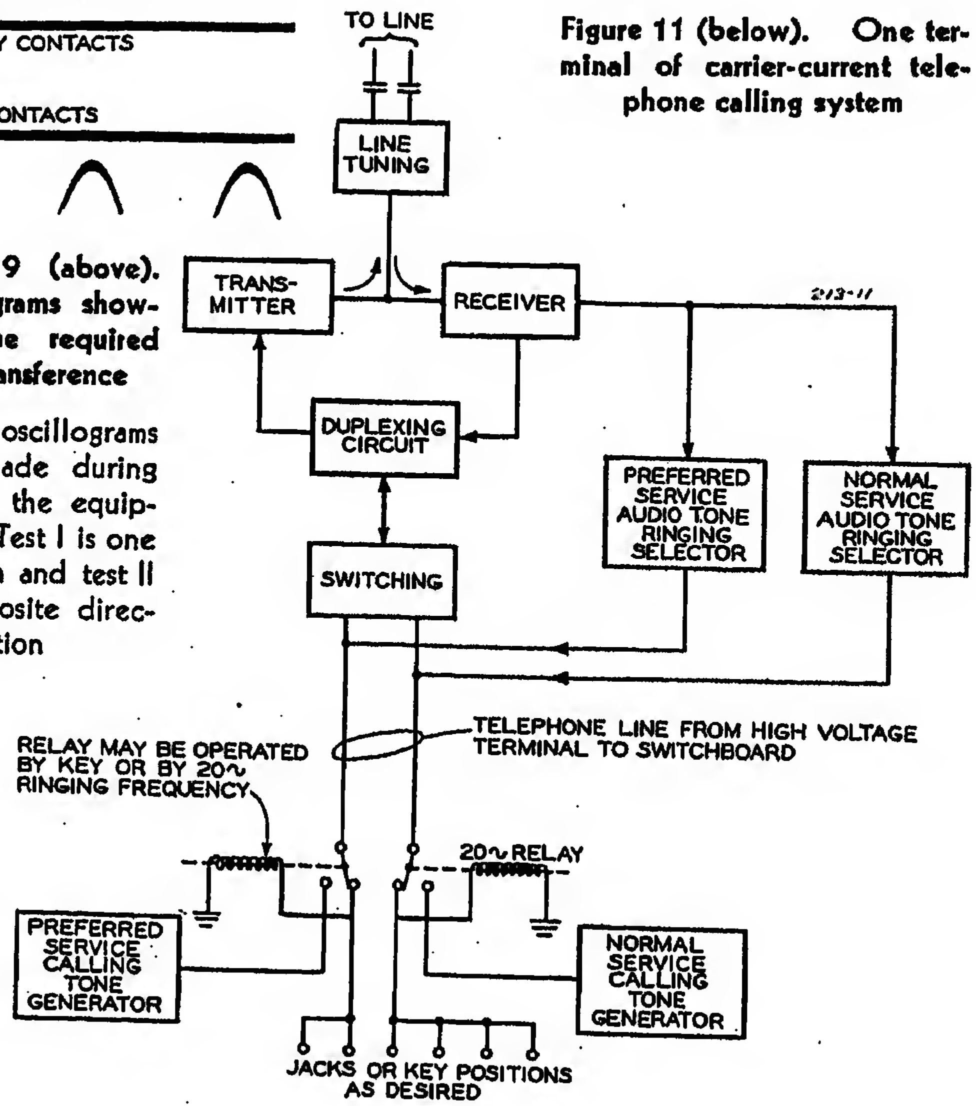

Figure 11 (below). One terminal of carrier-current telephone calling system

able frequency generator was connected to the phase wires, a pair at a time, and the transmission over the frequency band from 50 kilocycles to 150 kilocycles was obtained. Readings were made by vacuum-tube voltmeters at the sending end and the receiving end. Figure 10 shows the circuit used and the curve of response from A to B phases. For actual use, the received voltage should be doubled, since the terminating resistors are not present.

It was felt that noise would be the worse possible source of trouble so far as the transferred trip circuit was concerned, particularly noise from lightning. The blocking system was designed to prevent harm from this type of noise, but a defect was present at first. Whenever a noise pulse was received it overloaded the receiver and wiped off the modulation. It also gave a large pulse of negative voltage to the automatic volume-control circuit. When the noise pulse disappeared the automatic volume control was biased too far negative and the carrier signal was not received. As a result the blocking relays dropped out. In order to correct this the time constant of the automatic volume-control circuit was shortened to about $^1/_{60}$ of a second and with this arrangement the blocking relays are not affected when a noise is received. In actual practice these noise pulses are normally due to lightning discharges in immediate vicinity of either terminal. A noise pulse apparently does not affect the tripping-frequency relay.

So far in the operation of the equipment little trouble has been experienced in maintaining the audio signals. In the original setup of the frequencies it was necessary to separate the audio tones by at least 30 per cent and also to see that no frequencies were on the harmonics of lower frequencies. This rather limits the number of audio frequencies available in the band from 300 cycles to 3,000 cycles over which the equipment is designed to operate but there is sufficient space for the ten tones, the maximum number desired on this system. It has been found necessary to keep the percentage modulation of any individual frequency low to prevent interaction between any of the various audio channels. Even so, there is a slight interaction which thus far has not been serious. The signal levels in the modulator and amplifier at both transmitter and receiver must always be kept low to prevent the introduction of harmonics. It is not difficult however, to find working levels which are stable.

The Carrier-Current Telephone System

The problems which developed in the carrier telephone system were mainly due to long extensions and the type of preferred service desired by the system operator. At one end of the line, the problem was simple because the carrier set was near the telephone switchboard. At the other end, however, about eight miles of leased line were required to connect the telephone switchboard and the system operator's office to the carrier equipment.

This distance was too great for the dialing equipment provided in the carrier sets and an additional calling system was devised. Furthermore, the duplexing equipment had to operate from extensions varying greatly in length. It was found that the variation between extensions was more than 20 decibels.

A block diagram of the calling system which was finally adopted is shown in Figure 11. A single carrier frequency is used for the telephone work. The transmitter and receiver are controlled by voice-operated duplexing relays. The manufacturer supplied standard equipment for this purpose, but the control circuit was changed to operate from the automatic gain control to provide compensation for the great variation in voice level due to differences in extensions. Also built into the equipment are line selectors, dialing circuits, and ringing relays. Additional tone-operated relays were added to this equipment to operate in conjunction with it. These tone-operated relays use the same ringing circuits the dialing system would use but without going through the dialing system.

The telephone switchboard, to which the carrier is connected by the leased line, has fifteen positions with the possibility of using any one of 225-cord sets. The circuit was arranged in such a way that the placing of a plug in one of the terminal jacks of the telephone line would turn on the transmitter and prepare the carrier set for service. It was necessary to provide a circuit which would send out a calling tone when the ring key of the cord set associated with plug was operated. This was done by inserting a 20-cycle relay in the jack circuit to operate from the normal switchboard ringing signal controlled by the ring key; the relay connects a calling tone to the telephone line and from there to the carrier transmitter. Upon reaching the normally energized receiver at the distant end, the calling tone operates a relay tuned to its frequency and it, in turn, indicates a call by lighting a call lamp on the telephone switchboard. As soon as the ring key is in its normal talking position, the calling tone stops, and when the called line answers, the equipment is ready for service.

The calling-tone system makes it possible to provide instantaneous preferred service for the system operator. A line-holding relay at the near end of the line is arranged to seize the equipment whenever the operator desires. Operation of the calling-tone key will then send out the preferred-service calling tone. At the far end of the line, reception of the preferred-service calling tone will break the normal telephone circuit and ring the system operator's phone. In this way the system operator can always gain control of the carrier telephone, even though it may be in use for ordinary telephone purposes. Busy lamps are provided to indicate when the line is in use to prevent unnecessary interruptions.

Relays and Breakers for High-Speed Single-Pole Tripping and Reclosing

S. L. GOLDSBOROUGH
ASSOCIATE AIEE

A. W. HILL
MEMBER, AIEE

THE advantages of fast reclosing of transmission-line circuit breakers have been realized for a number of years. This experience has been gained on the basis of three-pole reclosures. One step beyond three-pole tripping and reclosure is single-pole operation. It is arranged so that on single phase-to-ground faults only the faulty phase wire is disconnected at each end of the line and then immediately reclosed. This allows synchronizing current to flow over the two sound-phase conductors during the time the faulted phase wire is out of service. With single-pole tripping slower speed reclosing, as compared to three-pole operation, can be utilized with a definite gain in the stability limit.[1]

The Phase-Selector Relays

Single-pole tripping from a relay standpoint has brought up a number of problems. At first thought it would appear to be only necessary to separate the trip circuits of the conventional relay equipments into three separate paths to the single-pole trip coils. This is true to a certain extent, depending upon the type of relay protection being considered. For instance, in the case of the simple overcurrent relay where phase relays will also operate for ground faults, it would be only necessary to arrange each phase relay to trip its respective single-pole breaker. However, it is the general practice at present to employ a separate ground relay operating on residual current and voltage or line residual current and power-bank neutral current in order to obtain adequate sensitivity to ground faults. The chief problem, therefore, involved in single-pole tripping is to find an effective way of indicating to the conventional residual-type ground relay which phase conductor is supplying the ground current. One way of providing this indication would be to employ under voltage relays energized from line-to-ground voltage. A fault to ground on one-phase conductor would drop out the corresponding voltage relay whose back contact in series with the conventional directional ground relay would trip its associated single-pole breaker. Another possibility would be the use of voltage-restrained overcurrent relays operating on line current and line-to-ground voltage. In general, neither of the above schemes is considered satisfactory on the basis that adequate sensitivity is not provided. It is quite possible that a high-resistance ground fault will not reduce the voltage sufficiently to provide a safe margin of discrimination.

The ideal approach to the problem would be to find a method of phase selection which can be made just as sensitive as the conventional directional ground relay and one which is, furthermore, totally independent of all normal conditions and dependent solely on fault conditions.

The method described below utilizing the phase shift of one sequence component with respect to another sequence component meets the above requirements.

Figure 1 shows the phase shift among the three sequence components for single phase-to-ground faults on different phases. It will be noticed that the zero-sequence component rotates around a given phase of the negative-sequence system in 120 degree steps. For instance, on a phase-A-to-ground fault the zero-sequence current is equal to and in phase with phase A of the negative sequence. This is, of course, on the basis of the total fault current. For a fault on phase B the zero-sequence component is in phase with the B-phase negative sequence, and, similarly, for a C-phase-to-ground fault the zero sequence is in phase with the C phase component of the negative sequence. Therefore, a selector element utilizing zero- and negative-sequence current will act in one direction for phase-A-to-ground fault but will act in the opposite direction for ground faults on B and C phases. Thus, if a directional element with watt-element characteristics is supplied with the zero-sequence current in one coil and the phase-A component of the negative-sequence current in the other coil, then, on a phase-A-to-ground fault this element will have maximum torque in the contact-closing direction. For a fault on phase B the zero-sequence current leads phase A of the negative sequence 120 degrees, and for a fault on phase C the zero-sequence current lags phase A of the negative sequence by 120 degrees. The element will, therefore, have torque in the contact-opening direction for phase-B and phase-C ground faults. If another similar relay element is used with its corresponding coil energized by the zero-sequence current, but its other coil energized by the phase-B component of the negative sequence instead of the phase-A, then, for faults on B phase it will be operating at maximum torque and will close its contacts but will have reversed torque for ground faults on phases A and C. Likewise, a third element energized by zero-sequence current and the phase-C component of the negative-sequence current will close its contacts for phase-C-to-ground faults, but open its contacts for faults on the other two phases. The schematic connections for this relay are shown in Figure 2.

The phase-selector relay consists of three elements similar to the conventional directional element. The polarizing coils of all three elements are energized by the zero-sequence current. The other coil on each element is energized by a component of the negative-sequence current obtained from the three-phase negative-sequence filter. This filter is so connected that the phase-A component of the negative-sequence system is supplied to the phase-A element, the B component supplied to the B element and the C component supplied

to the *C* element. The connections (Figure 2) show the inclusion of phase relays which may be of the conventional type and also a conventional directional residual-type ground relay. This relay is necessary to provide directional ground protection as the selector relay, while employing elements similar to the directional element, does not indicate the direction of power flow but merely the particular phase wire which is grounded. The trip connections are shown at the bottom of the diagram where D_0 and I_0 are the directional ground-relay contacts and S_A, S_B, and S_C are the make contacts on the phase-selector elements.

The negative-sequence filter connections are shown in Figure 3. This device consists of three filters similar to a filter which has been described previously and which has been in use for a number of years.[2,3] Three of these standard filter units are connected to form a three-phase unit so that it is entirely unresponsive to zero-sequence currents or positive-sequence currents, and the output consists of all three phases of the negative-sequence system.

Other pairs of sequences besides the negative- and zero-sequence currents may be used to produce a phase-selector action. For instance, zero-sequence current and positive-sequence voltage is a feasible combination, also, zero-sequence voltage and positive-sequence voltage. However, it is considered that the zero- and negative-sequence current combination described above is more desirable, since all voltage connections are avoided and the selector elements operate on quantities which appear only during fault conditions, and, for this reason, its sensitivity can be very easily made to match the sensitivity of the conventional directional residual-type ground relay.

An essential feature of any phase-selection scheme is that after a faulted phase has been selected for tripping, the phase-selector scheme should not operate, under the conditions obtaining while one phase wire is disconnected, to disconnect the unfaulted phases. It can be shown that the above selector scheme gives the same tripping indication after the faulted phase has been tripped out. With one phase wire disconnected, there will be load current

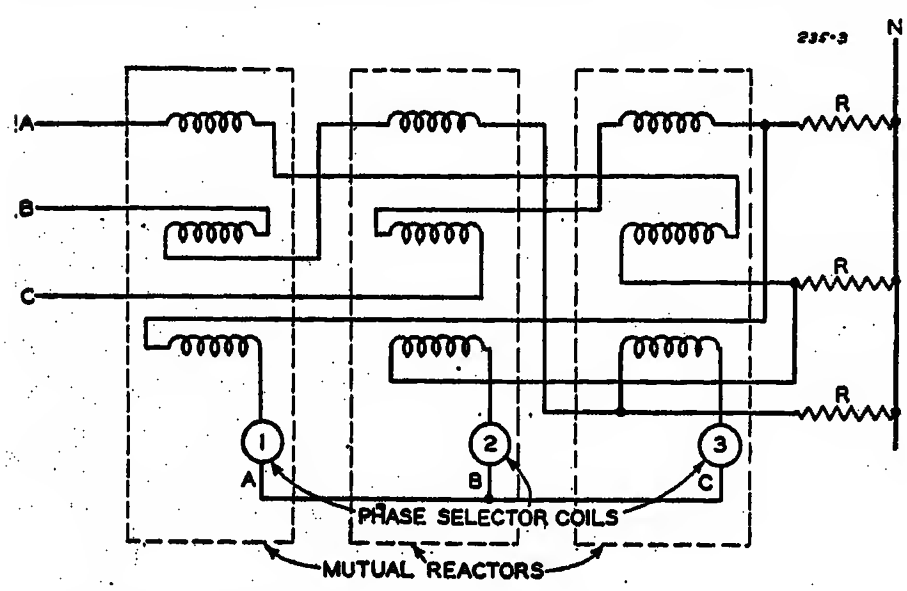

Figure 3. Schematic diagram of connections of three-phase negative-sequence filter

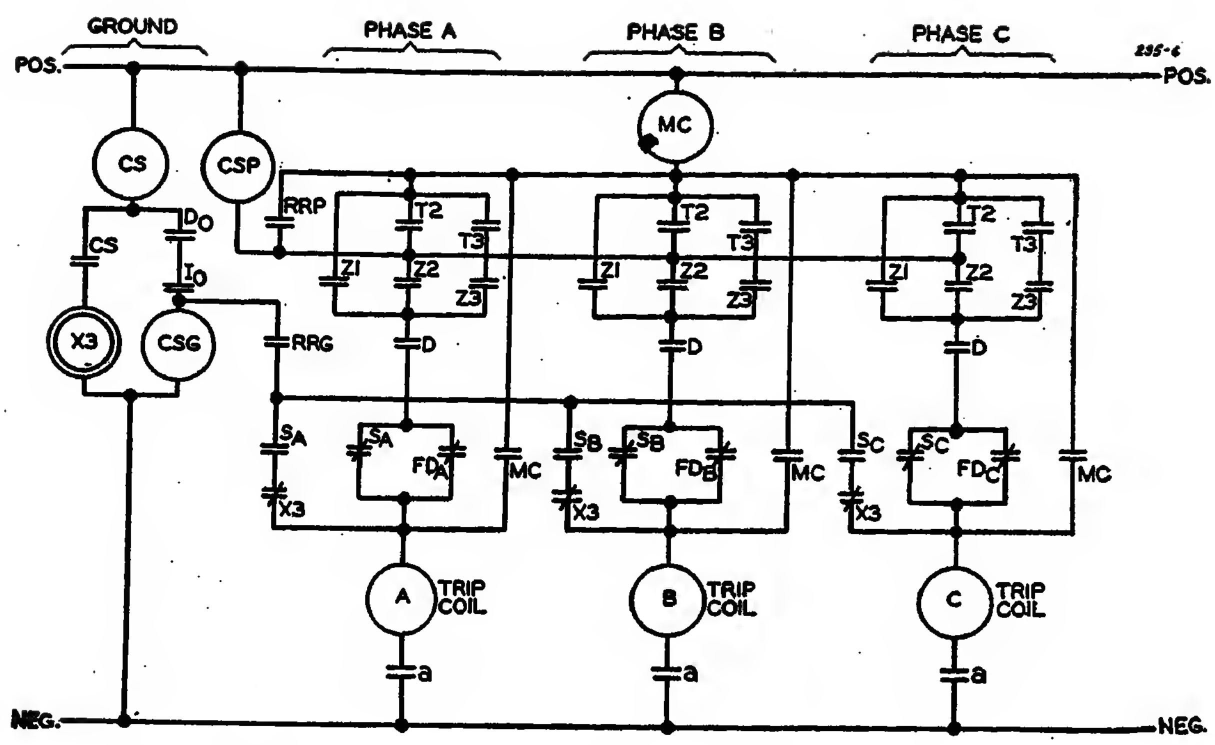

Figure 6. Complete schematic diagram of trip circuits for carrier-current single-pole relaying

on the other two phases, in general, equal and 120 degrees out of phase upon the assumption that each end of the protected line is fed from a grounded source.

Figure 4A shows this condition for the case where phase A has been tripped. It is seen that the zero-sequence and the negative-sequence currents are in phase on phase-A selector element. The phase selector, therefore, gives the same indication during the time a phase wire is out of service, thus preventing inadvertent tripping of the unfaulted phases. Figure 4B shows the vectors for a two-phase-to-ground fault on phases B and C and, it will be noted that this is a very similar condition to that obtaining when one phase wire is disconnected, in that the zero- and the negative-sequence currents are essentially in phase. On two phase-to-ground faults, therefore, the phase-selector relay selects the unfaulted phase.

The grounded phase-selector scheme can be applied in any system of phase and ground relays, but a description is given here of its use in a carrier-current step-type distance-relay scheme, as installed on the Public Service Company of Indiana system. In this application the following features were incorporated:

1. All single-phase-to-ground faults to be tripped single pole and reclosed immediately.
2. If fault still exists, then all three poles to be tripped.
3. On phase-to-phase faults, two phase-to-ground and three-phase faults all poles to be tripped and not reclosed.

It is interesting to examine how the simple phase-selector relay as described above is incorporated in a complete distance-type carrier-current system.

The schematic connections in Figure 5 have been simplified in order to show this incorporation as clearly as possible. The ground-relay trip circuit is made through the directional contact, D_o, overcurrent contact, I_o, the carrier-receiver relay contact, *RRG*, and one of the phase-selector contacts, S_A, S_B, or S_C. The phase-relay trip circuit is composed of the *RRP* carrier-receiver contact, the Z or distance-element contact and the directional-element contact, D. The purpose of the S_A, S_B, and S_C, back contacts in series with the respective phase-relay contacts is to prevent three-pole tripping in case a phase relay responds to a close-in phase-to-ground fault. Distance relays for phase protection will, in general, have a tendency to operate on heavy close-in ground faults and since it is arranged that all three poles are tripped when a phase relay operates, the single-pole tripping feature would not be obtained in the case where a phase relay operates on a ground fault. It is necessary to arrange the scheme so that even though the phase relay operates on a ground fault simultaneously with the ground relay and the ground-phase selector, the phase-relay trip circuit cannot be established. This is done by the inclusion of the back contacts, S_A, S_B, and S_C, which are located on their respective phase-selector elements. In other words, for a phase-A-to-ground fault, D_o, I_o, *RRG*, and S_A contacts close to trip the trip coil A, and at the same time the S_A back contact opens and prevents the phase-relay contacts, Z and D, from picking up the *MC* relay which would attempt to trip all three poles. In some applications these phase-selector relay back contacts would not be necessary, since the response of the distance-type phase relay to close-in ground faults depends upon the actual ohm setting of the phase relay and the magnitude of the ground current.

It is seen, therefore, that the additional contacts fundamentally necessary for single-pole tripping consist of the three-phase-selector make contacts which permit the splitting of the conventional ground-relay circuit into three parts. Depending upon the type of phase relay with which single-pole tripping is used, it may be necessary to employ three auxiliary blocking contacts to prevent interference by the phase relays.

The complete schematic connections are shown in Figure 6. The additional contacts which have been added over and above those shown in Figure 5 are the Z_1, Z_3, T_2, and T_3 contacts which will be recognized as being connected in the conventional manner for one of the present standard distance-type carrier systems.[4] No attempt is made here to describe the function of these contacts, as this has been done previously. The significant additional contacts are FD_a, FD_b, and FD_c. These are purely precautionary contacts which have been added in parallel with the back-contact phase-selector contacts, S_A, S_B, and S_C, respectively, for the purpose of preventing incorrect action caused by errors in the current transformers. It will be noted that on phase-to-phase faults not involving ground there is no zero-sequence current present. Therefore, no torque appears in the phase-selector elements, and thus the back contacts, S_A, S_B, and S_C, should remain closed. However, due to errors in the current transformers a small current might appear in the zero-sequence coils of the phase-selector relay. The back contact may, therefore, be inadvertently opened, and this would, of course, prevent tripping by the proper phase relay. The *FD* contacts are back contacts on an auxiliary fault-detector relay energized by the zero-sequence current and set for a current sufficiently above any anticipated error current in the current transformer. If, therefore, any of the back contacts, S_A, S_B, and S_C, are momentarily opened by the current-transformer error current, the circuit

* Interrupting times given in parentheses are for second opening where breaker did not stay in after reclosure.

is still maintained through the fault-detector contact. On any fault involving ground, the fault-detector contacts open and leave the blocking function entirely up to the phase-selector back contacts.

In the Indianapolis installation a condition obtains which requires the addition of a blocking contact, $X3$. In this case the ground relay at both ends of the line was polarized by power-transformer bank neutral current and while one phase wire is disconnected, a zero-sequence current circulates in such a manner as to give the directional element, D_o, at each end of the line a fault indication. In other words, while one phase wire is open, the directional elements at both ends close, thus preventing a carrier signal from being transmitted, and this, of course, results in a tripping indication during the time one phase wire is disconnected. In order to prevent the immediate retripping of the breaker upon reclosure, the $X3$ contact was inserted. The $X3$ relay is energized at the same time that the trip current is established in the ground relay through the operation of the CS auxiliary relay whose contact energizes the $X3$ relay coil. The $X3$ relay picks up and opens its back contact with a time delay of about two cycles and resets with a time delay such that its back contacts become closed again a few cycles after the breaker pole has been reclosed. The choice of this $X3$ blocking contact was demanded by the fact that the ground-relay directional element was current-polarized and by the particular load and grounding conditions on this system. In the general case and also where voltage polarization is used, this contact would not be required.

The Reclosing Relays

The problems concerning the reclosing relays introduced by single-pole operation are simple of solution. The reclosing relays used on the Indiana installation were of the conventional type, and nothing of a particularly novel nature was required. Therefore, for the sake of simplicity, these reclosing relays have been grouped in the box of Figure 7. Each breaker-closing coil is energized through the make contact of auxiliary switches, CS_a, CS_b, and CS_c, which are operated whenever tripping occurs through the phase-selector contacts, S_a, S_b, and S_c. If phase-A conductor is faulted, the CS_a contact will close and energize the phase-A-breaker closing coil. The MC back contacts are on the MC relay (Figure 5), which is operated whenever a phase relay initiates tripping. Thus, on any phase fault the opening of the MC contacts prevents the energization of any of closing coils. To accomplish the feature of three-pole tripping after reclosure of a single pole on a solid fault merely requires the addition of auxiliary relays to the conventional reclosing relays and is not shown, since nothing novel is involved.

The Breakers

The fault having been detected and identified as one requiring a single-pole breaker operation, the next step in maintaining system stability is handled by breakers differing only slightly from the conventional type.

At the New Castle station of the Indiana Public Service Company a new breaker has been installed, each pole independently operated for either closing or tripping and so arranged that upon demand it will reclose within 30 cycles (0.50 second) after the trip coil has been energized. The operating mechanism is a solenoid, a unique feature of which is its "magnetic brain."

For fast reclosure it is desirable that the solenoid be nonmechanically trip-free; that is, that energy applied to the closing coil will arrest the opening movement of the breaker and return it to the closed position without the delay necessary with a trip-free linkage. The latter, of course, requires that the mechanical tie between two levers is broken by the action of the tripping latch and must be restored, as by retrieving springs, before the closing core can again be used to close the breaker. This means that the breaker opens practically its entire stroke, and the over-all time consumed becomes excessive. At the same time, there are circumstances under which trip-free operation is desirable, as when the breaker is to be tripped while still under the influence of pull of the closing magnet. It is here that this magnetic interlock performs, and with only one trip magnet, makes a choice between two latches, one of which opens the breaker "nontrip-free" for fast reclosure from the closed position, while the other provides "trip-free" operation in case the closing coil is still energized.

The operation of this magnetic interlock centers about a floating bar above the trip magnet, either end of which can be blocked to form a fulcrum point and cause the opposite end to rise when the trip coil is energized, thus providing for proper selection between the two latches. The choice of a proper point for blocking this bar is determined by an armature piece located within the field of flux of the closing magnet, but biased by springs to such a position that it releases the "nontrip-free" latch normally. Only when there is some magnetism in the closing coil, is it pulled to the opposite position to permit tripping on the "trip-free" latch.

The electrical connections for this operating mechanism remain as simple as for any of the solenoids in use for many years, as there is only one trip coil. The usual number of auxiliary switches is provided, or this can be amplified as desired if added circuits for other relays are needed.

The entire operating mechanism with control relays is mounted in a weatherproof sheet steel housing and attached to the tank wall, one such assembly for each pole of the three-pole breaker. Within this housing are also mounted the terminal blocks for bushing-type current-transformer secondaries. It is possible to make connections to any of the several transformer taps as required, at this one convenient location, and all conduit to the breaker is brought into the one house, whether intended for transformer secondaries or for control.

The scheme of single-pole operation has been worked out for revamping old three-pole breakers as well as for new apparatus. The experience at the Lenore end of this line demonstrates that the operation can

High-Speed Single-Pole Reclosing

J. J. TRAINOR
NONMEMBER AIEE

J. E. HOBSON
MEMBER AIEE

H. N. MULLER, JR.
ASSOCIATE AIEE

THE first application of high-speed single-pole reclosing to a high-voltage transmission line was recently made, tested, and put in service, on a 50-mile section of 138-kv single-circuit line on the system of the Public Service Company of Indiana, Inc. This paper discusses the reasons for choosing single-pole reclosing, and the installation and field testing of the equipment made under operating conditions. A companion paper by S. L. Goldsborough and A. W. Hill[1] describes the relaying and circuit-breaker equipment in detail.

When a single-circuit transmission line is used to interconnect two major systems and the line is used to transmit firm power between systems, considerable dependence must be put on the performance of this line. Under such circumstances unusual precautions are justified:

1. To prevent faults occurring on the line.
2. To minimize the disturbances created by faults.

The first objective is approached by using good line construction, by designing the line to be as nearly lightning proof as is economically possible, sometimes by the use of protector tubes, or possibly by the use of ground-fault neutralizers to prevent line-to-ground arcs from developing into faults.

It is not economical to design lines so that faults will never occur, although this ideal may be approached. Granted that a certain number of faults will occur, it is important to minimize their effect on the interconnected system. The objective when a fault develops is to remove the fault and re-establish the circuit without losing synchronism between the systems, so that there is no interruption in service over the interconnecting line.

Since the concepts of power-system stability were first recognized and the various factors influencing stability studied, means have been sought to improve the performance of power systems during transient disturbances.[2] A multiplicity of measures are now recognized, most of them directed toward minimizing the severity of the fault. During earlier years attention was particularly focused on improvements in stability limits obtained by design characteristics of machines and transformers, bussing arrangements, location of intermediate switching points, and the design of the transmission line itself. In the last decade high speeds for relay and circuit-breaker operation have become practical and extensively applied. High-speed apparatus, minimizing the duration of transmission-line disturbances, has been a major factor in improving system performance

The use of reclosing circuit breakers provides a means for furthering the advantages made possible by high-speed breakers and relays used for rapid fault isolation. The fundamental idea of reclosing circuit breakers was conceived by F. E. Picketts and filed with the United States Patent Office in 1916. Reclosing is particularly advantageous in the case of single-circuit transmission lines, for, while high-speed apparatus serves to remove the fault in the quickest possible time, loss of synchronism between the sending and receiving systems will quickly result if the line remains open. If loss of synchronism is not to occur, not only must the fault be cleared promptly, but the line must be restored to service after the fault is removed before the two systems have drifted far enough apart to cause instability.[3,4] High-speed reclosing has been used successfully, recently with simultaneous tripping and reclosing of the three-breaker poles.[5–8] This type of operation is known as gang-operated or three-pole reclosing. For a given time of reclosure the maximum power which may be transmitted without loss of synchronism depends on the relative inertias of the two systems (which determines the speed at which the systems drift apart when a particular fault is on, or when the line is open) and the initial operating angle between the systems. The latter is primarily a function of system reactance and transmitted power.

The time that the line can remain open without loss of stability is in most

Paper 42-24, recommended by the AIEE committees on power transmission and distribution and protective devices, for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 13, 1941; made available for printing December 9, 1941.

J. J. Trainor is chief engineer with the Public Service Company of Indiana, Inc., Indianapolis, Ind. J. E. Hobson is director of the department of electrical engineering of Illinois Institute of Technology, Chicago, Ill. H. N. Muller, Jr., is a central station engineer in the industry engineering department of Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

The authors acknowledge the fundamental work done by E. L. Harder on transient power limits obtained by the use of single-pole reclosing, the work done by S. B. Griscom on arc deionization time, and the work of H. M. Smith, Jr., in performing the calculations necessary to the preparation of the paper.

be practically as fast even with fifteen year old breakers. In this case the contact structure of the old breaker was modernized with "De-ion Grids" to get the benefit of modern high-speed interrupters and, particularly, to have a device well able to withstand instantaneous reclosure.

The results of the recent tests on the Indiana Public Service system show the benefits of single-pole reclosure. Breaker reclosing times of from 22.5 to 30 cycles were secured.

Conclusions

1. The fundamental relay problem introduced by single-pole tripping and reclosing concerns an adequate sensitive means of selecting the faulty phase. This problem has been solved by utilizing the phase-angle shift between two sets of phase-sequence quantities.

2. An actual installation of a phase-selector relay co-ordinated with a distance-type carrier scheme has been made and tested with very satisfactory results.

3. It was observed that the breakers showed no outward display during any of the tests, indicating the suitability of the combination of modern "De-ion Grid" interrupters and fast-reclosing solenoid mechanisms for this duty. Adequate contact travel was secured before the breaker was reclosed, thus providing ample time for the fault arc to become de-energized, without crowding these operations to the limit as would be required for maintaining stability when opening all three poles.

cases very short, thus high speeds of circuit-breaker reclosing are dictated. The reclosing time is measured from the time the breaker trip coil is energized until the breaker has opened, and the contacts are again closed. Commercial breakers are available today with reclosing times of 35 and 20 cycles at 138 kv on a 60-cycle per-second basis, and several installations employing breakers using such reclosing speeds are in service. The limit to which the reclosing time may be shortened depends upon breaker opening time and the speed attainable with reclosing mechanisms. One other factor, the actual deionizing time of the arc is of primary importance, since nothing will be gained if the circuit breaker is reclosed before the arc path has deionized, for the fault would then restrike after reclosure. Table I gives approximate data (obtained from tests on typical systems) of the minimum reclosing time permissible without re-establishment of the arc. These deionizing times are of course variable, depending upon line design, wind conditions, and so on, and the figures of Table I are to be taken as typical of expected results under average conditions.

The foregoing discussion has assumed simultaneous tripping and reclosing of all three circuit-breaker poles which will be referred to in this paper as gang-operated or three-pole reclosing. In all discussions of high-speed reclosing pertaining to line sections having sources of power at both ends, simultaneous operation of the circuit breakers at both ends of the transmission line is assumed, since, otherwise, the de-energized time of the line would be shortened, and the possibility of restriking would be increased. Simultaneous tripping is accomplished by pilot-wire or carrier-current relaying or, when possible, by setting high-speed impedance-type relays to cover the entire line section.

Utilizing high-speed relays and gang-operated breakers and the high speeds of reclosure mentioned above, cases will arise in which the desired power cannot be transmitted without loss of stability during fault conditions. A step toward raising the transient power limits, beyond three-pole reclosing, may be achieved by single-pole reclosing of circuit breakers. Single-pole reclosing consists of opening only the breaker pole connected with the faulty phase and reclosing this pole after the fault has cleared. Single-pole reclosing has application only to grounded-neutral systems. An increase in the transient stability limit is realized as compared with gang operation, since a considerable amount of power may be transmitted over the sound phases while the faulty phase is isolated. For a given amount of power transmitted over a particular transmission line, the permissible de-energized time to maintain synchronism is appreciably longer, if single-pole reclosing is used as compared with three-pole operation. Hence, in very high-voltage systems where speeds too fast for adequate arc clearing might be required with gang operation, slower speeds, providing ample time for arc clearing may maintain stability conditions if single-pole reclosing is used.

The actual gain in transient-stability limit realized with single-pole operation can be visualized by reference to Figure 1. This figure shows power-angle diagrams for a typical system, illustrating the relative transient-stability limits obtained with 35- and 20-cycle, three-pole and single-pole reclosing. The curves were drawn for a hypothetical single-machine station feeding a high-voltage line terminating in a very large system, assumed to have infinite inertia. The curves serve to illustrate qualitatively the expected increase in transient limits and the relatively large amounts of power which can be transmitted over the unfaulted phases while one phase is open.

Table I. Typical Arc Deionizing Times

Application

The principal transmission lines of the Public Service Company of Indiana, Inc., including the major interconnections with neighboring companies, are shown on the map of Figure 2. The principal generating stations of the Public Service Company of Indiana, Inc., are at Dresser and at Edwardsport. Considerable generating capacity is available at Indianapolis, through the interconnection with the Indianapolis Power and Light Company, and from the south through interconnection with the Cincinnati Gas and Electric Company. Interconnection is made at Muncie and Kokomo with the Indiana section of the American Gas and Electric system.

Figure 3 shows in greater detail the Lenore–Newcastle–Muncie interconnection installed during the past year which is the principal subject of this discussion. Approximate generating capacity at the major points of application to the interconnected system is indicated on Figure 3. The Indiana section of the American Gas and Electric system is extensive and includes a multiplicity of sources of generation, so that the generation at Muncie has not been assigned a definite capacity.

The Lenore–Newcastle line, a part of the new interconnection, was also built to supply firm power to the load at Newcastle, the required capacity of the line to be at least 50,000 kva. The Newcastle–

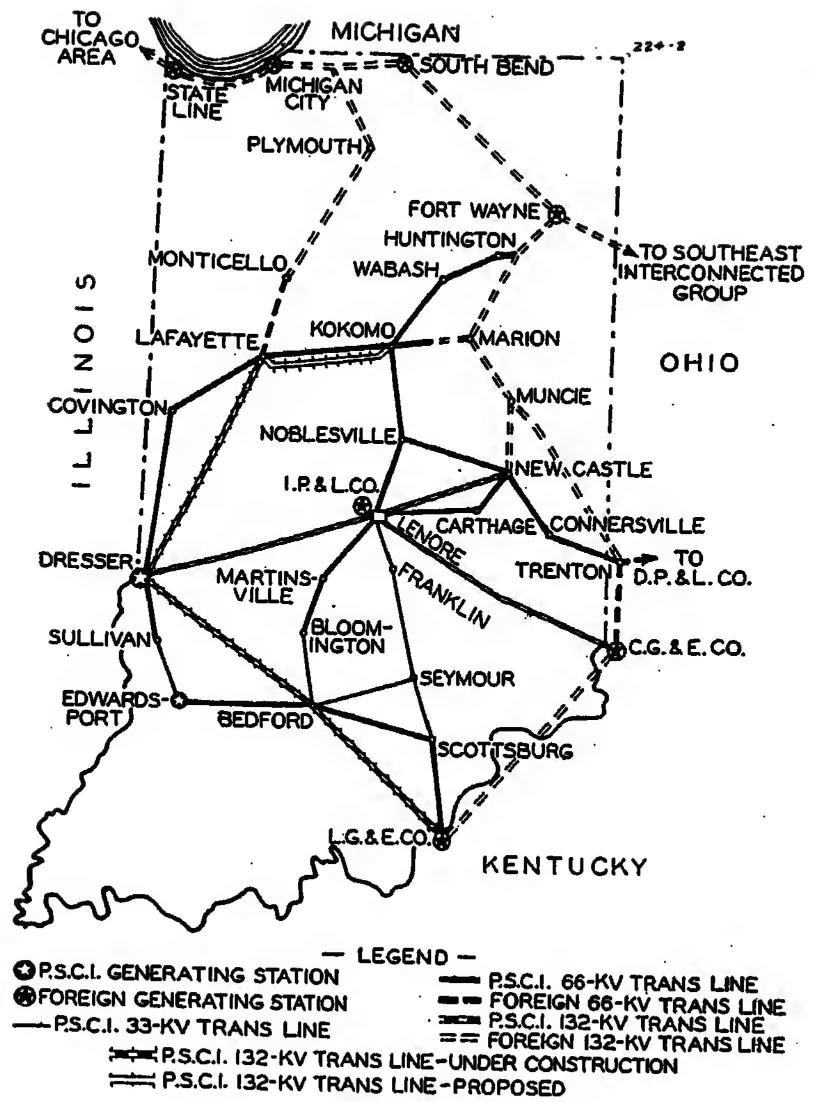

Figure 2. Major high-voltage interconnected lines of the Public Service Company of Indiana, Inc. and neighboring systems

Muncie line was proposed to provide an interconnection, ordinarily floating, between the Public Service Company of Indiana, Inc., and the American Gas and Electric system. Under emergency conditions interchange of power in either direction is permitted. The Lenore–Newcastle line and the Newcastle–Muncie line are now single-circuit lines. The Lenore–Newcastle line is ultimately planned to be double circuit, as indicated by the tower structure shown in the photograph of Figure 4. The line is designed to have nine insulator units used in suspension and eleven insulator units used in strain. The single ground wire now installed on this structure is three-strand, $^3/_8$-inch galvanized steel conductor. The line conductors are 300,000 circular-mil copper. The line route is east and west over relatively flat terrain, and the tower-footing resistances test well under five ohms.

Other circuits parallel the new line from Indianapolis to Muncie, as shown in Figure 2. The existing ties are, however, relatively weak and of high impedance. If an interruption should occur on the Lenore–Newcastle line while an appreciable block of load were being transmitted over the line to Newcastle, the paralleling ties through Noblesville, Kokomo, and Marion would not be able to pick up the load, because of their high impedance, and instability would occur. Consequently, it is of prime importance to keep the Lenore–Newcastle line in continuous operation. Although the line is designed to be relatively lightning-proof, some interruptions of the Newcastle supply would inevitably result unless means were taken to re-establish the line immediately following an interruption, and before instability could occur. Consequently, high-speed reclosing was considered necessary to keep interruptions to the Newcastle load at an absolute minimum.

The 138-kv line from Newcastle to Muncie is provided with 20-cycle reclosing circuit breakers, 1,500,000-kva interrupting capacity, at each end of the line section. Conventional carrier-current relaying is used for both ground and phase relaying. The circuit breakers are conventional eight-cycle breakers and are equipped with gang-operated mechanisms.

Both gang-operated (three-pole) reclosing and single-pole reclosing were considered for the line from Lenore to Newcastle. Speeds of reclosing of 35 cycles and 20 cycles were considered. Table II gives the results of calculations made to determine the transient power limits for both speeds of reclosure considered and for both gang-operated and single-pole reclosing. Simultaneous tripping (and reclosing) of two circuit-breaker poles was assumed in the calculations for faults involving two-line conductors. With the type of construction used, a very high percentage of the faults will originate and persist as single line-to-ground. Primary consideration was consequently given to the transient power limits achieved during single line-to-ground fault conditions. Breakers and mechanisms for 35-cycle single-pole reclosing can be obtained at approximately the same price as breakers and mechanisms for 20-cycle gang-operated reclosing. The figures of Table II show considerably higher transient power limits during single line-to-ground faults for 35-cycle single-pole reclosing than the limits achieved using 20-cycle gang-operated reclosing. The power limits for 20-cycle single-pole reclosing are yet higher, but it was felt that the gain in power limits on this application did not justify the considerable increase in cost for higher-speed breakers and mechanisms. On the basis of this comparison, 35-cycle single-pole reclosing was adopted for the line section.

Existing 138-kv breakers at the Lenore end of the line were provided with 35-cycle single-pole reclosing mechanisms. A new breaker was installed at the Newcastle end of the line—a 138-kv, 8-cycle 1.5-million-kva unit, equipped with a 35-cycle reclosing mechanism on each pole. Carrier-current relaying is used to permit simultaneous operation of the breakers at the two ends of the line. The phase relaying is of conventional type, and it was necessary to develop a new ground-relaying scheme to select the faulted phase. The scheme for selecting the faulted phase is described in a companion paper by S. L. Goldsborough and A. W. Hill.[1] The equipment is designed to operate as follows:

For single line-to-ground faults the breaker pole connected to the faulted phase at each

end of the line is tripped and reclosed. If the fault persists after reclosure, all breaker poles are tripped and locked out. All breaker poles are tripped and locked out for all faults involving more than one conductor.

On most future installations of single-pole reclosing it is expected that two poles will be tripped and reclosed for two-phase faults, and three poles tripped and reclosed for three-phase faults, but such operation is not necessary on the Lenore–Newcastle installation at the present time.

Figure 5 is a photograph of the new 138-kv breakers at the Newcastle substation equipped for single-pole reclosing.

Tests

Extensive field tests were made on the system of the Public Service Company of Indiana, Inc., on March 16, 1941 and were primarily intended to check the functioning of the relays and reclosing equipment. Two oscillographs were stationed at Lenore to record simultaneously the following quantities:

Phase currents in the Newcastle line.
Residual current in the Newcastle line.
Carrier signals at Lenore.
Lenore 138-kv bus voltages.
Phase C voltage on the line side of the Newcastle line breaker at Lenore.
Phase C current in the Dresser line.
Phase C current in the Indianapolis Power and Light Company line.
Phase C current in the Lenore condenser.
Phase C current in the Columbia line.
Residual current in the Lenore transformer neutrals.
Travel for the reclosing breakers.
Trip coil currents for the reclosing breakers.

Two oscillographs were stationed at Newcastle to record the following:

Phase currents in the Lenore line.
Residual current in the Lenore line.
Residual current in the Muncie line.
Residual current in the Newcastle transformer neutral.
Carrier signals at Newcastle.
Phase C voltage on the line side of the Lenore breaker.
Travel of the reclosing breakers in the Lenore line.
Trip coil currents of the Lenore and Muncie line breakers.

Additional oscillographic records were obtained by the American Gas and Electric Service Corporation at Muncie.

Faults were applied to the system at the points marked as F_1, F_2, F_3, and F_4 in Figure 3. The fault locations and types of faults were selected to provide a comprehensive test for the relays, reclosing mechanisms, and breakers associated with the Lenore–Newcastle line. Since it was necessary to run the staged tests on a Sunday, during system light-load conditions, the tests could not indicate directly the ultimate transient-power limits which can be achieved. Indirectly, however, the records should provide a very good indication of stability conditions by showing the disturbance to the system initiated by the fault.

The complete test schedule is outlined in Table III. Arcing faults were initiated by closing a circuit breaker which connected a line conductor to ground through a fine wire suspended across an insulator string. The arc resulting when the switch was closed is shown in Figure 6. Solid faults were also initiated by the closing of a breaker.

Test Results

The tests were entirely successful, the single-pole reclosing relays and breakers operating satisfactorily in all tests. Typical of the performance recorded for all tests, the Newcastle breaker in tests 1 and 2 interrupted 1,300 amperes in six cycles after initiation of the fault and four cycles after energization of the trip coil. The line remained de-energized 19 cycles before reclosure, giving a reclosing time of 23 cycles. The breaker remained closed on the arcing fault of test 1 but tripped a second time and locked out on the solid fault of test 2. The reclosing times for the Lenore breakers were somewhat longer, averaging about 29 cycles, but still well under the nominal 35 cycles. A typical oscillogram is given in Figure 7, which is one of the oscillograms taken during test 12 of Table III. The total reclosing time of the Newcastle breaker is shown to be approximately $25^1/_2$ cycles. The breaker interrupted the fault in $5^1/_2$ cycles after fault inception and $3^1/_2$ cycles after trip-coil energization. Trace number 9 shows a flow of residual current for 31 cycles, indicative of the reclosing time at Lenore. The times to arc extinction and reclosure were remarkably consistent on all tests. It is of interest that in test 3 the three-pole 20-cycle reclosing breaker at the New-

castle end of the Newcastle–Muncie line reclosed on the arcing fault on the Muncie line in approximately 17 cycles (because of adjustment for faster reclosing speed than necessary) and the arc restruck. This performance may indicate that times of reclosing less than 20 cycles cannot be used on 138-kv systems.

The disturbance to the remainder of the system on all tests was negligible. On test 12 the total Newcastle load, 40,000 kw, was supplied over the Lenore–Newcastle line, with all paralleling ties open. No disturbance was noted at Newcastle or other points on the system and the oscillograms revealed that very little swinging of the Newcastle condensers and other connected machines occurred. During this test approximately 500 amperes residual current appeared at the inception of the fault in the Newcastle line at Lenore. When the faulted phase was opened, before reclosure, the residual current in the line at Lenore decreased to 85 amperes. The residual current in the Muncie line, during the period that the faulted phase was de-energized, was so small that it could not be accurately scaled from the oscillograms but was well under 50 amperes.

Figure 6. Arcing fault initiated by connecting a fine wire from line to ground

General Discussion

The field tests demonstrated that the relaying scheme developed to select the faulted phase, trip the breaker pole connected to the faulted phase, and reclose the breaker, functioned properly for both arcing and solid faults. The scheme also operated properly for single-phase faults and for faults involving more than one phase. The Lenore–Newcastle line has not had an automatic-breaker operation, other than during the test program, since the line was put in service even though a rather severe lightning season has been experienced, and neighboring lines in the same territory have suffered several interruptions. The past year's experience indicates the adequacy of the line design to minimize the occurrence of faults caused by lightning.

Calculations indicate that single-pole reclosing results in considerably higher transient power limits than can be achieved with three-pole reclosing, if due consideration is given to the high percentage of single line-to-ground faults, the relatively small percentage of faults involving two-phase conductors, and the very small percentage of three-phase faults occurring on a well-designed transmission line equipped with apparatus to provide high-speed clearing of faults. The curves of Figure 8, calculated for an assumed system consisting of a 50,000-kva waterwheel generator feeding into an infinite system (compared to the 50,000-kva station) over a single 138-kv line, illustrate the relative transient-power limits attained with single-pole reclosing for single line-to-ground faults (curves *a*), double line-to-ground faults (curves *b*), and three-phase faults (curves *c*). Two assumed speeds of operation were chosen for the calculations: 4-cycle fault clearing with 20-cycle reclosing (the solid curves), and 8-cycle fault clearing with 35-cycle reclosing (the dotted curves). Length of line connecting the systems was varied to show the effect of change in system "through" reactance. Similar curves calculated for a 250,000-kva steam turbine-generator station feeding into an infinite system over a 138-kv line are given in Figure 9. It is not strictly correct to compare curves *a* and *c* in these figures, for example, to show the improvement in power limits obtained by using single-pole rather than three-pole reclosing, since curves *a* assume a single line-to-ground fault and curves *c* assume a three-phase fault. The error in direct comparison lies only in the fault severity before the fault is cleared, a factor largely concealed by the number of phases opened before reclosure and the time of de-energization of the line.

In the above paragraphs the principle of single-pole reclosing has been described and its advantages with respect to transient stability pointed out. Other advantages accrue from its use, but single-pole reclosing must not be considered as a panacea for all transmission-line problems. Other methods of improving transmission-line operation with respect to transient stability limits and service continuity are available, and the choice of apparatus or method will be a function of several variables in each individual case.

The use of ground wires to prevent transmission-line outage has widespread acceptance. It is not economical to de-

(*b*) Double line-to-ground fault
(*c*) Three-phase fault

sign lines to completely eliminate fault occurrence, although in the higher-voltage classes, this ideal may be approached. If a line is being operated near its stability limit, or if the few faults occurring on a well-designed line are objectionable from the standpoint of service continuity, high-speed reclosing, either gang or single pole operated, may be used to advantage. It is expected that single-pole reclosing will find considerable application on existing transmission lines, even those lines designed to be relatively lightning proof, particularly as line loads increase and the present transient stability limit is approached. On new lines, the economic choice between high-speed reclosing and other means for improving performance will depend upon line length, soil conditions, stability considerations, line costs, and so on.

Single-pole reclosing can be compared to the result achieved with the ground-fault neutralizer in that its salient advantage applies for single line-to-ground faults. On well-designed high-voltage transmission lines a large percentage of all faults are single line-to-ground in nature, and practically all faults originate as single line-to-ground. Single-pole operation to clear single line-to-ground faults will, in most cases, include two-pole operation for double line-to-ground faults and gang-operated reclosing for phase-to-phase faults. This extension leaves one pole at each end of the line connected during the double line-to-ground fault to achieve some increase in transient stability limits. The installation described in this paper does not include individual pole operation for any faults other than single line-to-ground for reasons indicated above.

Table III. Schedule of Single-Pole Reclosing Tests, Public Service Company of Indiana March 16, 1941

Test No.	Time	Fault Location*	Type of Fault	System Conditions
1	8:01 a.m.	F_2	Phase *C* to ground-arcing	Normal megawatts, Lenore to Newcastle. Muncie line closed
2	8:57 a.m.	F_2	Phase *C* to ground-solid	Normal
3	9:40 a.m.	F_2	Phase *C* to ground-arcing	Normal
4	11:23 a.m.	F_1	Phase *C* to ground-solid	†I.P. and L. open, Muncie–Newcastle open
5	11:43 a.m.	F_4	Phase *C* to ground-solid	†I.P. and L. open, Columbia open at Columbia
6	12:20 p.m.	F_1	Phases *B* and *C* to ground-solid	†I.P. and L. open

†Indianapolis Power and Light Company.

Compared with ground-fault neutralizers, single-pole reclosing clears ground faults without the necessity of operation with two-phase wires at full line-to-line voltage above ground, saves the cost of neutralizers, and permits the use of grounded-neutral transformers and lightning arresters so that better lightning protection of equipment connected to the transmission system is attained. During single line-to-ground faults, however, single-pole reclosing involves unbalances, and as much power cannot be transmitted during a line-to-ground fault condition as can be transmitted with neutralizers. During faults involving more than one phase, the reclosing provides a possibility of maintaining stability not enjoyed by the neutralizer system. It is probable, in view of the above comparison, that single-pole reclosing will find preference over neutralizers, particularly on major high-voltage, single-circuit, interconnecting lines.

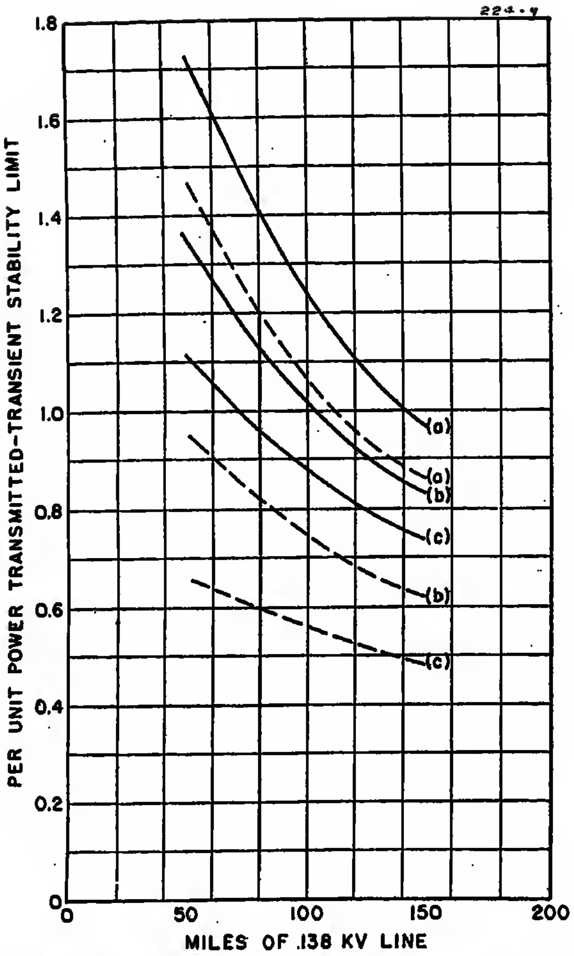

Figure 9. Comparison of transient stability limits with 35- and 20-cycle single-pole reclosing for a 250,000-kva turbine-generator station feeding an infinite system over a 138-kv line

——— 20-cycle single-pole reclosing
– – – – 35-cycle single-pole reclosing

(*a*) Single line-to-ground fault
(*b*) Double line-to-ground fault
(*c*) Three-phase fault

As a general comparison for a single-circuit line, the conventional system has zero-power transmitting ability through all faults; the neutralizer system will have no outages for transient single line-to-ground faults (about 70 per cent of all faults), but will result in outages for all other faults; single-pole reclosing can be applied to have no outages for all self-clearing faults. The advantages of single-pole reclosing over three-pole reclosing are minimized if the transmitted power is kept low enough so that no outages occur for self-clearing three-phase faults, although there is still the advantage of less shock to the system during the more common single-phase and two-phase fault conditions. The higher the probability of single line-to-ground fault occurrence, compared to multiphase faults, the greater

is the advantage of using single-pole reclosing. High-speed reclosing can be used, either three-pole or single-pole, to prevent outages for all types of self-clearing faults, a very high percentage of all faults.

In all applications of high-speed reclosing, the desired power limit, the probability of fault occurrence, the probability of the type of fault, and the percentage of time during which the line is expected to operate at the maximum stability limit should be considered in determining the speed of reclosure and the type of reclosing (three-pole or single-pole) to be applied.

Although this discussion has been confined largely to the application of reclosing on single-circuit lines, it should not be inferred that reclosing (both three-pole and single-pole) does not have application to multicircuit systems. The use of reclosing on power lines can be considered as an alternative to the addition of parallel circuits to obtain a desired transient stability limit. In many cases, this will result in large savings of capital investment. Single-pole reclosing shows up to particular advantage on multicircuit systems, for opening one conductor to clear a single line-to-ground fault, in effect merely inserts a higher impedance in one phase. Ground relaying on lines paralleling the faulted line must be arranged not to trip on the ground current circulated during the interval when one or two phases are de-energized, although relays will usually not trip for this condition if they are adjusted not to trip during the fault. The ground current, while persisting for several cycles, will usually be small—depending upon the load transferred over the lines, line impedances, and so on.

The two principal objections offered to the use of single-pole reclosing, namely, the possibility of telephone interference created by the flow of ground current during the period that one phase is de-energized, and the possibility of false ground-relay operation in adjacent line sections caused by the circulation of ground current during the de-energized period, were not encountered in this installation. It is anticipated that neither factor will be objectionable in most contemplated installations, since the ground current resulting from the open phase is small and persists for only a short time. The disturbance to other ground relaying on the system is quite small if good ground sources are available at both ends of the faulted section.

The Dresser–Lafayette line shown in Figure 2 is now under construction. The breakers for this new line will be equipped for individual reclosing mechanisms, and relaying for single-pole tripping and reclosing will be added when the 132-kv bus is established at Lafayette. Another new 132-kv line—to extend from Dresser south to Bedford, Indiana, and from there to Louisville, Kentucky—will be similarly equipped for single-pole reclosing. This line will constitute a major interconnection between the Public Service Company of Indiana, Inc., and the Louisville Gas and Electric Company.

Conclusions

On high-voltage systems where most transmission-line faults are single line-to-ground in nature, single-pole reclosing provides higher transient-power limits than gang-operated reclosing. This permits the transmission of more power over given line sections, and permits slower speeds of reclosure on very high voltage systems where adequate time allowance for arc clearing becomes of importance. If the design of a particular line is such that a larger percentage of all faults will be double line-to-ground, the advantages of single-pole reclosing over gang-operated reclosing are not as pronounced. Single-pole reclosing will find application on multicircuit as well as single-circuit lines. Entirely satisfactory relay and breaker operation is indicated from comprehensive tests made in the field.

Evening Courses at Graduate Levels—a Challenge to Colleges of Engineering

ROBIN BEACH
FELLOW AIEE

DURING the past months with the hysteria of war about us and with the nation struggling to convert its peace-time activities into a gigantic war-time arsenal of fighting and defense implements, the most urgent demands have been made for a trained personnel. The present dearth of technically trained workers and skilled artisans has been strongly felt in nearly every phase of this controversion of industry—ranging from the highest levels of engineering research and design, on through the vast varieties of supervisory positions in manufacture and inspection of materiel, and into the front line trenches of industry where plowshares are being turned into proverbial swords.

Suddenly, in the dismay of a nation awakened to its utter weakness in national defense because of its years of disregard of preparedness, overnight efforts were launched to gear industries into high-speed production of war machines and their munitions, and to multiply national output many times beyond normal. Leaders of industry sought on every hand, among the millions of unemployed, the highly skilled and trained personnel by which to double and treble their plants and to multiply their manufacturing operations. Obviously, and naturally, these leaders met with disappointments on every hand, as they soon found that the personnel which they sought, already trained, was not to be had.

War Demands on Training and Education

Then came the boom in education and training, "the gold rush," if you please, to the classroom, the laboratory, the drafting and design training rooms. On every hand, in every nook and corner, national defense training courses sprang into being, some of which were fair, some indifferent, and some worthless. An attempt was here being made to do the impossible—to make up, in a few short weeks or months, for the neglects—the depreciations—in the discarded ranks of labor for the prior years of disuse of skilled hands and trained minds.

For the first time since the halcyon days of 1928 and 1929, the engineering students, soon to be graduated, were eagerly sought, with few questions asked as to their scholastic attainments. Loud lamentations were heard because double and treble the number of graduates were not available. Proposals to shorten college curricula were urged in some quarters, and in other quarters even outstanding junior students were ill-advisedly enticed away from their engineering courses.

During this extreme urgency of employing all available engineering graduates, the members of the day classes were, for the most part, the ones who were readily available. The prospective employers found these well-prepared young men virtually in the ranks of the unemployed, or at least among the nonproducers. In consequence, their number added tangible substance to the personnel of industry. Now, if you please, let us turn our attention to another source of technical graduates—a supply of considerable and growing numbers, the graduates of evening sessons from the many colleges of engineering throughout the urban areas of our land.

Perhaps in this emergency these young men do not appear to personnel recruiting agencies to stand forth as prospective "knights in shining armor" because they have, long since, been employed in industry and, in consequence, they are already in harness, sharing responsibilities effectively and intelligently with their fellow workers as a result of their educational attainments. Of these graduates from evening sessons in engineering, and of the facilities for their training, we hear much less than of the conventional facilities for the instruction of day students.

Night Courses in the New York City Area

Here in the metropolitan New York area seven colleges of engineering have been offering evening courses leading to baccalaureate degrees. Of these the Polytechnic Institute of Brooklyn has had a long career in its service to the young men of this area, having pioneered in this type of engineering education in America, and having organized itself for this additional sphere of activity as early as 1904. The curricula and the standards of the day and the evening sessions are identical.

In those urban communities where the concentration of industry is relatively dense, obviously large numbers of young technical graduates are found among the personnel who are engaged in engineering supervision, design and planning, of industrial research, and of semi-engineering activities of countless types. The more ambitious of these feel a challenge offered to their abilities by the increasingly complex problems which they encounter in the rapid march of technological progress. They find need for more specific knowledge of engineering science in order better to cope with the growing intricacy of electrical systems with which they are engaged.

It is natural that they should turn to the engineering colleges near them in seeking advanced education to aid them in the more intelligent pursuit of their daily tasks. At this critical period of their professional lives, they know precisely wherein they lack certain educational facilities to cope with their new and advanced problems. It is then they need most the help which graduate study can give them. They have already become oriented in the field of their life's work, and perhaps quite a different one from that which they envisioned upon the day of graduation, so they can now choose more intelligently the character of advanced study which will serve them best.

The Organization of Graduate Courses

The Polytechnic Institute recognized this call for graduate instruction from these young men of industry as far back as 1925. In a community where so many utilities are engaged in the public service of electrical communications, of power and light, and of transportation, a course of basic and common interest to the many engaged in these various fields was that of advanced electrical-circuit analysis, in which the spectrum of frequencies considered was from commercial power values to those then employed in radiobroadcasting. From this small start, with but a handful of students, all eager to learn, appreciative of the opportunities offered,

Paper 42-34, recommended by the AIEE committee on education, for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted November 12, 1941; made available for preprinting December 10, 1941.

ROBIN BEACH is professor of electrical engineering and head of the department with The Polytechnic Institute of Brooklyn, Brooklyn, N. Y.

and hoping for additional facilities in such evening instruction, we launched upon our program of evening graduate study.

The results of our adventure into the then little explored field of evening graduate service have led to the development of the present programs of courses culminating in the master's and doctor's degrees in electrical engineering. It is of passing interest to note that the handful of students of the earlier years has grown into a registration of about 100 students of electrical engineering per year in continuous attendance throughout the period of the past decade. Of more recent years, other engineering colleges here in the New York area have likewise added evening courses of instruction at the graduate level to help in this service of affording the facilities of advanced education to the thousands of engineering graduates employed within our metropolitan area.

The programs of evening graduate study may be readily inspected by reference to the appropriate college catalogue. This listing of courses, citation of their contents, and enumeration of the assigned members of the teaching staff, whereas enlightening and informative, do not, however, give any indication of the problems encountered in the organization, administration, and growth of this graduate service, and of the different emphases in the philosophy of education as applied to this particular type of education.

With the hope that the review of some of these specific problems which confronted us may be of value or assistance to those who are now entering upon enterprises of a similar character, the author, with apologies for the close personal nature of these citations, ventures to describe those elements which played a dominant role in the evolution of our present electrical engineering evening curriculum.

After a brief experience with the instruction of these graduate evening students, several observations served us well in establishing subsequent procedures of organization and administration for this type of instruction. We found that these young men differed from the conventional graduate students of the day session in a number of essential characteristics. Most of them had the advantage of from three to five years, or more, of engineering experience which provided them with the motivating urge to develop further their mental facilities through evening study in advanced courses. These young men were matured, serious, and purposefully minded. They recognized in these opportunities for graduate instruction a possible means of enabling them to rise more rapidly above their present engineering status.

Many of them were engaged in various advanced phases of electrical engineering work, frequently of the industrial research type, wherein they discovered their knowledge to be deficient in meeting effectively, and with necessary dispatch, the problems of the day. They too often realized this disadvantage when attempting to study collateral bibliography because of their unfamiliarity with the various branches of advanced mathematics which they repeatedly encountered. Therefore, they sought a knowledge of advanced mathematics and a facility with its applications to a wide variety of electrical problems, as well as a thorough training in the more theoretical phases of electrical science—all to equip them with the ability to appreciate and to understand the literature in their respective fields. In addition, they expected that their increased knowledge at these higher levels of engineering and scientific attainments would provide them with the facility of technical expression by which they, in turn, would be enabled some day to contribute to engineering literature.

One of the prerequisites, or gratifications, granted to those of us who are in close association with this type of educational enterprise, is to observe the realization of the hopes of these young men to achieve such objectives and to actually contribute technical papers of commendable character to the various engineering and scientific periodicals. In fact, such achievements might well serve as an effective measure of the performance of these young men at the graduate levels of education.

The Instructor

It may appear trite and needless repetition to put into words the personal, industrial, and scholastic qualifications, the specifications, if you please, for instructors who contemplate this type of graduate teaching; but be assured that no phase of organization in this endeavor stands paramount to that of the selection of the most capable and highly qualified engineering educators. For the instructor of evening graduate students to enjoy the fruits of success in his endeavors, he should possess a rich, full educational background in the broader aspects of general engineering and, of course, he should be a master in the restricted confines of his primary interests. This should be supplemented with the invaluable experience to be gained from a period of engineering service in industrial practice in order to become intimately conversant with the varieties of problems of industry relating to his special field. He will then have a clearer perspective of the objectives of his instruction. The educational facilities of his courses will also serve his students better in meeting their urgent day-to-day needs, and they will also help to provide a more technically trained personnel for industry.

On the personal side, this instructor should have a cordial respect for the aspirations, the motivating influences, and the eagerness for learning of these evening students. His prestige as a scientist, an engineer, and an educator should invite a warmth of response from his class members. He should be their inspiring and cultural leader, and an enthusiastic proponent of this type of cooperative education. Nothing short of these essential attributes of the capable graduate instructor will meet with more than mediocrity in this challenging venture of higher education.

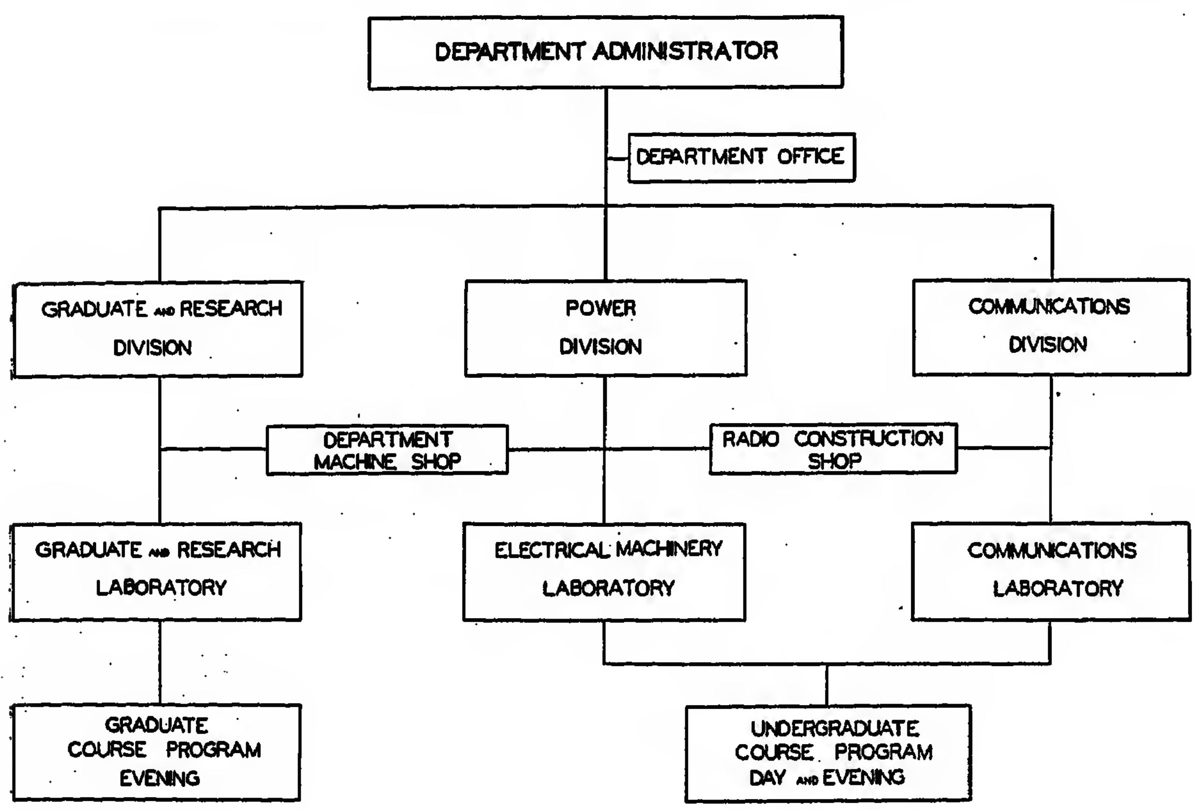
Those individuals in graduate engineering education who possess these requisite qualifications for teaching are indeed rare. This situation exists largely as a result of the natural and inexorable economic law of supply and demand. The prospective young teaching initiates—those exceptional young men of high scholastic attainments who can perform and think effectively at the doctorate level and who possess the many other attractive attributes of a cultured scientist-engineer are urgently importuned to remain in the industry wherein they are serving their internships in acquiring the practical experience prerequisite to teaching. Why shouldn't industry want to retain the services of such promising young men? If the graduate classrooms and research laboratories of our colleges of engineering are to be graced with the capabilities of these industrially groomed protégés of advanced engineering education, obviously such prospective young teachers can only be induced back to the campus by sufficiently attractive rewards. Industry pays them their current market worth. Do we expect them to sacrifice their careers in industry to teaching for less? Some apparently do.

Colleges have been known to accuse industry of unethical practices of competition when they have been frustrated in their attempts to employ these highly educated scientist-engineers by unattractive offers of salary. The problem appears to be one of justifiable competition in the open market of personnel. If we seek gems, we must be prepared to meet their market values. Perhaps the colleges

are not overly ethical at times in bartering too low for highly qualified engineering teachers. In our perplexing problems of personnel, of which we have had many, we found industry genuinely co-operative in its willingness to help. Many of the industrial leaders are farsighted in such matters. They envision that their research and design engineers of tomorrow, their future executives as well, are the offspring, let us say, of university adventures in the higher technical educations of today. In consequence, they want these prospective employees taught with utmost thoroughness. They would prefer the colleges of engineering to administer the basic instruction, but because they have not found the graduates well grounded in basic science and engineering, a number of the larger companies have felt impelled to do the job themselves concurrently with their inductive training for specialized branches of service.

As though to lend support and credence to this implied malignment of the incompetence of instruction, how often do we see the graduate instructor who is, figuratively, but a hop, skip, and jump ahead of his class—the instructor who can lay claim to no achievements in his sphere of technical activity? He is restricted in his services by a lack of knowledge and facility with mathematics; he is circumscribed by a "low ceiling" of vision in his specialized field; and he has literally a complete "black-out" of knowledge in the general field of engineering and science. How can the instructor who has achieved no success at the levels of graduate endeavor, lead, inspire, or encourage his students to the attainment of what he, himself, has been unable to attain?

Figure 1. The organization chart for the electrical-engineering department, Polytechnic Institute of Brooklyn, showing the lines of delegated responsibilities



The Administrator

The administrator of an active, well-organized department finds himself with a full-time job of attending to its manifold activities. His services to the college and to his department divide themselves into two major lines of responsibility. On the one hand, the dispatch of the minutiae of normal routine—in trying to keep the multiple divisions of the department's activities progressing smoothly and effectively—constitutes his most time-consuming, but lesser important, function, while on the other hand, his major administration, and the one by which his competence is primarily judged, is his leadership in engineering education. Does he promote high standards of instruction; does he stimulate in the students and faculty members inspiring ambitions; and does he encourage in his associates the joy of planning for future developments and achievements?

In the execution of his duties he has probably discovered by experience how much more satisfaction is derived through the sharing of certain groups of these responsibilities with the fellow members of his staff. At the Polytechnic Institute, this plan has been effectuated in the electrical engineering department through the organization of three divisions—the power division, the communications division, and the graduate and research division. The organization and functional chart which shows the lines along which the department has developed over a period of years is portrayed in Figure 1 to indicate the major divisions of delegated responsibility. In each of these, further delegations of duties are carried down even to the grade of assistants and graduate fellows, so that everyone on the staff has his part in the administration of duties commensurate with his position and in addition to his major function of service.

In this paper we are primarily concerned with the organization of the graduate and research division which coordinates and administers all matters pertaining to the evening graduate courses and to programs of research. The organization chart for this division is shown in Figure 2 to illustrate the lines of responsibilities here. Under this plan each member of the staff is charged with definite duties of a restricted scope which he is encouraged to administer within a certain degree of autonomy. His efforts and accomplishments are given full recognition, and his initiative and enterprise are factors which are considered in his advancement. Ideas and plans for improvements in the service of the division are discussed in meetings of its personnel, and when necessary department meetings are held to discuss the broader aspects of those plans and proposals wherein the composite judgment of the staff members is desired.

The department head co-operates to his fullest extent in trying to relieve the staff members of the graduate division from any arduous duties of administration that will unduly distract their attentions from their graduate and research endeavors. He should recognize that needless distractions from their absorbing problems demoralize their interests and dissipate their efforts. Among the administrative problems which he may find at times almost insurmountable, and which have their origin in just such distractions and interruptions, are those of providing required space facilities, of acquiring expensive pieces of necessary specialized apparatus, and of securing adequate and capable mechanician services and laboratory assistants. These problems arise largely, of course, because of inadequate appropriations—a subject mentioned with respect and without comment.

A word of caution which the administrator should impart to all instructors of evening graduate courses is that of urging them to so allocate their time as to provide unfailingly for adequate preparation of all phases of their course notes. The lure of research must not be allowed to unbalance their sense of proportion. Unpreparedness for a session is no less disastrous to the success of the course

than is incompetence. The young men of industry who enroll for graduate study are making sacrifices of their marginal time, and, too, they are paying well for the privilege. They have confidence in the integrity of their neighboring engineering college to provide instruction of the highest quality. The administrator of the courses should make doubly certain that he is not inadvertently selling to these ambitious young men "gold bricks" of education.

In the graduate instruction of these young men, almost the entire gamut of engineering practice may be represented in the experiences of the combined membership of the class, so that questions of a wide variety, and of astounding degrees of depth, may enter the discussions of even the first-class session. It is by no means uncommon to have numbered among the class members, those with an enviable array of technical publications pronouncing them authorities in their particular fields of endeavor.

How obvious it appears, then, that these young men should expect in their mentor one thoroughly versed in his field in order that he should stimulate them to their greatest attainments, and inspire them to carry on far beyond the confines of the class lessons. Let the administrator spend more time and more resources to provide his department with a staff of research investigators and graduate teachers who will meet the fullest expectations of these young men.

The problem which confronted us at the Polytechnic Institute in the beginning of this new venture, and one which may perplex others who are contemplating the organization of this form of education, or its counterpart in nonresident instruction, was how to provide this highly qualified instructing personnel. In those early days we were feeling our way along through the shoals of both economic and educational hazards. The "pay as you go" policy which we adopted from the start certainly did not make easy the problems of providing graduate instructors. We solved this problem temporarily by affiliating with us some of the foremost scientists, engineers, and industrial research specialists here in the metropolitan New York area.

We induced a few of these specialists who were especially well qualified through the breadth of their educational background and of their experience, through their love of their work, and through their demonstrated ability to impart their knowledge to others, to join, as part-time members, our graduate staff. They organized and offered instruction in certain prescribed basic courses in which they were pre-eminently qualified to bring to the class a wealth of experience in industrial applications, a broad vision of the frontier problems of present day science, and a richness of enthusiasm for their subjects. By this means we were enabled to establish and maintain high standards in regard to the qualifications of our teaching personnel.

The department was also privileged to have associated with it, during the formative period of this venture, the part-time services for two years of Vladimir Karapetoff, the revered dean of America's electrical engineering teachers, and the full-time services for one year of Bernard Hague of the University of Glasgow, the pre-eminent authority on electrical measurements, as a visiting professor.

The Curriculum—at the Master's Level

The development of a curriculum of courses leading to the master's degree and to the doctor's degree is a subject charged and surcharged with controversy. The adherents of the "free choice" of subjects at the graduate level would probably not condone the curriculum that contains a large percentage of required sub-

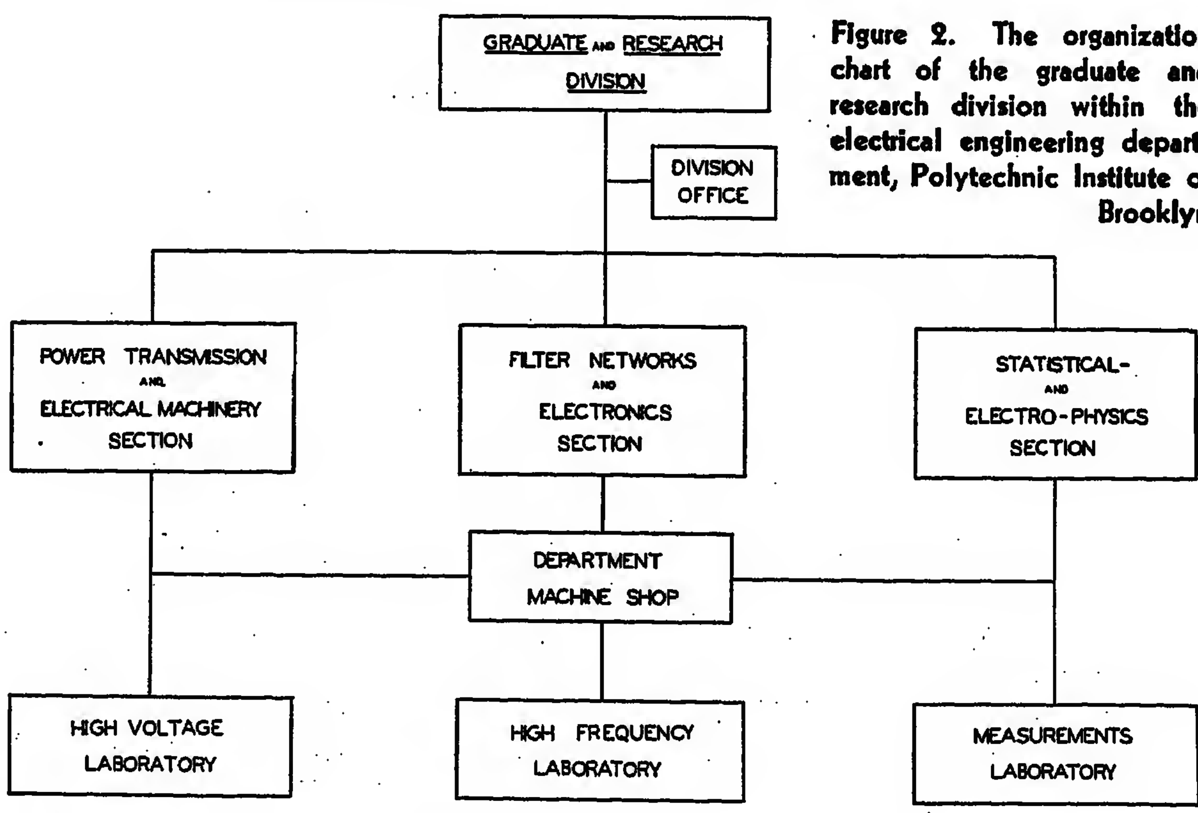

Figure 2. The organization chart of the graduate and research division within the electrical engineering department, Polytechnic Institute of Brooklyn.

jects. After lengthy consideration of this important subject, and based upon several years of experience, we are the more convinced that, in the curriculum leading to the master's degree, certain subjects are so basically important that the omission of any one would seriously weaken the foundation upon which the superstructure of the student's subsequent educational endeavors is based.

The subjects which we require of all electrical engineering students are:

1. Vector analysis.
2. Introduction to the theory of functions.
3. Analysis of transient phenomena.
4. Electromagnetic theory.
5. Electrical engineering seminar.
6. Thesis

These courses make a total of twenty semester hours of the minimum of thirty which are required for the degree. The elective subjects, totaling ten or more semester hours, are chosen by the student in conference with the department adviser, and these subjects are generally more or less closely allied to the field in which the student is employed during his day hours.

These lines of specialized study have been formulated into three general "major" classifications in each of which the following subjects are included:

Power Engineering. Electric-power generation, transmission and distribution, system calculations, electrical protection, system stability, design of machines, transient behavior of machines, and a selection from several subjects in mechanical engineering.

Communication Engineering. Electronic tubes, their theory and their circuits, network and filter theory, advanced network theory, fundamentals of electronics, ultrahigh-frequency theory, conformal mapping, theory of electrical measurements, fundamentals of mechanics, and a selection from several basic subjects of physics, including acoustics, introduction to theoretical physics, and fundamentals of radiation.

Electrophysics. Conformal mapping, theory of electrical measurements, fundamentals of electronics, fundamentals of mechanics, and a selection from several basic subjects of physics, including fundamentals of radiation, physical measurements, conduction of electricity through gases, statistical mechanics, quantum mechanics, and physical properties of metals.

Reference to Table I will provide a perspective of our present program of evening graduate courses leading to the master's and the doctor's degrees in electrical engineering. Here are shown the basic, or required, courses, the major course groups, and the minor course groups.

An analysis of our records shows that students who have been granted the master's degrees have been in attendance, on the average, about three and three-fourth years. The first year is devoted largely to the subjects of mathematics, while in the second year the required subjects of circuit analysis and electromagnetic theory are taken; during the third year the student generally completes the elective subjects and starts thesis work, and in the fourth year his time is wholly devoted to the thesis investigation. Occasionally students with less call on their marginal time by outside activities, or home ties, take an extra course or two in their first two years—thereby sometimes completing their thesis work and all other requirements for the degree at the end of the third year. Attendance without credit is required at the electrical engineering seminar during each year of enrollment in electrical courses. The speakers at these seminar sessions, who are invited to address the students and staff members and lead the discussion, are outstanding men of science and engineering here in the New York area.

The Thesis

Of the many aims and objectives in graduate study, the outstanding one is, in a few words, the development in the student of his capabilities to carry on a coordinated program of original thinking and independent investigation. We believe that the thesis is an essential means of appraising the student's ability to conduct an advanced and original investigation of an appropriate engineering or scientific subject, of showing his mastery of the subject matter of the courses he has taken, of demonstrating the development of his processes of clear analytical thinking, and of proving his facility in expressing his thoughts and his developments of theoretical conceptions, properly and adequately, in technical language.

The competence of these evening graduate students to undertake and vigorously attack their thesis assignments will be a revelation to those who have had no previous experience with this type of education. Let it be remembered that these students have already taken and completed their formal courses in mathematics, and that they have applied most of it many times subsequently in the study of their basic electrical subjects. After they have completed all of these required courses and most of their specialized subjects, they then have the psychological advantage of undertaking the thesis investigation with an assurance of mind and the educational advantage of an advanced viewpoint.

With this training as an educational background, naturally these thesis enrollees may be expected to achieve superior results, provided they are inducted into this new undertaking with a personal understanding of their possible pitfalls and of their inhibitions to use all they have learned to the best ends. The assignment and guidance of thesis work requires a particularly careful vision as to the probable length and character of the problems, the facilities for laboratory measurements, and the general nature of the theoretical aspects of the problems. It is so easy to extend beyond the bounds of a reasonable thesis, unless proper care is exercised.

Not infrequently students are enabled to carry on their investigational work under the co-operative auspices of their supervisors on their jobs, in which cases a close collaboration is maintained between an assigned member of the graduate division of the department and the direct supervisor in the company with which the graduate student is employed. This co-operative plan for the thesis investigation is especially helpful in certain projects that involve a wealth of specialized apparatus with which the company may be well equipped.

We have been operating under another co-operative plan for the past three years by which employees of the Westinghouse Electric and Manufacturing Company may receive graduate course credits, to a maximum of fourteen, towards the master's degree at the Polytechnic Institute for courses which they have passed with honor grades in the company's graduate program. Reciprocally, our students may elect to take certain courses, for credit, offered by company specialists on the Westinghouse plan. These courses for interchange credit are restricted to the applied types, in particular. New York University and Stevens Institute of Technology also share in this Westinghouse plan in the New York area.

The Doctorate Program

Having organized and administered for several years the curriculum leading to the master's degree, an insistent demand kept growing for the extension of our graduate program into the doctorate level. Several of those, who had made meritorious achievements in their work leading to the acquirement of the master's degree, were engaged in the research activities of various neighboring industries. Most of them had already published papers setting forth the results of these various research investigations, but they wished additional knowledge in the collateral fields of electrochemistry, electrophysics, and mathematics, and in the frontier science of electrical engineering. For their immediate benefit, a number of these young men continued their studies in the various ad-

vanced courses which were being offered in mathematics, physics, and electrical engineering, although they expressed their hope that eventually the electrical engineering department would offer a program of study leading to the doctor's degree. This step was formally taken in 1936.

In organizing instruction at this level, we departed basically from our objectives and philosophies underlying the master's program. Here, we held that "freedom" should be allowed the students in choosing broadly from those courses which would focus their attentions most specifically upon the lines of study in which their life's work seemed directed. To assure definiteness of purpose, it seemed desirable that these subjects be classified within a major field and within one, or possibly two, minor fields of concentration, and at least one of the minors be chosen outside of the offerings within the major field. Students who enroll for doctorate study are referred to individual guidance committees whose purposes it is to direct their selection of courses of study and collateral reading, and to advise them in the preparation for qualifying examinations in the subjects of their major and minor fields, in gaining an adequate understanding of two foreign languages, and in undertaking the investigational program that constitutes the dissertation.

Thus far we have graduated three students with the doctor of electrical engineering degree, but an increasing number are aligning themselves for qualification in the near future. The prospects look favorable for the granting of three, or possibly four, doctor's degrees at the end of the current academic year. Actually, about twenty evening students are at various stages of doctoral preparation above the master's level at present. The number of course credits above the master's degree leading to the doctorate is a minimum of twenty-four and the time required for the dissertation is the equivalent of at least sixteen additional credits. The selection of students for this level of educational attainment is rigorously based upon the evidence of ability which they have displayed in prior years in achieving honor grades for courses at the master's level, and in conducting meritorious research work. Students are not allowed to enroll in the doctorate program unless they have conducted thesis investigations for the master's degree.

It is too early in the progress of our venture in this division of graduate service to draw conclusions. Yet from our experiences in the instruction of those who have already obtained the doctor's degree and of the twenty now enrolled in this advanced program, we believe that we are headed in the right direction. If such is possible, our applied philosophy is one of overemphasis on thoroughness, high quality, depth of specialized study, and unquestioned ability to carry on independent studies and investigations.

This process of education, through evening study, imposes an unrelenting and self-administering firmness in maintaining the quality of its attainments by discouraging those who cannot stand its rigors. Those possesssing lesser qualifications, who, in consequence, must devote abnormal time to the preparation of their assignments, or who just cannot orient themselves to originality of thought are self-prompted to withdraw voluntarily. At this level of education, the students are not given the benefit of doubt in the event of their work falling slightly below honor grade. We believe that at the doctorate level the time for the "mollycoddling" of students has definitely passed. They are expected to perform at high levels of excellence in all of their work and at all times.

Decentralized, or Nonresident, Instruction

The basic elements in the organization of nonresident graduate evening courses which must be given careful consideration by those who contemplate embarking upon this type of educational enterprise are

1. The choice of subject to be offered.
2. The selection of a well qualified instructor.
3. The development of the content of the course.
4. The establishment of prerequisite courses, especially in mathematics.
5. The procurement of suitable housing facilities.
6. The qualifying of applicants.
7. The provision for critical supervision.

The ultimate objectives of this decentralized instruction determine to a large degree the specific emphasis of those policies which influence the decisions on some of the above elements. For example, is it contemplated that the courses are to constitute a miscellany of specialized subjects in electrical engineering to provide advanced instruction for employees in industry who seek immediate answers to their urgent problems of design and manufacture? If so, are the courses to be organized at a truly graduate level, with prerequisite courses made available, and with admission allowed only to qualified applicants? In this case, graduate credit for the courses could be allowed by the college, although this is an emolument of doubtful value unless a full program of nonresident courses is planned whereby the applicants may be encouraged to continue for the master's degree.

On the other hand, perhaps the contemplated courses are to form a co-ordinated program of basic and applied subjects in science and engineering which will provide the equivalent of the day instruction leading to the master's degree that may already be in operation at the college. The latter plan, of course, encompasses an elaborate duplication of facilities at the urban center which now constitutes a part of the campus organization. In effect, this plan anticipates the establishment of another division of the department of electrical engineering, which is specifically organized to offer graduate evening instruction within the confines of the neighboring urban area. A plan of this magnitude is, of course, a major undertaking and one which should be subjected to most careful economic analysis and critical study.

The former plan of offering a few specialized engineering courses at graduate level, either with or without college credit, may be readily initiated, and the present time seems to be particularly favorable for starting them. Such courses could be organized to meet the current demands of industry for intensified technical specialization by providing instruction for those employees who find themselves inadequately prepared to cope effectively with the exacting problems of this critical period. This plan, if effectuated now, would possess the dual advantages of meeting the present training needs of a war-time industry in its present emergency and of being organized at a most favorable time to encourage its financial support. With the present dearth of personnel possessing specialized training which now exists in many quarters, financial aid could probably be obtained from the government, but if not, where the need really justifies it, neighboring industries could, most likely, be induced to sponsor the courses and to subsidize small deficits of operation.

The Polytechnic Institute has offered some instruction, by request, on a nonresident basis, wherein a considerable number of employees at a distant plant wished a specific course. In these cases it was possible for a member of our normal staff to conduct the course. Graduate credit was allowed only to those who fulfilled our normal qualifying requirements. We are now finding a most urgent de-

Resistance-Welding Transients

E. E. KIMBERLY
MEMBER AIEE

Synopsis: This paper discusses quantitatively the effect of indiscriminate (random phase-angle) switching in the primary of a resistance-welding transformer supplying a resistance welder. The current and power transients occurring because of "off-angle" switching are investigated through oscillographic records of transients in loads built up to simulate actual welder-head loads as nearly as possible.

In the switching of loads of either high or low power factor and those with or without iron at high-flux densities, the power transients were found to be damped to unimportant values within the time of a very few cycles after the instant of switching. In spot and projection welding, the first few cycles may be extremely important, however, determining the quality of weld even though the total time of the weld period is much greater. This investigation is limited to 60-cycle frequency and to welding periods of two cycles or more.

The General Problem

WHEN a circuit containing resistance and reactance is energized from a source of alternating current, its initial current is likely to be greater than it will be after a few cycles have elapsed.[1,2] The current is also likely to be affected by the momentary unusual resistance voltage drop in the primary winding of the supply transformer. Inasmuch as this paper applies only to heat transients in the weld itself, the surge of current in the supply transformer primary will be considered only as it affects the heat produced in the weld because of its effect on the secondary voltage. The transformer used had an impedance of about 10 per cent.

Because of the great diversity of types of resistance-welding loads in which both ferrous and nonferrous metals are placed in the welding throat, generalization is somewhat difficult, and only a limited number of specific cases can be considered in detail in a paper of this kind. All resistance welders have a common characteristic, however, in that their welding heads carry heavy currents, and the leads to the transformer secondary coil enclose an area which accommodates a flux which produces an inductive reactance of some importance. Whether the metal introduced into the throat be ferrous or nonferrous, the welder head and its transformer leads can be considered theoretically and practically for transient analysis the same as any other circuit consisting of resistance and inductive reactance in series. This investigation was carried out using three types of artificial circuits built up to simulate representative welding loads.

Circuit 1 was of unusually high power factor of 0.85. Circuit 2 was of medium power factor of 0.5. Circuit 3 was of more common power factor of 0.22. The power factor of a welding circuit is, of course, fixed by the ratio of resistance to the reactance caused by the magnetic flux enclosed by the throat. From this fact it is apparent that a large throat or ferrous metal in the throat will be conducive to low power factor. With the shortest possible throat depth in a practical design it is difficult to obtain a power factor when spot welding of more than about 0.6 with a frequency of 60 cycles.

No attempt was made to control the residual flux of either the transformer or of the load, because it was considered reasonable to assume that the stock to be welded has no remanent magnetism and that the transformer residual flux will produce in these tests the same secondary-circuit effects as in an ordinary welder transformer. The welding current used was about two times the permissible continuous current in the transformer.

Method of Testing

To examine the power transient characteristics of the three representative circuits, they were switched on at a great variety of instants on the applied voltage cycle, and many visual observations were made. Only those found to indicate special conditions, such as maximum additive or subtractive power transients were repeated, photographed, and reproduced in this paper. The curve sheets, therefore, show extreme results of "off-angle" switching for the various circuit conditions. The time constant of flux decay as expressed by the ratio of inductance to resistance, L/R, is affected not only by the resistance of the welder and transformer secondary coil and the flux enclosed by the throat but also by the entrapped flux in the transformer core itself. Because of this fact, the rate of decay of transient current is influenced by the size of transformer used relative to the welder requirements; the rate of decay being less as the transformer size is increased.

The energy delivered to the weld for any period was found by planimeter integration of the power curves on the oscillogram. The power oscillograms were taken by a power galvanometer with the current coil in series with the welding circuit and the potential coil connected across the secondary of the welding transformer. While the power transient had not entirely subsided in some cases by the time the end of the oscillogram was reached, the steady-state energy per cycle was available in every case from another oscillogram in the same series with the same load.

Results and Conclusions

1. Random switching may result in a good weld, a cold weld, or a hot weld when the welding period is less than about 20 cycles.

2. Random switching may cause as much

Paper 42-25, recommended by the AIEE committee on electric welding, for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted May 8, 1941; made available for printing November 25, 1941.

E. E. Kimberly is professor of electrical engineering, Ohio State University, Columbus, Ohio.

mand from neighboring industries for instruction in the theory of ultrashort waves, their production, transmission, and reception. This course was included in our current curriculum for the second semester, and we are advised to expect a large enrollment. In fact, we have been requested to consider the organization of certain classes in the subject at remotely located plants where a sufficient number might warrant nonresident instruction.

The call of the junior engineers of industry for more and more of this type of graduate evening instruction offers a resounding challenge to the technical schools, in or near the urban centers, to organize their facilities for taking an active part in this growing enterprise. Already a number of colleges of engineering throughout the United States has responded to the opportunities offered in this attractive field, and others are now formulating their plans to inaugurate programs of advanced courses in the near future. These colleges will soon find, too, that the fruits of their new adventures bear to them deep satisfaction and stimulating pride in the achievement of their discovery of a new and broader field of service.

as 50 per cent variation in the heat produced in a weld having an "on" time as short as two cycles, because of unpredictable transients. Such transients may also soften the electrodes and materially shorten their useful lives.

3. Random switching will cause an error not in excess of five per cent in the heat produced in a weld having an "on" time exceeding 20 cycles at a line frequency of 60 cycles. This statement is true only on condition that the welding circuit is opened between welds, or that the time interval between consecutive welds is sufficient to permit the complete dying out of entrapped flux in the throat. Any entrapped flux lingering from a previous weld period will tend to be accumulative in further saturating the transformer core.

In the case of projection welding even when the weld time does exceed 20 seconds, a transient of added energy in the first two or three cycles may be disastrous, because of the exploding away of the projections, and for that reason accurate switching control is imperative.

4. When the welding period is less than about ten cycles the heat delivered to the weld may be appreciably increased or decreased at will within small limits, depending upon the number of cycles of the period by controlling the instant of closing the primary circuit of the transformer. This procedure is permissible, of course, only if the voltage disturbance caused by the transformer primary-current inrush is not excessive when the switching point on the voltage wave departs from that at which the minimum transient occurs. Such practice may, however, result in the softening and extrusion of the electrodes.

Shielding of Substations

C. F. WAGNER
FELLOW AIEE

G. D. McCANN
ASSOCIATE AIEE

C. M. LEAR
NONMEMBER AIEE

As compared to transmission lines, it is more important that overhead ground wires or vertical masts over substations be correctly located so as to provide shielding of the structure against direct strokes of lightning. In a previously published paper[1] the authors discussed the shielding characteristics required for transmission lines. The present paper extends these investigations to the shielding of substations.

The previous paper indicated that the essential characteristics of natural lightning, that must be correctly simulated so that laboratory sparks and scale models can be used to study shielding effects, are the relative development of the initial streamers of the discharge. Schonland[2] and his associates found that lightning strokes to ground or to relatively low objects, such as transmission line towers, are initiated by a streamer propagating from the cloud practically the total distance to ground. Only very short, if any, upward streamers from the ground end are found to be present. The path taken by a stroke and its resulting terminating point on the earthed end is determined by the initial downward streamer, called by Schonland, the pilot streamer. The direction of propagation of the pilot streamer depends, at any point along its path, upon the electric field produced by the charges in the cloud, at the ground, and in the streamer itself, and upon localized conditions of ionization at the tip of the streamer. These localized effects tend to make the path erratic so that, as shown by laboratory tests, for the same configuration of cloud and ground, no two strokes will follow the same path.

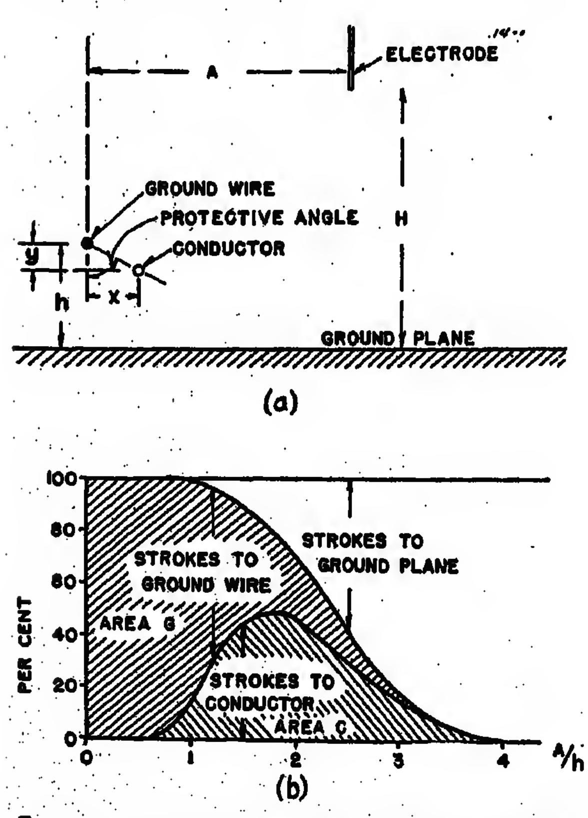

Figure 1. Symbols utilized with stroke-distribution curves for overhead ground wires

It was found that, although natural lightning is predominantly negative in polarity, the relative streamer development is best represented in the laboratory by positive polarity sparks, that is, strokes from a positive cloud. For negative laboratory sparks, upward streamers are more likely to originate from the most exposed object and span the greater portion of the gap spacing, thus giving rise to more optimistic shielding results with models than would be expected for actual strokes in nature.

Description of Model Tests

As in the previous work, this investigation employed $1^1/_2$x40-microsecond impulses of positive polarity at the minimum voltage required for breakdown of the gap. A vertical pointed rod was used as the cloud source of the stroke and a smooth metal plane for the ground plane. For the determination of the shielding properties of overhead ground wires protecting horizontal line conductors, the arrangement shown in Figure 1a was used, in which the symbols are clearly defined. Owing to the localized variations at the tip of the pilot streamer, all strokes from a given position of the cloud electrode do not follow the same path and terminate at the same point at the ground. Thus, the strokes divide between the three possible terminating points: the ground wire, the conductor, and the ground plane. It is found that the probability of the protected object being struck although decreasing as more favorable protection is afforded does not necessarily become zero.

Because the shielding characteristics are the same at any point along the line, they can be determined from a two-dimensional plot such as shown in Figure 1b. This curve was determined by increasing A from zero and counting the proportional distribution between the three possible terminating points until A reaches such value that all strokes strike the ground. The ratio of area C to the sum of areas C and G represents the proportion of the total strokes to the system that strikes the conductor.

The shielding characteristics of a mast involve a three-dimensional problem, as shown in Figure 2a, which defines the symbols used. The origin of the stroke is located by the dimensions A and θ, and the distribution curves now become the three-dimensional surfaces of Figure 2b. The volume C, that resembles a rounded cone, represents the total strokes to the protected mast and the volume G, that resembles an inverted basin with the volume C removed, represents the total strokes to the shielding mast. The ratio of volume C to the sum of the two volumes is the proportion of the total strokes to the system that strikes the protected object. For a given position of the cloud electrode, 50 strokes were found sufficient to determine the percentage distribution of strokes between the three possible terminating points.

Since the effect of varying model size had been found[1] negligible for positive polarity, a fixed ground wire or shielding mast height, h, of 10 inches was used for all the tests. To determine the effect of mast diameter, tests were made with rods having rounded tips varying in diameter from $^1/_{16}$ inch to $^1/_4$ inch. Substantially, the same results were obtained, regard-

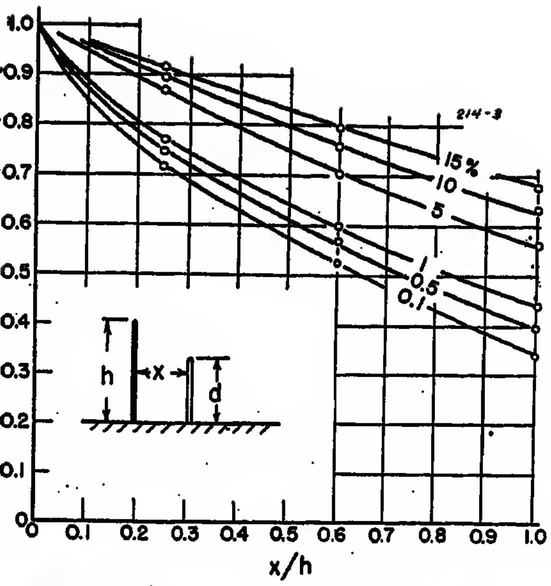

Figure 3. Exposure of an object protected by a single mast

less of the size or combination of rods, as long as positive polarity was used, and the rod sizes were held within this range. From this it can be concluded that the data obtained with one rod size are applicable to practical construction. For subsequent tests $^1/_8$-inch rods were used. Previous tests[1] showed that the same conclusions apply to horizontal ground wires and conductors.

To determine the total effect of cloud height, the relative frequency with which strokes originate from a given height should be known. Sufficient data of this type are not available and considerable variance undoubtedly exists in different regions. It is known that the base of thunderclouds[1] varies in height from a minimum of about 500 feet above ground to as high as 20,000 or 30,000 feet. A common minimum for relatively flat terrain is about 1,000 feet. Since more pessimistic results are obtained with lower cloud heights and ratios of H/h, minimum values should be used. A ratio of H/h of 5 was taken for this study, which for a 200-foot mast results in a 1,000-foot cloud height and for a 100-foot mast in a 500-foot height. The use of this ratio should give conservative results.

Shielding of One Mast by Another

In Figure 3 are plotted the results of the tests made with the configuration of masts shown in the insert. The strokes that contact the protected mast, expressed as a percentage of the strokes to the system of masts, are plotted as a function of the ratio of d/h and x/h.

The actual configuration of the equipment to be protected, such as a substation bus structure, may vary widely and it would be very difficult to make a study of all configurations. However, it will be shown that a few fundamental configurations, such as the one discussed, are sufficient for practical purposes. The performance of one mast protecting another is applicable to the case for which a single mast protects a structure having a single prominent projection.

Shielding of a Ring of Masts by One Mast

If a number of points on a structure have equal exposure with respect to a single shielding mast, the probability of at least one being struck is increased. This can be seen with reference to Figure 2b. If there were another mast of the same height, d, and distance, x, from the shielding mast but at an angle θ equal to 180 degrees, there would be then another volume C, and the number of strokes to the two protected masts would be twice that to one. As the number of masts increases, forming a circular ring around the shielding mast, the exposure increases until the limit of an infinite number of such masts or a solid ring is reached. The distribution curves for such a case are independent of θ. A conservative estimate of the shielding performance of such ring can be obtained by assuming that these distribution curves are the same as that of a single protected mast for θ equal to zero.

Thus, the volume C is a single volume of revolution about the shielding mast whose cross section is the heavy curve of Figure 2b. This is somewhat conservative, because, as the number of masts in the ring is increased, they eventually become so close that more than one mast becomes involved in the distribution curve and less than the number indicated by the curve for one mast for θ equal to zero will strike any one of the masts.

It was in this manner that the data for the curves of Figure 4 were obtained. These data are directly applicable to a structure having all points of equal height and equal distance from the shielding mast. Almost all practical cases of shielding by means of a single mast will lie between this condition and that of one protected point.

These objects are in regions of isoceraunic levels varying from 25 to 45 storm days per year.

Shielding of Two Horizontal Conductors by a Single Overhead Ground Wire

The shielding characteristics of two horizontal conductors protected by a single overhead horizontal conductor are given in Figure 5. These curves can be applied to such cases as an overhead wire shielding a substation or shielding the incoming lines to a substation.

Shielding of Objects Between Two Masts or Ground Wires

Data similar to that given above are presented in Figures 6 and 7 for a protected mast located midway between two shielding masts and for a single horizontal conductor located midway between two parallel overhead ground wires. The increase in shielding, which is obtained when several masts or ground wires are used and placed such that they more or less surround the protected equipment, is not generally realized. The area protected by two masts or two ground wires is considerably greater than twice the area protected by one.

Total Number of Strokes to Substations

The degree of shielding necessary for adequate protection can only be determined after it is known how frequently the system is struck. Data available to the authors on the number of times per year objects of varying heights are struck in regions of isoceraunic levels, varying from 25 to 45 storm days per year, are listed in Table I. All but the data on the Empire State Building[3] were obtained from lightning investigations being conducted by the Westinghouse Electric and Manufacturing Company.[4]

The curve of Figure 8 was obtained by grouping the data of Table I into mean values of height and averaging the strokes per year for each group. The range of this curve as applied to substations, would fall below 200 feet. A mast of such height can be expected to be struck about once every one and one-half years, and a 100-foot mast about once every three years. Laboratory tests indicate that for strokes that do not have appreciable upward leaders, the strokes attracted to a mast increase linearly with the height of the mast. This relation is indicated by the general shape of the lower part of Figure 8. The upward trend of the curve for high objects is probably due to the upward streamers that occur in nature from objects of such height.

A further estimate of the number of strokes to a substation can be obtained from the data of Waldorf[5] and others[1] on the frequency of strokes to transmission lines. The average figure for lines of from 60 to 100 feet in height is one per mile of line per year. The previous model tests[1] show that, in this height range, strokes will be drawn to the line from an effective lateral distance on each side of the line of about 3.5 times the height. Assuming an average height of 80 feet for the foregoing transmission lines, one stroke per line per year is thus equivalent to $5{,}280/(2\times3.5\times80)$ or 9.5 strokes per year per square mile of sky area. If W and L designate the width and length, respectively, in feet of the substation then the total strokes to the substation should be approximately, in the height range from 60 to 100 feet,

$$\frac{(W+700)(L+700)}{(5{,}280)^2}\,9.5$$

The strokes to a substation for which $W=L=100$ feet, are

$$\frac{(800)(800)}{(5{,}280)^2}\,9.5=0.22 \text{ per year}$$

or once every four and one-half years. This compares favorably with the data of Figure 8.

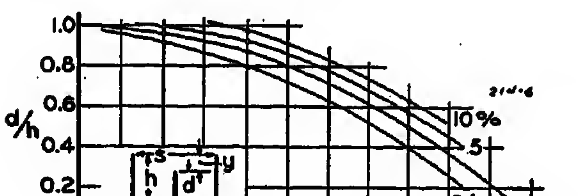

Figure 6. Exposure of a single mast midway between two shielding masts

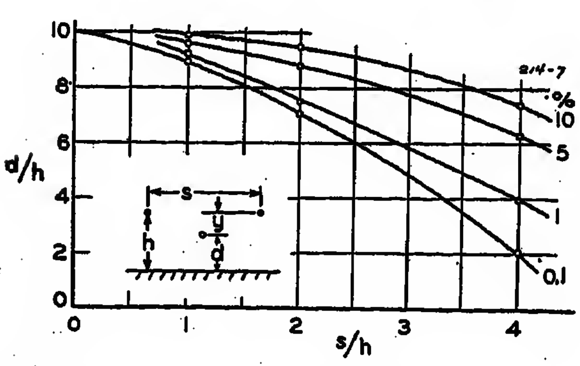

Figure 7. Exposure of a single conductor midway between two ground wires

Figure 10. Height of shielding object above protected object, y, plotted as a function of the horizontal separation, x, and the height of the protected object, d, for 0.1 per cent exposure

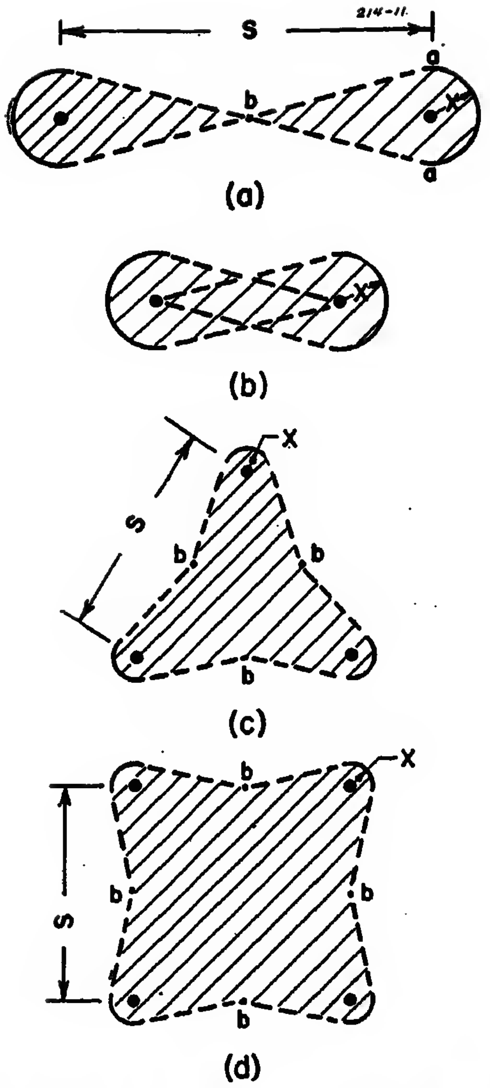

Figure 11. Areas protected by multiple masts for point exposures of 0.1 per cent

When considering a single substation and a figure of one stroke to the structure every two to four years, then, if an exposure of 10 per cent is assumed, the live parts will be subjected to one stroke every 20 to 40 years. One per cent exposure results in one stroke every 200 to 400 years, and 0.1 per cent exposure in one stroke every 2,000 to 4,000 years. However, many systems have a large number of substations, which increases the overall exposure.

Balanced against the desirability of perfect shielding must be considered the increase in cost incident to taller shielding structures. Certainly not over one per cent exposure should be permitted, and, when a comparison between the height of shielding structure required to obtain 0.1 per cent exposure over that for one per cent exposure, as obtained from Figures 3 to 7, is made, it will be seen that, in general, the added height can be obtained with little increase in cost. For this reason, the authors have chosen an exposure figure of 0.1 per cent in discussing the shielding of structures.

Working Curves

Figure 9 shows the relative configurations for a single mast or ground wire required to reduce the exposure to 0.1 per cent and Figures 10a and 10b show the same data in more usable form in which distances are plotted in feet directly, thus eliminating the necessity of using the ratios d/h and x/h. In these figures is introduced the distance y which represents the vertical distance between the protected object and the top of the shielding object. Similar data for two masts and two ground wires are presented in Figure 10c from data given in Figures 6 and 7.

Protection of Substations

To this point, consideration has been given to the protection afforded by one or two infinitely long wires, such as the overhead ground wires on transmission lines, to the protection afforded by one mast, and to the protection afforded to objects located at the mid-point of a line connecting two masts. Substation configurations are so diversified in construction that it becomes impossible to test each type individually. The best alternative is to convert the information already obtained to a form that can be utilized to best advantage.

A single mast protecting a substation offers no particular difficulty, the curves of Figure 10a being used directly. If the structure has a single prominent projection or several projections in a limited region, to be protected, such as a set of disconnects, the dotted curves should be used. On the other hand if live parts are more generally distributed at a given height, then the full-line curves should be used and applied to the most remote object.

For horizontal wires the data of Figure 10b apply to long spans, such as transmission lines. Substations involve much shorter lengths, some being so short that consideration must be given to the end effects. By comparing Figures 3 and 5 and Figures 6 and 7, for which Figures 3 and 6 approximate end conditions and Figures 5 and 7 apply to straight-away conditions, it may be seen that the per cent exposure for a given configuration is always slightly less for the end than for the straight-away Thus, the working curves, Figures 10b and 10c, can be applied directly to ground wires, even if they are short and the per cent exposure figures apply to the total strokes to the substation structure.

If two masts are used to protect an area, the data presented give shielding information only for the point b, midway between the two masts, and for points on the semicircles drawn about the masts as centers as shown in Figure 11a. For given values of d and y, a value of s from

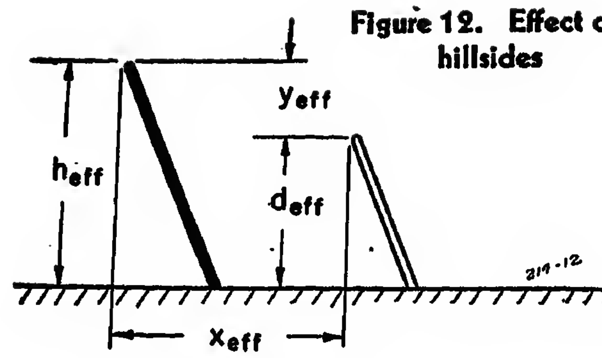

Figure 12. Effect of hillsides

Figure 10c and x from Figure 10a can be determined, which will give an exposure of 0.1 per cent. The locus shown in Figure 11a, drawn by the semicircles around the masts as centers and connecting the point b, represents an approximate limit of 0.1 per cent exposure. Any single point falling within the cross-hatched area should have better protection than 0.1 per cent. This arrangement is likely to leave some points of a rectangular substation protected by two masts with higher exposure than desirable. If, however, the distance between the masts is decreased, the protected areas are, at least, as good as the combined areas obtained by superposing those of Figure 11a. For example, if the distance between masts is halved, the resultant protected area is somewhat as shown in Figure 11b.

On this basis, to form an approximate idea of the width of the overlap between masts, first obtain a value of y from Figure 10c corresponding to twice the actual distance between the masts. The width of overlap is then equal to x corresponding to this y as obtained from Figure 10a. This undoubtedly gives a conservative width of substation that can be protected.

For three masts located at the points of an equilateral triangle or for four masts located at the points of a square, the protected areas are as shown in Figures 11c and d. The height of the shielding mast should be so chosen that the b points provide 0.1 per cent exposure as obtained from Figure 10c for the mid-point between two masts. The x radii are obtained from the data for a single mast.

Effect of High Earth Resistivity and Terrain

The data presented here apply to stations located in regions of relatively flat terrain and low earth resistivity. As shown in the previous work,[1] high earth resistivity lowers the effective ground plane below the surface of the earth and results in poorer shielding for a given configuration. This effect is appreciable, however, only for very high values of resistivity, and, since most substations are provided with an extensive grounding

Field Tests on High-Capacity Air-Blast Station-Type Circuit Breakers

H. E. STRANG
MEMBER AIEE

W. F. SKEATS
MEMBER AIEE

IN January 1940 there was presented before the Institute a paper[1] describing a new high-capacity air-blast circuit breaker. Since then, breakers of higher interrupting rating have been built, following out the general principles of design and construction disclosed at that time. As part of an organized development program, such breakers have been subjected to extensive interrupting tests under factory laboratory conditions. However, it is recognized that the final proof of the interrupting performance of high-capacity circuit breakers comes as a result of tests made on actual operating systems.

The engineers of the Consolidated Edison Company offered to make such tests up to the full short-circuit capacity available on the bus of the Hell Gate Station in New York.

First Series of Tests

A breaker rated 15 kv, 1,200 amperes, 1,500,000-kva, 8 cycles, mounted in a steel cell, was submitted for field interrupting tests in September 1940. Out of seven tests, up to 1,480,000 kva, the breaker failed to clear on two occasions, resulting in a fault to ground inside the steel cell, which was cleared by the back-up protection. On the first of these, there was no damage whatever to the test breaker, and after the parts were inspected and the insulators cleaned, the tests were resumed. In the second case damage was limited to the upper barrier of the arc chute in the test breaker, and the glaze of some of the porcelain insulators. Adjacent equipment, such as the control equipment and current transformers located in the test cell, and the sand bags and tarpaulin outside and at the top of the test cell, was undamaged. Arc durations were unexpectedly long as compared with those found in factory tests. This caused gas to escape around the blade, and produced the faults to ground. When the breaker was returned to the test laboratory, it was found possible to reproduce this condition, and it was then discovered that alterations inadvertently made just prior to the field tests had interfered with the full flow of air across the contacts and had, therefore, resulted in long arcing time.

This specific difficulty was corrected, and, in addition, further development work, using the improved synthetic method of testing as the basis of study, produced other refinements in the design of the interrupting structure, vastly increasing its margin of safety. A breaker with these refinements performed perfectly in a second series of field tests in May 1941.

Paper 42-30, recommended by the AIEE committees on power transmission and distribution and protective devices, for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted November 5, 1941; made available for printing December 8, 1941.

H. E. STRANG is engineer with Philadelphia Works, General Electric Company, and W. F. SKEATS is technical assistant to the engineer, Philadelphia Works, General Electric Company, Philadelphia, Pa.

Description of Breaker

The breaker which successfully passed this second series is shown in Figure 1. As in the earlier breaker, the mechanism and air tank are mounted on top, the contacts and arc chute of the individual phases are mounted in separate steel compartments immediately below, with provision for conveying the exhaust gases up past the mechanism to openings at the top.

Without any sacrifice in operating performance or efficiency, this arrangement of major components provides adaptability to back or bottom connection equal to that of any oil circuit breaker.

Figure 2 shows one of the arc chutes with one side plate removed. The stationary finger contacts are shown in the bottom of the left-hand chamber. The moving blade passes down through openings in the top walls of this chamber to make contact with the fingers and thus close the circuit. To interrupt the circuit, the blade contact is withdrawn upward, and a blast of air is blown across the arc from the opening visible at the left. This forces the arc against the cross barriers on the right-hand side of the chamber where it is extinguished at current zero.

The arcing chamber through which the blade passes is narrow, and beyond the leading tips of the cross barriers, the path expands rapidly, both horizontally and vertically so as to increase the cross-sectional area available for exhaust of the gases. Beyond the stacks of copper cooling plates all four passages lead into a common chamber whence the gases are carried off by the vertical exhaust tube.

In the full open position the moving blade pulls clear out of the opening in the top of the chute. In order to prevent the escape of gas around the blade at some intermediate position during the inter-

---

system, this is probably not an important factor. The effective ground plane in regions of high soil resistivity can be raised to the earth's surface by laying counterpoise wires to distances from the shielding masts of two or three times their height. However, in most cases it is probably more economical to increase the height of the masts.

Local terrain conditions are usually more important. The previous investigation[1] showed that, for transmission lines the nominal protective angle, which is defined as the angle between the vertical and a line joining the conductor and ground wire, should be modified for lines constructed on hillsides. The true protective angle for this case should be the angle between the perpendicular to the side slope and the line joining the conductor and ground wire. Similarly for the application of the data presented here to substations on hillsides the dimensions h, the shielding mast height, and d, the height of the protected object, should be measured perpendicular to the earth's surface. The distance x between the object and shielding mast should be measured along the earth's surface. This is illustrated in Figure 12.

rupting operation, an air lock has been provided in the form of a chamber about the blade opening. This chamber is fed by fresh air bled from the blast stream back of the orifice. There is also a corrugated turbulent seal both between the chamber and the chute and between the chamber and the outside air.

The operating mechanism is of the pneumatic type utilizing air for both the closing and the opening operations. It controls the blast valve in such a way as to insure that the air blast is available prior to contact separation.

Factory Tests—the Synthetic Circuit

There has previously been described before the Institute[2] the so-called synthetic method of making short-circuit tests on interrupting devices. This method consists essentially of passing heavy current at low voltage through interrupting contacts and causing high or normal recovery voltage to be applied across the contacts at the instant of interruption at current zero. The new and improved circuit, which differs somewhat from that previously described, is shown in Figure 3. In this case the high-voltage source is connected through to the circuit breaker under test and is subject to practically full excitation at all times. This facilitates proper timing in that it causes the recovery transient from the high-voltage circuit to appear automatically upon momentary extinction of the arc in both the test breaker and the auxiliary breaker rather than making the appearance of this transient dependent upon the breakdown of a gap.

Referring to Figure 3, the heavy lines indicate the high current circuit. This passes from two terminals of the generator through

1. A station breaker for finally de-energizing the circuit.
2. Reactors for controlling the current magnitude.
3. The test breaker and an auxiliary breaker in series.

One terminal of the test breaker is grounded. The auxiliary breaker must be arranged to interrupt at the same time as the test breaker. A second pole of the same breaker or another identical breaker is usually the most convenient thing to use.

The high-potential circuit starts from the third terminal of the generator, passes through a reactor, a step-up transformer and a resistor to a capacitor. By manipulation of the resistance and reactance of this circuit, the magnitude and phase angle of the voltage at the capacitor is subject to close control. The usual phase-angle adjustment is such that the capacitor voltage leads the current through the test breaker by 90 degrees so as to give the same phase relationship between voltage and current as the conventional circuit. The high-voltage terminal of the capacitor is connected through a resistance and in-

ductance to the ungrounded terminal of the test breaker. The magnitude of the resistance in this circuit was usually such as to give a current between 5 and 50 amperes. The inductance was much smaller in ohmic value than the resistance and so had no appreciable effect on the current in this connection. Its purpose was to introduce a controlled amount of oscillation into the recovery transient at the test breaker.

For a circuit-opening test, this circuit operates as follows:

Both the test breaker and the auxiliary breaker are initially closed. The station breaker closes applying the short circuit. This allows current to flow in the high-current circuit and also energizes the high-voltage circuit, setting up voltage at the capacitor and current in the resistance-inductance circuit between the capacitor and the test-breaker terminal. This current leads that in the high-current circuit by about 90 degrees, and causes the current in the test breaker to lead that in the auxiliary breaker by an angle which, expressed in terms of time, usually amounts to a few tenths of a microsecond.

This condition continues until the circuit breaker contacts are separated and the arc is interrupted. When this occurs the current in the resistance-inductance circuit has its previous path to ground interrupted and must complete the circuit via the capacitance of the connection between the two breakers. Were there no inductance in this circuit the voltage across the test breaker would respond by rising along a logarithmic curve to the voltage of the capacitor, without oscillation or overshoot. By inserting a small amount of inductance, however, a controlled amount of oscillation can be obtained, so that it is possible to obtain a range of recovery characteristics quite representative of a good number of those occurring in actual service. Curve *A* of Figure 4 shows a cathode-ray oscillogram of a voltage-recovery transient actually obtained in this manner for simulation of the duty represented by curve *B*, which was obtained on a conventional test circuit.

In common with other synthetic circuits, the present one gives the breaker an opportunity to extinguish the arc at a given current zero or allow it to reignite. Whether extinction or reignition takes place is indicated on the cathode-ray oscillogram. Extinction is indicated by the rapid establishment of voltage across the breaker contacts and the absence of breakdowns on the voltage-recovery curve. Failure to extinguish is indicated by a delay in voltage establishment or breakdowns on the voltage-recovery curve. Curve *C* of Figure 4 shows a cathode-ray oscillogram indicating failure to extinguish for comparison with curve *A* showing prompt extinction.

Severity of the Synthetic Circuit

The goal of synthetic testing is to produce conditions of arc current and recovery voltage for a circuit breaker which are of equal severity with those that may be encountered in service in an interruption of short-circuit current. Shapes of the recovery-voltage characteristic occurring in service vary widely, but reasonable simulation of a service characteristic may be considered to be achieved in the synthetic test if the voltage rises to the same value in the same number of microseconds without necessarily duplicating all oscillations.

The circuit has been criticized occasionally on the basis that the use of two interrupting units in series reduces the duty on the test breaker. In modern a-c circuit breakers the current is allowed to flow substantially without hindrance until it reaches the normal cyclic current zero. The insertion of a second interrupting unit will increase the effective arc voltage, but this will cause only a slight modification of the current wave, and when the tests are properly evaluated, this modification tends, if anything, to result in a synthetic test which is too severe rather than too lenient. This is explained by the following analysis of the ways in which the modification may manifest itself.

The additional arc-voltage effect may

1. Reduce the crest value of current reached during arcing. Any error from this source can be nullified by evaluating test results in terms of the current actually reached rather than in terms of what would have been reached had only one breaker been present in the circuit.

2. Shorten the current loop. Misleading conclusions from this effect can be avoided by interpreting the test results in terms of the ability of the breaker to interrupt on a current zero occurring at a given contact separation.

3. Cause the current to fall to zero more rapidly at the end of the loop. This will result in a higher average current during the last thousand microseconds or so before current zero. Consequently, it will tend to increase the difficulty of clearing when the current zero occurs.

The duty of the test breaker might be considerably reduced if the auxiliary breaker were in series with it for the recovery voltage. As will be apparent from inspection of the circuit, however, this voltage is applied across the test breaker alone.

Tests made for comparison of the severity of the synthetic testing scheme with that of conventional tests confirm this analysis. The air-blast breaker is well adapted to such tests, for, in the reduction of tank pressure, it offers a convenient means of adjusting the interrupting ability of the breaker to the power available from a conventional circuit. Further tests may then be made with the synthetic circuit set up to simulate this conventional circuit.

Tests of this type have been made on two different breakers. The first of these breakers was rated 500,000 kva at 15,000 volts, so that tests could conveniently be made close to full rating, and the second was very similar to the breaker finally tested in the field and described above.

The first group of tests was made at from about 10,000 to 13,000 amperes with 14,500 volts across a single pole of the breaker. The results are shown in Figure 5. Here the contact separation corre-

sponding to a given current zero is plotted as abscissa and the tank pressure used in the test is plotted as ordinate. Points are coded according to whether the arc was extinguished or reignited at the current zero in question and according to whether the test was conventional or synthetic. A few of the points indicate clearing at zero contact separation. This occurs because, with the blade and finger contacts, contact separation is measured from the point where the tip of the blade is flush with the tips of the fingers rather than the point of metallic contact.

On this plot one curve is drawn to indicate the border line between extinction and reignition as shown by the synthetic tests, and another to indicate the corresponding border line for conventional tests. There are not enough test points to determine both curves with high precision throughout their length, so there may be some question as to whether the curves should be exactly as shown. With any reasonable change, however, the border line for the synthetic tests lies to the right of the border line for the conventional tests, showing that at any given pressure more contact separation is required to clear the synthetic circuit than the conventional circuit. These tests, therefore, indicate the synthetic circuit to be somewhat more severe than the conventional.

The second series was made at about the same current and voltage as the first series, but at a higher recovery-voltage rate and on a breaker of higher interrupting rating similar to the breaker tested in the field. In this case the line of demarcation between extinctions and reignitions lay between 70 and 90 pounds per square inch both for the conventional circuit and for the synthetic circuit, indicating approximate equivalence of the two circuits.

These series may be taken as concrete evidence that the synthetic circuit produces test results sufficiently close to those obtained conventionally to serve as an acceptable procedure for determining ability of a circuit breaker to interrupt at the first current zero of arcing.

Synthetic Tests at Breaker Rating

After making conventional tests on this breaker up to the limit of the laboratory both at 14,500 volts and at a reduced voltage with currents extending up to and beyond the rating, the synthetic circuit was applied in order to obtain performance data upon the application of both rated voltage and rated current in the same test.

Tests were made with a restored voltage of about 15 kv rms across a single pole of the breaker and at currents varying for the most part over the range from 50,000 to 62,000 amperes. Under these conditions with a tank pressure of 150 pounds it was found that occasionally the breaker would not clear at the first current zero after contact separation. Increasing this pressure to 200 pounds sharply reduced the probability of carrying over for extra loops of current, and at 250 pounds in all cases the breaker was found to clear at the first zero point after the contacts had separated 0.4 inch.

Other tests made by varying the rate of rise of recovery voltage, keeping all other conditions the same, indicate that the tank pressure required to insure clearing at the first current zero increases as the circuit recovery rate goes up.

The use of 250 pounds of pressure instead of 150 pounds, therefore, provides an increased margin of safety in insuring half-cycle arcing time for high-capacity breakers under conditions of high rate of rise of recovery voltage, and since it imposes no economic or operating burden on this type of breaker, this pressure was selected for the second series of field tests.

Second Series of Field Tests

The results of the field tests on the modified breaker are shown in Table I. The series consisted of an opening and a closing-opening test, three-phase, at each of three steps, at approximately 40, 80, and 100 per cent of full interrupting rating. Root-mean-square currents in the first cycle on the closing-opening tests varied from 28,000 amperes to 111,000

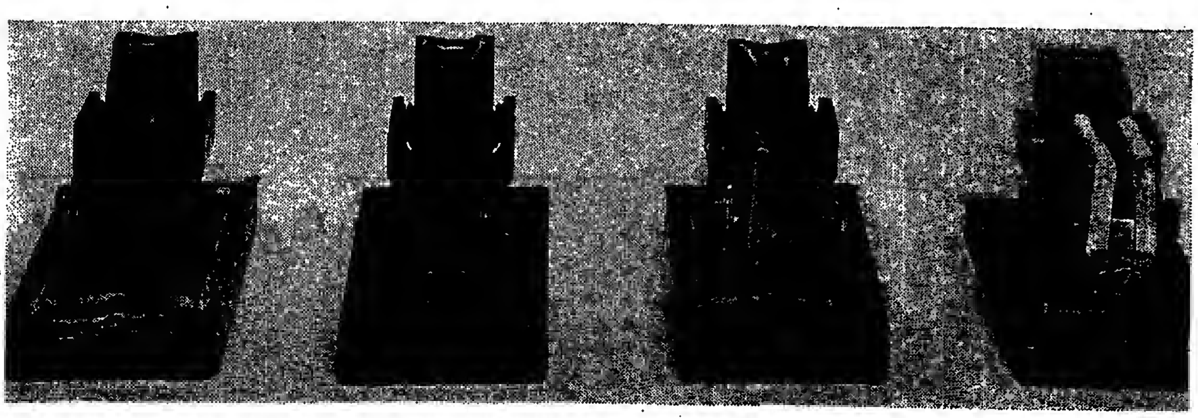

Figure 7. Stationary contacts after test, with new contact

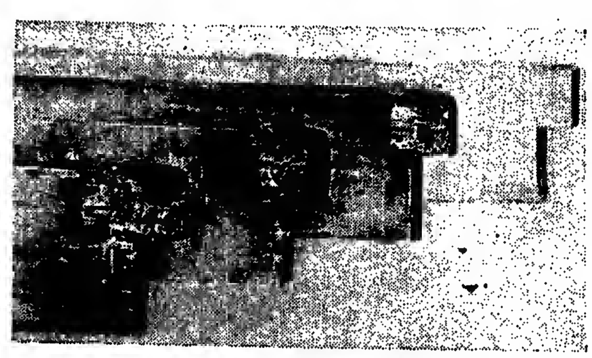

Figure 8. Movable contacts after test, with new contact

amperes. These three-phase tests were followed by one single-phase operation at about 350,000 kva which was a system, and not a breaker test. All of these tests were completely successful. The breaker operating time ranged from 4 to $4^1/_2$ cycles. The arcing time never exceeded one-half cycle, confirming the prediction of the synthetic tests made in the factory. There was no sign of fire throw either from around the contacts or from the vents on either opening or closing-opening tests.

Figure 6 shows the oscillograms of test 6-C.

The condition of the contacts from all three phases (compared with new contacts) is shown in Figures 7 and 8. Burning of the metal is detectable for a short distance up the trailing edge of the blade, at the hump of the arcing fingers, and on the arcing plate at the back of the finger assembly. Loss of material was very light, however, and conservative estimates placed the useful life of the contacts before requiring replacement at several times this amount of service.

Figure 9 shows the interior of one of the arc chutes following the tests. Here also burning is very light. The piece most severely burned is the first fibre barrier, and this could be expected to last approximately as long as the contacts.

Figure 9. Interrupting chamber after test

Conclusions

1. Although assuredly unpremeditated and unscheduled, and at the moment extremely disappointing, the eventual result of the difficulties on the first series was to build up confidence in the air-blast breaker principle, for there resulted no damage whatever to adjacent equipment, and very minor damage to the test breaker itself.

2. A 15-kv, 1,500,000-kva air-blast breaker has demonstrated its ability to perform satisfactorily over the entire range up to full rating, and to close currents as high as 111,000 amperes, under field conditions, in the first such tests ever made at generator voltage.

3. Close agreement has been demonstrated between the results of factory synthetic tests for high-capacity circuit breakers and field-interrupting performance. Recognizing that such field tests, however desirable, can serve as only an occasional check on laboratory results, this agreement is significant in that it establishes confidence in the present method of developing high-capacity interrupting devices.

Electric-Power Distribution Systems in Wartime

PHILIP SPORN
FELLOW AIEE

I—Introduction

WE are living today in some of the most critical times in the world's history. Throughout a large portion of the world men and machines are engaged in titanic struggles that may, and undoubtedly will, affect the future of Western civilization as we know it, for a century, perhaps for centuries. We, ourselves, in this country have, against our will, been drawn into this world reaching cataclysm. We are now dedicating a large part of our energies and resources and even our lives to the task of assuring that the democratic idea and way of life will emerge victorious over its counterpart and deadly enemy—the totalitarian idea. We are at war.

I have referred to the dedication of a large part of our energies. But more specifically I meant to emphasize—energy. For truly, as in no other armed clash in the history of civilized man, this is a struggle between opposing horsepower. Consider, for example, the fact that our monthly output (August 1941) of airplane engines alone has reached the figure of four and one-half million horsepower. Add to it, the engine horsepower of tanks, trucks and the numerous auxiliary vehicles going into direct military effort, and the power being built monthly for the propulsion of the numerous varieties of ships being built by, and for, the American navy, and the supreme importance of the horsepower in this particular defense program becomes strikingly clear.

Equally significant are some figures from the electric power industry—public and private. During the 12 months ending September 1941 it generated some 159 billion kilowatt-hours. As of the same date it had an installed capacity of over 42,950,000 kw. Further, it is expected that during the year 1942 there will be added over 3,000,000 kw of capacity and during 1943 close to 2,000,000 kw. One single system alone—the electric system with which the author is associated—has added during the past year over 230,000 kw of steam electric capacity, and it has under construction and will add during 1942 and 1943 over 500,000 kw of additional capacity.

All of the vast reservoir of power is designed to back up the man power of the nation and to make certain that energy, to the fullest extent that energy can be used to complement the human effort, is available to meet the requirements for increased production of all the materials needed to wage modern war.

Most of this energy has to be distributed before it can reach the utilization point. It has, in other words, to utilize the facilities of a distribution system. It is a well-known fact that the distribution system represents the largest single item of plant investment in any well-balanced electric utility system. Hence, it represents the largest aggregation of skilled effort and materials. But materials composing the distribution systems, and particularly items like copper, steel, and electrical assemblies of these, represent some of the most critical materials in the present all-out defense effort. The factories normally engaged in manufacturing these materials into finished usable products to take their place in a distribution system are, in a great majority of the cases, engaged also in manufacturing similar materials, or materials of a sufficiently closely similar nature, so as to require the same human and machine facilities, for direct use in vital defense instruments both on land and in war vessels of various kinds.

Distribution systems, as we know them, and as they exist today, are the products of concepts and ideas developed into plans, and built of materials and labor utilizing the concepts and ideas of human beings, generally engineers. These concepts and ideas, in turn, have usually been based upon knowledge of physical and electrical requirements of a distribution system and of the corresponding abilities of certain materials to meet those requirements. In many cases, however, the requirements themselves, although the result of a great deal of experience and a knowledge of fundamental engineering characteristics, are based upon more or less arbitrary criteria of what is required to give satisfactory performance. For example: It is apparent that, while there is much experience and sound distribution engineering behind the common criterion of designing distribution feeders for two per cent voltage drop to the distribution center or point of primary take-off, it is possible to design, build, and operate distribution systems with higher voltage drops. This is but one example illustrative of the fact that many parts of distribution systems have been built to meet more or less arbitrary standards.

This is not said in derogation of distribution engineering as currently practiced. We all recognize that certain standards of performance are prerequisite to any rational design of any distribution system, but many of the standards are not only based upon judgment as to the level of performance that the standards have to reach, but, in many cases today, are the

Paper 42-60, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted November 21, 1941; made available for printing December 17, 1941.

PHILIP SPORN is vice-president and chief engineer of the American Gas and Electric Service Corporation, New York, N. Y.

product of a continuous raising of such levels. Only to the extent that they do not represent the minimum that can be safely used, particularly in times of necessity, do I mean to label them as arbitrary standards. To that same extent, the limitations from a load-carrying standpoint are, in many cases, man-made and they, therefore, offer possibilities of being unmade and their use expanded in times of necessity, by man.

Considering the necessity of utilizing all available effort to the utmost in a war for survival, it is obvious that, to the extent that distribution systems, so vital to the delivery of power and energy to all war industries, have to be expanded in order to meet the increasing need for electric power and energy, it behooves us at this time to re-examine the peacetime ideas and concepts behind the planning and building of our distribution systems. It is necessary to ascertain how far ideas that were perfectly sound only a short time ago are still sound today and how far they can be modified; to what extent new ideas can be used, particularly for the duration of the emergency, so as to reduce to the practical minimum the total efforts expended on expansion of distribution systems.

II—The Object and Scope of This Symposium

The object and scope of the symposium, to which this paper forms an introduction, is to survey, study, and analyze all phases of the distribution system with a view to not only developing new ideas and concepts, but even more so to altering previous concepts of what has to be done on a distribution system under conditions facing the electric supply industry and industry of the country in general, today: to determine means and methods that can be employed for adapting, expanding, and operating existing distribution systems for the maximum broad overall benefit. This will recognize first, that all distribution systems (at least distribution systems that have maintained what might be called normal standards of adequacy) have inherently considerable elasticity, or rubber, or stretch, to use more common terms. A good deal of that stretch, it would appear, can and must be used under present conditions. The exact methods of utilizing such elasticity, the ways and means, will be developed in detail in the principal papers. Again, it will recognize that, in many of its aspects, distribution engineering as practiced today is a result of slowly developed standards and concepts of what is adequate quality of service. Side by side with such development has been an acceptance, during the past two decades at any rate, of the idea that quality of service should be continually improved. In general, these ideas have been sound, at least for peace times. But in making such a statement, it needs to be recognized that service can be rendered on several—perhaps an infinite number of—different quality levels, ranging from the very highest level to one that is definitely below the passable or acceptable. But in between these two limits there is a broad band for latitude. Where a national emergency exists and where the national interest dictates the desirability of modifying such standards of quality, there most certainly is every reason for analyzing *de nova*, determining, and then adopting a newer concept of what is adequate for the emergency period.

Not only in operation, but in maintenance also, a closer examination of the true needs of a distribution system is in order. More than ever in times of a national emergency, the question of indispensability of any proposed program needs to be gone into thoroughly. Not only that, but the long-term concept, even the reasonably long-term concept, may have to be disregarded and be permitted to give way to the concept of immediate or reasonably immediate need. It is true that all this may result in somewhat greater eventual cost. Deferred maintenance, for example, always results in greater ultimate costs. But here again, there is considerable margin of latitude between what might be called clearly deferred maintenance and what is merely anticipatory maintenance. The latter will frequently result in a total saving over a long enough period of time. However, under the situation confronting the country today, a program involving somewhat higher ultimate costs may be the more sound, and therefore, the desirable one, if not the necessary one, to follow.

From the standpoint of the materials situation and the help that can be given here, it is necessary to give consideration to the fact that many defense industries are in direct competition for the same or allied materials used on a distribution system. This is true, for example, in materials like copper, steel, tin, zinc, and any number of others. In other cases, the competition extends beyond the raw material and enters into the manufactured product itself. Typical examples of that are transformers, electric cables, circuit breakers, protective devices, and numerous others that can be cited. Hence, the need to critically examine not only the extent to which existing materials and devices can be more intensely employed, but where new materials or devices are needed, to determine what substitutes for critical materials might be employed. This symposium will concern itself with this also.

The development of the idea of the importance of the distribution system to the task of making available adequate electric energy to successfully prosecute the war leads directly to the thought that the defense or the protection of that system is likewise a most vital matter. But this subject is a difficult one to handle, particularly in a public forum. A discussion of weaknesses of any system is an automatic indication of the logical point of attack by those sufficiently motivated to carry on the work of the saboteur. Hence, such a discussion has to be, of necessity, most limited. But such limitation of the scope of the discussion does not alter the fact that certain plans, ideas and ways and means of providing secondary lines of defense, so to speak, can be developed, and in many cases have been developed and put into effect. To that extent, discussion is not only possible but can be fruitful in bringing about greater safety.

III—The Limitations of the Symposium

Even the brief discussion of the distribution problem that has been given here, should have indicated fairly conclusively that the problem undertaken is a complex one. What is of even greater significance is the fact that the distribution system, more perhaps than any other part of an electric supply system, is a local problem. It is a polygon full of local angles. All of this has been fully recognized. The fact still remains, however, that certain principles are more or less universally applicable. These, in particular, it will be the aim and purpose to explore.

In arranging the series of papers here presented, and in their writing, it has been neither the aim nor the intention to prepare a complete text on the subject, or on any phase of it. On the contrary, it is fully recognized that a task of that sort would be practically impossible, and certainly so, within the time and the space that has been made available for that purpose. Rather has it been the thought that this series of papers will result in a stimulation of thinking along new avenues and that that will lead to further work that will be undertaken. This work will have to be done in the scores, possibly

Underground Distribution Systems in Wartime

L. R. GATY
ASSOCIATE AIEE

Synopsis: This paper reviews the underground distribution system, suggests methods to conserve existing facilities and ways of utilizing latent capacity, and summarizes some of the known information available. Additional information is given on duct-bank load limitations and on time-temperature factors for cable and duct.

THE war program requires that we take every advantage of existing equipment and unused capacity to carry the unusual loads which are being supplied. Unpredictable new loads and load increases must be supplied promptly, although materials and equipment progressively become scarcer. Expedients will be necessary which would not be considered during normal times and all of our combined ingenuity will be required.

The experience from previous operation must be utilized to the greatest extent, but since the conditions at present are becoming so extreme, previous experience under normal conditions may be of value largely as a sign to point the direction. The opportunity to obtain valuable data must not be overlooked. Field studies, investigations, and surveys should be continued or expanded so that the road can be mapped as we travel over it. Information gathered now will be of great value for present operation and future design.

Method of Supply

In those cases where a radial distribution system is used advantage may be gained, both in capacity and in regulation, by changing to a network system. A properly designed network will increase the capacity of existing facilities in a given area and improve the service reliability. If maximum use is made of the capacity increase, there will be very little voltage improvement. However, it may be necessary, for the duration of the emergency, to modify our existing concepts of satisfactory voltage regulation in order to make available the maximum capacity to carry the load. This does not necessarily mean exceeding the existing limits of minimum and maximum voltage, but it may mean a wider band than has been considered good practice. The change from radial to network will only be economical in certain cases. In general, the increase in capacity alone will not justify the expense of changing over, and the material required may be more than to obtain the same capacity increase in other ways.

A radial system usually has a number of dual-service customers supplied from it. Standard practice requires that capacity must be available on each service for the entire load of the customer. This reserves *normal* capacity of twice the load being supplied. More liberal use of the emergency capacity of the system will permit this load to be supplied normally from one feeder without overload, but will not reserve capacity on a second cable so that when the second supply is required the emergency rating of the cable will be used. In some cases, additional load transfers at the time of the emergency can be made to relieve the overload. Emergency service may have to be restricted to the customer's essential load. As capacity limitations become more critical, it may become necessary to make available emergency service only to essential war industries, although this does not appear necessary at this time. Control of the use of emergency service by the utility instead of by the customer will provide greater flexibility for the use of existing capacity. A review should be made of the facilities supplying all dual-service customers to release all possible capacity for new loads and increased loads.

Paper 42-62, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1941. Manuscript submitted November 18, 1941; made available for printing December 17, 1941.

L. R. GATY is assistant electrical engineer with the Philadelphia Electric Company, Philadelphia, Pa.

The author acknowledges the assistance of H. A. Dambly, A. R. Eaches, and others, and the information and suggestions given by Herman Halperin, M. W. Ghen, and W. B. Elmer.

Additional capacity may be made available by the parallel operation of primary feeders. This must be done with care so that a large area will not be without service in case of a cable failure. The interrupting duty on equipment connected to such parallel lines will be materially increased, and fuses and circuit breakers may be inadequate. The same advantage may be gained by transferring customers between feeders, in order to obtain the highest load factor. As an example, if there are two feeders into an area, one industrial and the other commercial and residential, it may be advantageous to change both to combination feeders.

Reliability of Supply

All reasonable precautions should be taken to guard the system against damage to cables and accessories. This damage may be intentional or unintentional and may be mechanical, thermal, or flood. Mechanical includes both external and internal explosions as well as other types of mechanical damage. Thermal includes fire as well as overload.

Damage should be prevented if possible, but when it does occur, the organization must be prepared to repair it promptly and restore the equipment to service. This will require suitable trucks and trailers equipped with splicing materials and pumps. Careful study should be given to the amount and efficiency of this equipment.

Fire fighting equipment mounted on a truck or trailer should be provided which can be quickly moved to any part of the system. More than one may be required for complete coverage of a large property. Mobile fire fighting equipment of the CO_2 type has been designed and is available.[1] This is useful not only for manhole and vault fires, but also for other types of fires on the system. An ample reserve supply of CO_2 should be kept on hand at all times.

Fireproofing of cables in manholes and vaults should be very liberally applied to minimize the danger of a fault being communicated to adjacent cables and to

hundreds, or even thousands, of distribution systems.

The experience in the application of these ideas, and the development of new ideas that effort along this line is bound to bring, will eventually give a great deal more knowledge and information. But there is no time to await the full gathering of that experience. Even though all the facts necessary for a complete solution of all the phases of the problem are not available at the present time, a beginning must be made at once. All engineers, and distribution engineers among them, must pitch in and contribute their share to the common task.

reduce the damage which will result from a manhole or vault fire. In special cases, it may be advisable to install barriers to segregate one group of cables from another. A highly important transmission cable in the same manhole with old distribution cables might justify special precautions.

Spare materials must be checked and watched to assure ourselves that any reasonable emergency can be handled promptly and efficiently. A proper stock of cable in the various lengths required should be given careful study. The stock of reserve cable should be higher than normal, due to the probability of a higher failure rate with heavier loads, the possibility of extensive damage under emergency conditions, and the extended delivery required on new cable. Other spare materials should include complete kits of splicing material, and necessary switches, transformers, fuses, network protectors, potheads, and any special equipment such as oil reservoirs, gas pressure tanks, and various types of fittings. Emergency conditions caused by explosions, washouts or cave-ins, and fires must not be overlooked. Manhole frames and castings should be available. Consideration should be given to using precast manholes for emergency replacement in cases of extended damage. The installation of precast manholes has already been shown to be practical and economical[2] and may meet certain emergency conditions.

Fault-locating equipment and methods should be checked. Fault-locating equipment is available for distribution cable which will generally give a prompt and accurate location. This is necessary before much other work can be done to start repairs.

Repairs must be made as quickly as possible. Temporary repairs which have to be remade later are usually not justified. This has been verified by incomplete reports from England. Some experiments have been made with a "cold-setting" material for making a temporary high-voltage cable joint which does not require a lead wipe.[3] This has been found to be practical and usable where conditions require it, such as with very extensive damage requiring prompt repair with minimum skilled labor.

Salvage methods should be reviewed so that maximum advantage is obtained from removed cable and material. Duct splices have been found uneconomical for short lengths of cable but may be necessary to conserve material and maintain emergency stocks. Cable which is unfit for use at its rated voltage may be usable at lower voltage. Material must not be discarded if it can be reused to conserve new material.

A supervisory and alarm system giving temperature and pressure indication and alarm is a tool which can be used to obtain the maximum capacity with safety from a given system. Temperatures and pressures can be watched and the necessary steps taken to relieve any unsafe conditions as they arise. All such systems which have been installed or are being installed should be checked to see that the maximum benefit is being obtained from them. By combining supervisory indication with remote control of switches, a very flexible system will result.

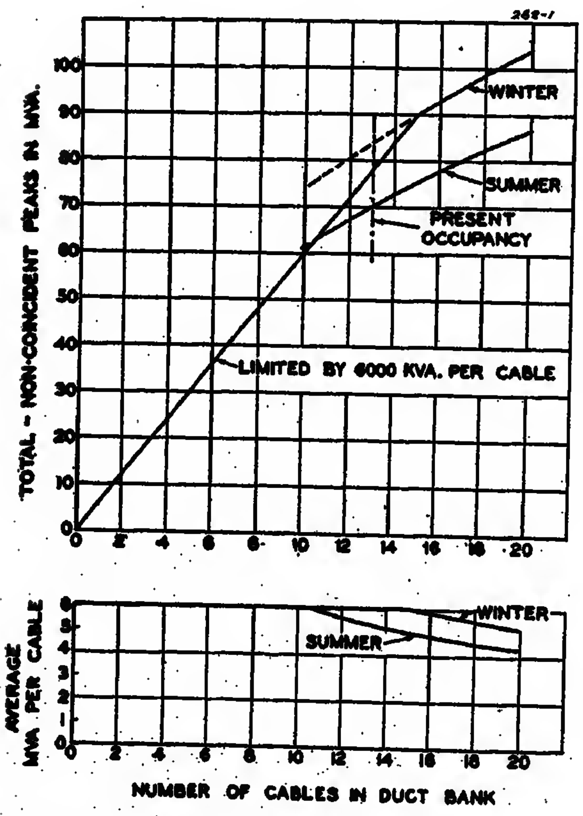

Figure 1. Duct-bank thermal capacity

Three-conductor 350,000-circular-mil 13-kv belted paper and lead cable

Underground Equipment Limitations

A considerable amount of research has been done on the underground system. Cables, ducts, manholes, transformers, and cable accessories have been studied and related to each other and to the ratings which may be used with safety. Additional work is in progress in many of the companies. In presenting the following material, liberal use has been made of the information now available, some of which has been previously presented to the Institute.

Table I

	Ratings in Amperes (2-Phase 3-Wire—A and C Conductors)		
		Emergency	
	Normal	2-Hour	4-Hour
As received from field	160	240	200
After reconditioning and silver-plating	200	300	250

The above ratings are based on maximum temperatures as follows:

	Temperature—Degrees C.	
	Normal	Emergency
Contacts under oil	70	90
Terminals above oil	85	90

Circuit capacity may be limited by apparatus in the circuit, such as switches. Tests were made at Philadelphia on a subway-type oil switch rated at 200 amperes. These tests revealed that the current-carrying capacity of the switches was relatively low, although their appearance was good. Silver plating of the contact surface was found necessary to put them in satisfactory condition. Table I summarizes these tests.

The B phase leg was the limitation in each case. The B phase current is approximately 1.4 times the A or C phase, so that the switch would be rated somewhat higher on a three-phase system.

Equipment of this type, which imposes a capacity limitation on the cable, should be rebuilt, replaced, or removed. These switches are being replaced with a "drop-out" switch in all cases where there is a circuit limitation. The new switch has adequate carrying capacity and may be repaired or replaced without interruption to either cable connected to it.

Transformers and transformer vaults may be a limitation either on a network or on a radial system. In general, underground transformers have been operated at or less than name-plate rating whereas overhead transformers are operated considerably in excess of name plate. The peak load on network transformers averages only 50 per cent of name-plate rating,

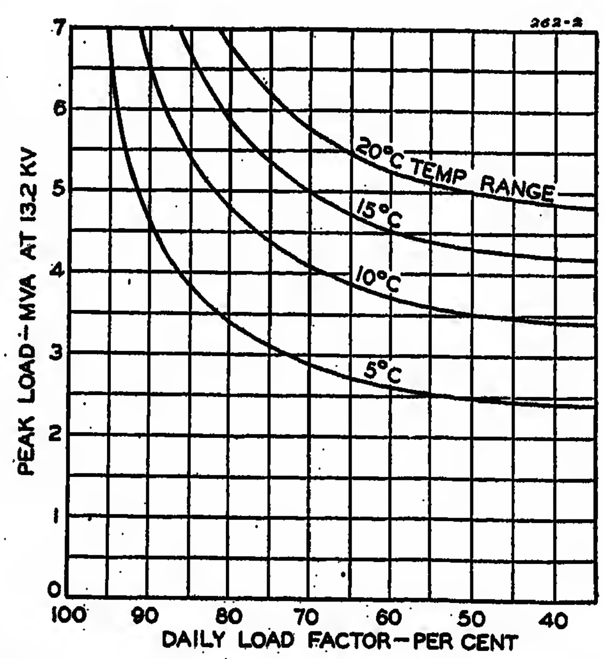

Figure 2. Allowable daily peak load for various conductor temperature ranges and daily load factors

Three-conductor 350,000-circular-mil 13-kv belted paper and lead cable

although individual units may operate close to capacity. This is due to fault capacity requirements, provision for load growth and use of standard sizes. However, individual transformers in a network may become overloaded and require relief. Vaults designed for a single bank may be large enough to install a second bank or a three-phase transformer. Either operating above name plate or operating with excess capacity in the vault will require added ventilation. Natural ventilation may be improved, or forced ventilation controlled by a thermostat may be required. Considerable reduction in ambient temperatures with a corresponding capacity increase may be obtained by ventilation improvement.

Improvement of vault ventilation and subway-transformer cooling has been investigated by the Boston Edison Company. The maximum safe operating copper temperature is established as 100 degrees centigrade at 100 per cent load, which results in a top oil temperature of approximately 80 degrees centigrade. During the summer of 1938 the problem of excess temperature on subway transformers became critical and was temporarily solved by flooding the vaults with water from the city mains. This method of cooling was entirely satisfactory as an emergency expedient, but a more permanent method of correction was necessary.

A fabricated steel grating was designed and used to replace the four-foot-two-inch-by-three-foot-two-inch solid rectangular covers in the roof of the vault.

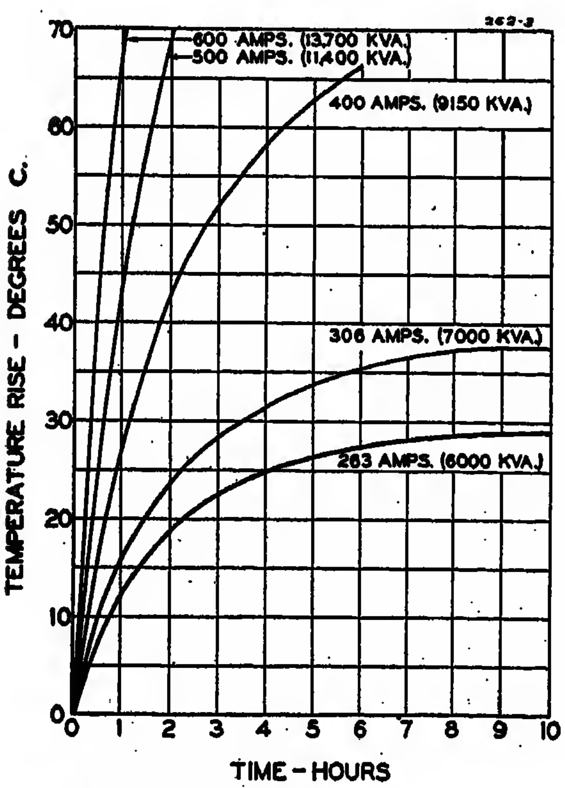

Figure 3. Conductor temperature rise above ambient

Laboratory test data

Three-conductor 350,000-circular-mil 13-kv belted paper and lead cable

This resulted in a reduction of 14 degrees in the manhole ambient temperature, although the differential between the top oil temperature and the manhole ambient temperature remained at 22 degrees centigrade. A net capacity increase of 15 per cent resulted from the reduced manhole ambient temperature provided by the open grating.

The transformer loading was so high that this reduction was insufficient to reduce the hot-spot temperature to 100 degrees centigrade. Experiments were then conducted with supplementary external radiators installed on the transformers. Two cast-iron radiators of $26^1/_3$ square feet of rated radiation each were used on a 100-kva three-phase cast-iron-tank transformer. One of two transformers in a vault with the open grating was equipped with these radiators and a ten-day heat run made on each transformer. This resulted in an indicated increase in capacity of 21 per cent for the transformer equipped with radiators when installed in a vault with the ventilating grating.

These tests showed that the combination of an open grating and external radiators on the transformer is equivalent in its cooling effect to flooding the manhole with water, and results in a more permanent remedy.

Insulation Limitations

The problem of cable loading cannot be separated from duct and manhole design. In order to determine the rating of any cable, the number and arrangement of ducts, the other load in the duct bank, the length of the duct run between manholes, the depth of the duct run, the length of the manhole, and the offset in the manhole must be known. Other factors involved are the soil conditions, the earth temperature, and local heating due to steam mains or other subsurface facilities.

Valuable work on the over-all problem has been done by the Commonwealth Edison Company and the results of these investigations presented by Halperin in 1939.[4] Investigations of safe operating temperatures and of the economics of duct loading have been made by the Consolidated Edison Company of New York and reported by Franklin and Thomas in 1939.[5,6] The over-all problem should receive greater attention both in the field and in the laboratory. Present conditions will give a large amount of field experience, and adequate data should be collected. This will supply information for the operation of the system at its maximum capacity and indicate critical conditions which can be corrected before they become serious. It will also add much to our present knowledge of how far we can safely increase ratings of cable and duct. In order to do this with the greatest benefit to the industry, an agreement should be reached on definitions and basic information to be collected.

The great majority of the cable which is in service in the classification being discussed is solid-type paper-insulated cable. Only this type of cable will be considered, although some of the factors may be applied in modified form to other types of insulation.

The maximum allowable copper temperature for solid impregnated paper-insulated cable under the AIEE rule is 90 degrees centigrade minus the rated voltage in kilovolts, but not more than 85 degrees or less than 60 degrees. This rule covers normal operation of the cable. Most users have developed certain working rules for emergency conditions. In some cases, these do not cause any material temperature rise above the basic rule but depend on the heat-storage capacity of the cable and duct. In other cases, the temperature is permitted to go substantially above the recommended level for short times at infrequent intervals. "Emergency operation" is defined in the Association of Edison Illuminating Companies Specification for Impregnated Paper-Insulated Lead-Covered Cable, Solid-Type (July 1941) as operation at temperatures approaching the maximum allowable emergency temperature for one period per year on the average and not for more than four periods in any one

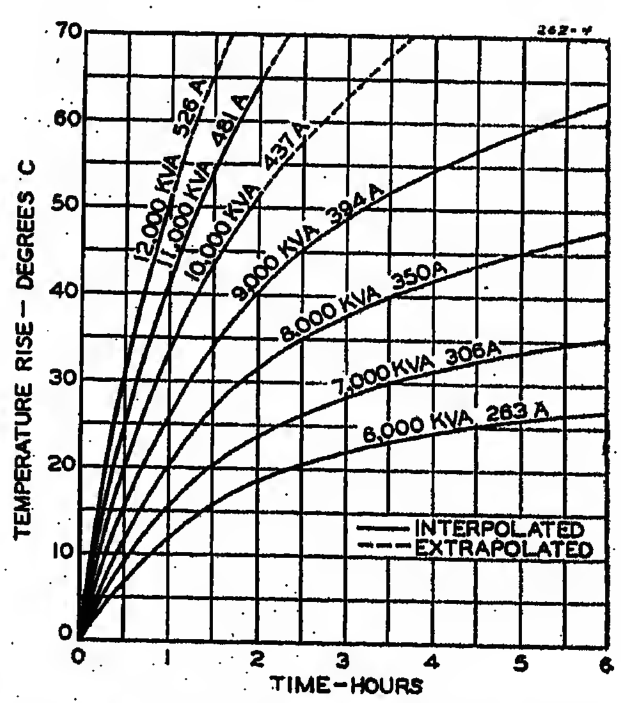

Figure 4. Conductor temperature rise above ambient

Interpolated from laboratory test data

Three-conductor 350,000-circular-mil 13-kv belted paper and lead cable

twelve consecutive months, each period being not more than 24 hours. The maximum temperatures permitted are 115 degrees centigrade for cables operating up to 1 kv, 102 degrees centigrade for cables operating up to 5 kv and 96 degrees centigrade for cables operating up to 15 kv. These temperatures are being exceeded in some cases, at least one company using 110 degrees centigrade for cables up to 5 kv. Cables up to 15 kv are generally being operated at a maximum emergency temperature of 90 degrees centigrade, although some experimental work has been done at higher temperatures.[4,5]

Duct Limitations

From the above rules, ratings can be developed for cable in various types of ducts, duct formations, soil conditions, and duct occupancy. Complete empty-duct temperature surveys are the most satisfactory method of determining the ratings which should be applied to the cables in any duct bank. In applying the temperature rule literally the hot spot must be used, since no part of the cable should rise above the recommended temperature.

Duct banks have a definite thermal limitation so that many of the old 16-, 20- or larger-duct lines may be thermally loaded, even though there are vacant ducts available. Figure 1 illustrates a typical summary of the analysis of test data for a survey made in Philadelphia on a 20-duct bank containing 13 cables. The survey consists of taking daily temperatures by thermocouples installed in empty ducts and hourly load readings for all cables in the duct bank. The average readings for three consecutive days are used.

The analysis considers the existing actual load factors of the cables in the duct bank. The load factor probably will not change sufficiently in a year to materially change the results.

This chart is predicated on the fact that the upper limit of duct bank temperature (empty-duct air temperature) is determined by the rise of copper above empty-duct temperature for a selected rating of the cable. The cable involved is a three-conductor 350,000-circular-mil 13-kv belted paper and lead cable. At the normal rating of 265 amperes it has a temperature rise of copper over adjacent empty-duct air of 27 degrees centigrade as determined by calculation and confirmed by test. With a maximum allowable normal copper temperature of 77 degrees centigrade for this class of cable, we must limit the empty-duct air temperature to 50 degrees centigrade. This

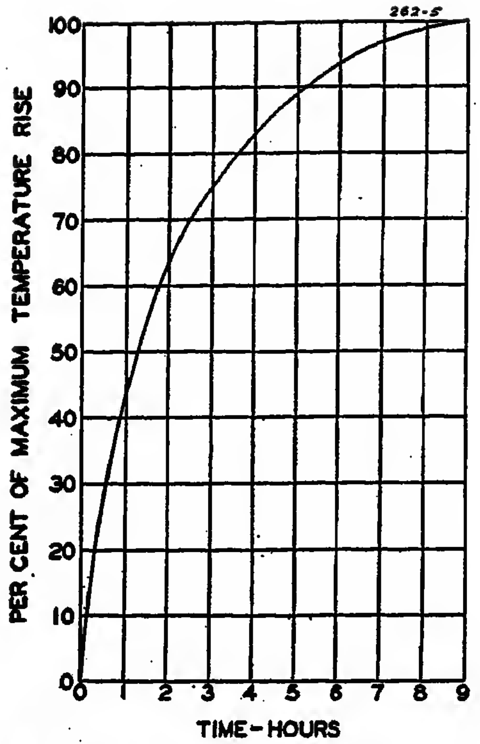

Figure 5. Heating time of cable in terra cotta duct (for all loads)

Three-conductor 350,000-circular-mil 13-kv belted paper and lead cable

agrees with the findings of Church,[10] Halperin[4] and others on the recommended maximum duct-bank temperature.

Similar charts are used to determine the need for additional duct lines and have been made for many of the critical locations.

Sheath Limitations

Insulation deterioration is not a serious problem with modern distribution cables operated at temperatures well above the AIEE temperature rule.[4–8] It is estimated that the sheath life is from one half to two thirds of the insulation life if recommended temperatures are observed. Temperature variation rather than temperature level causes the major damage to the cable by causing sheath deterioration. The absolute sheath temperature does not materially change the lead characteristics at temperatures below 70 degrees centigrade. Research to extend sheath life is being carried on in the laboratory, but field experience and investigation must come from the cable users to supplement the laboratory information.

Manhole size and design have a very definite relation to cable loading. Investigations have been made and reported,[4] and additional investigations are in progress. The majority of older manholes are too small from the standpoint of cable movement, and inadequate protection is provided at duct mouths. Modern practice provides for a longer and wider manhole and for fewer ducts with improved protection for the cable at the duct mouth. Badly congested manholes in critical locations can be materially improved by a program of rebuilding to more modern standards, which should result in a material reduction in failures due to sheath breaks. Such a rebuilding program would permit higher cable ratings on the rebuilt portion and require very little critical material. Present information is incomplete, but generous manhole construction should be provided wherever the space is available. Halperin[4] has recommended a minimum manhole of 10 by 6 feet for three-conductor 500,000-circular-mil 13-kv cable, and 8 by $4^{1}/_{2}$ feet for three-conductor 5-kv cable of 375,000 circular mils or less.

Small cables have less cable movement for the same temperature variation than large cables. Cable conditions can be materially improved by using three single-conductor cables of the same copper cross section in place of one three-conductor cable. This will result in a substantial reduction in the sheath damage without any decrease in the rated loading of the cable. One objection on certain applications is that the cable impedance will be increased approximately ten per cent so that such a cable cannot be operated in parallel with an existing three-conductor cable. However, on radial feeders a substantial increase of the cable rating will result from the use of single-conductor cables.

Cable movement has been related to temperature variation.[4] Cable movement has been related to sheath damage to show that increased movement results in increased damage although present information is incomplete. Factors to be considered include the size of cable, thickness of lead, type of lead, frequency of movement, size of duct, length of manhole, and man-hole offset. Halperin has shown that a long length of cable will have proportionately less movement than a short length for equal temperature variations.[4] More recent information has indicated that up to a variation of 25 degrees centigrade, the movement at the duct mouth for 800- to 900-foot lengths is the same as for 300- to 400-foot lengths. Long lengths of transmission cable have been installed in Chicago, Cincinnati, and Newark. The experience with these cables will be valuable for future installations.

Temperature variation is dependent upon load factor, since, if the load does not change, the only temperature variation is due to the duct-bank temperature change. Figure 2 shows the peak load plotted against the daily load factor for various temperature ranges. The range is the same for a 6,500-kva peak at 95 per cent

factor as for a 3,000-kva peak at 73 cent load factor. These values are puted but field investigation indicates are conservative. Origi- 1 1926 it was given a rating of 265 s per cable, which, due to duct con- , is about ten per cent above that ted by the AIEE rule. This was d at or above its rating for a num- years, and then in 1936 for station y reasons the rating was in- to 289 amperes. The failure ubled following this increase, and it was reduced to the original rat- he average failure rate during the of service has been 28.5 per 100 which is a high rate but, neverthe-less, would result in an average cable life of 29 years. Cable-failure rates of this order are extreme and cannot be considered good practice. However, in spite of this high failure rate, the life is so long that obsolescence and system changes have to be given equal weight with service failures. In the fifteen years of operation there have been 95 failures, 28 in the first 10 years and 67 in the last five years. This latter period includes the period of increased rating. During the past $2^1/_2$ years, accurate failure records have been kept and show that 80 per cent of the failures can be attributed to cable movement. Manholes in this entire duct run are small and severely congested, and much of the damage is attributed to this. More modern manholes with adequate space would result in a very substantial reduction in the failure rate. Cable can be punished severely year after year and continue to operate. The economics of this case indicate that it has been good business to operate the cables this way.[9]

Cable rating must be distinguished from cable loading in the operation of a system. The practice in some companies is to establish a rating for the cable but permit the loading to reach only 85 per cent or 90 per cent of the rating. If the system of rating is reliable, the forecasted load should be permitted to equal the rating. In one case[5] the cable rating for 50 cables was raised to a basis of 100 degrees centigrade copper temperature, but later records showed that cable loading had been very little higher than under the old rating. However load growth will gradually change this so that additional capacity will result. Capacity will be made available by working the cable loading right up to the rating. This should be on the basis of average loading and not on short-time swing peaks.

Conclusions

Past investigations and recommendations have been based on restricted experience obtained in the laboratory or on relatively small test installations in the field. There is every reason to believe that the period we are now going through will result in creating a giant laboratory out of our present systems. Our first responsibility is to continue to carry the load and all load which is added. To do this we must search out and eliminate the "hot spots" and "bottlenecks." Material must be used where it will give the greatest return. Secondly, we should get the greatest possible return from this condition to use in future design to build better and more economical systems. An investigation of the following conditions will permit us to do both of these intelligently:

1. Earth temperatures in the vicinity of duct lines.
2. Duct-bank temperatures—studies of various types of duct banks with respect to construction and environment.
3. Cable-sheath temperatures—correlation of cable-sheath, occupied-duct, and empty-duct temperatures.
4. Cable loading—hourly load readings with special consideration to emergency and abnormal conditions. This should be related to above surveys.
5. Cable movement—the relation of cable movement, load changes, section lengths, and load factor.
6. Cable operating performance—careful analysis of cable failures and sheath breaks. Particular attention should be given to failures due to expansion and contraction and to thermal insulation failure.

Table II. Emergency Ratings—13-Kv Three-Conductor 350,000-Circular-Mil Belted Cable—Amperes

Normal—265 Amperes

	After Normal Load	After Less Than $1/_2$ Normal Load
$1/_2$-hour emergency	460	520
2-hour emergency	365	395
4-hour emergency	330	350

Summary

1. Provide all reasonable safeguards for the system.
2. Prepare for emergencies and rapid restoration of service.
3. Provide adequate emergency stocks of cables and accessories.
4. Maintain an adequate inspection and maintenance program.
5. Maintain complete records for use in determining present ratings and future revisions.
6. Review ratings of all cables and permit load to reach rating.
7. Rearrange load connected to cable to improve load factor.
8. Provide adequate reliability to all load by alternate routes.

Power Supply to Distribution Substations in Wartime

H. P. ST. CLAIR
MEMBER AIEE

1. Introduction

THE purposes of this symposium in relating distribution engineering to the present war emergency have been fully introduced and set forth in the opening paper so that further elaboration will be unnecessary here. As indicated by the title, the discussion in this paper will be confined principally to transmission substations and subtransmission lines, all as a means of supplying distribution substations. An attempt will be made to explore ways and means by which more capacity can be obtained from a given amount of material and labor, both in existing facilities as well as in the design and construction of new facilities.

2. Transmission Substations

It might be said that transmission substations are the beginning of distribution, since such substations furnish the supply to subtransmission lines, which in turn supply the distribution substations. The importance of transmission substations in relation to the present war-emergency program is very great. With the exception of generating facilities, the possibilities of their becoming bottlenecks on the system may be more acute than almost any other system element, because of the larger size and more or less special design of equipment required for each particular substation. For this reason it is particularly desirable to explore the possibilities of getting more capacity from existing equipment, and to design new substations in such a way as to use material and labor most efficiently.

Transformer Capacity

While the problem of obtaining larger capacity from transformers is, in many respects, the same, whether these transformers are in a transmission substation or a distribution substation, there are some essential differences. For example, the transmission substation transformers are usually of much larger capacity and more or less "tailored" to fit a particular job, and, hence, there is less possibility of shuffling them around from one substation to another, as is often done to advantage with distribution-substation transformers. Also, because of the greater dependence placed upon such units in supplying not one, but a considerable number of distribution substations, relatively greater care in maintenance and in any procedure used in overloading such capacity should be exercised.

Several possibilities for getting increased capacity from transformers, some of which will also be discussed in a companion paper dealing with distribution substations, will be suggested below.

On existing self-cooled transformers it is possible in practically all cases to obtain an increase of 25 per cent to $33^{1}/_{3}$ per cent in capacity by the application of fans or blowers for forced-air cooling. Where the transformers were originally designed for such cooling, such a procedure would, undoubtedly, be adopted forthwith when increased capacity is needed, and no particular problem would be involved. Permanent blower or fan equipment should be obtainable within a few weeks.

On self-cooled transformers not originally designed for it, the application of forced-air cooling must include a check on the current-carrying capacity of leads, bushings, and so on, with a possible change, if necessary, in some of these to make sure that all parts of the circuit are adequate for the larger transformer output. In extreme emergencies, any type of fan, even a large portable fan, could be used to obtain a quick capacity increase.

In the case of self-cooled transformers already equipped with forced-air cooling, and for water-cooled transformers, an increase in capacity can be obtained by forced oil circulation with external coolers or radiators. These radiators can be air-cooled, or in extreme cases could be cooled by refrigeration.

It should be noted that to get the full cooling effect and resulting maximum capacity out of water-cooled transformers, the cooling coils must be maintained in good condition and free from internal scale or deposit. A thorough cleaning of cooling coils has often resulted in a substantial capacity increase.

The use of external water spray may be found of value in certain emergencies, particularly during hot weather. While this method does not offer a large increase in capacity, at the same time it is inexpensive where water is readily obtainable, and can be applied very quickly when needed.

Referring again to a companion paper on distribution substations, mention is made of the possibility of loading transformers on a temperature basis to values well beyond name-plate ratings, and references are made to material published on this subject. The basis of all of this, of course, is the fact that most transformers possess a certain amount of inherent overload capacity, varying with the load factor and ambient temperature conditions under which the transformers operate. Since we may be forced to use this overload capacity whether we choose to do so or not, it may be possible to do it more safely and intelligently in the light of quantitative analyses as to the effect of overloading on the over-all life of typical transformers, and from these, arrive at

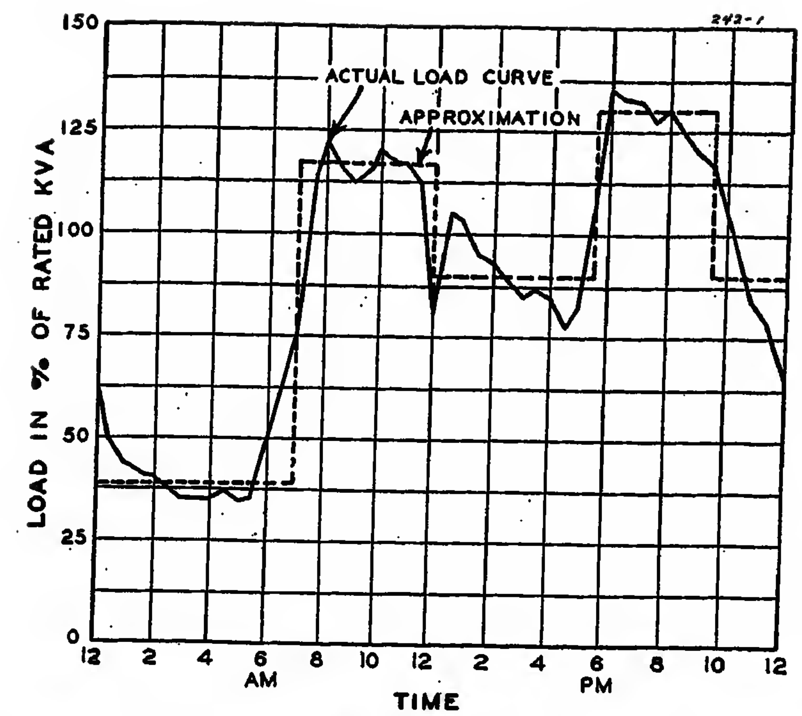

Figure 1. Typical assumed load curve for substation transformers

Load factor 67.5 per cent

Assumed peak load 130 per cent

some measure of the amount of overloading which can be reasonably tolerated.

As an example of the type of analysis which can be made, Figure 1 gives a typical assumed load curve in which the peak load is 25 per cent above the transformer rating. Based upon this loading, Figure 2 has been prepared showing the loss or consumption of life in this transformer for various levels of ambient temperature. This analysis has been made on the basis of data published by Nichols and others[1,2] and obtained from exhaustive tests on the effect of temperature on the life of insulating materials in oil. It is obvious from Figure 2 that a lowering of the ambient temperature by only a few degrees very greatly reduces the effect of a given overload in consuming the useful life of the transformer.

Actually the data used in the above analysis are believed to be well on the conservative side. For one thing, the ratio between copper and core losses has been taken as 2.75, which is considerably higher than average practice. A lower ratio would obviously mean a smaller increase in heating on overload. This and other margins of safety in the figures used, along with results of field experience, tend to support the conclusion that actual transformer life would be considerably better than indicated by the analysis.

A particular instance where it may be considered entirely permissible to make rather liberal use of the inherent overload capacity of transformers would be in the case of an outage of one unit where two units are normally operated in parallel. While it should be done only on the basis of some knowledge or analysis as to the oss of life involved, nevertheless, a much

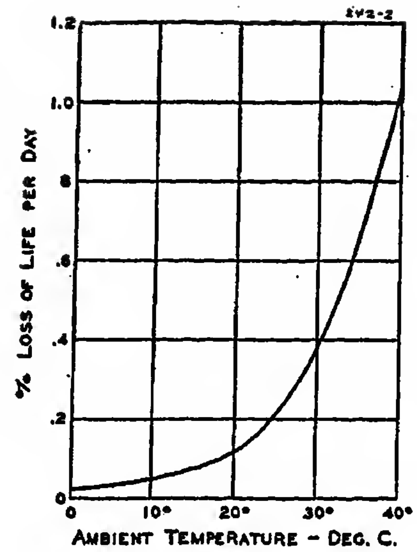

Figure 2. Daily loss-of-life curve for transformers operating on load curve of Figure 1 at various ambient temperatures

higher rate of consumption of life could be allowed in this case as against the cost and, particularly during the present emergency, the availability of full spare capacity to carry the entire load. As a matter of fact, this practice, at least to a degree, would be sound economics during normal times.

Portable Car-Mounted Transformers

As pointed out above, the transformers used in transmission stations are usually fairly large and more or less "tailored" to fit a particular job, as compared with distribution station transformers. For both of these reasons, there results the possibility of a serious bottleneck to the supply of power in case of

1. A serious transformer failure.

2. A sudden demand for increased power, either at an existing location or at a new location for which it may not be possible to obtain new transformers within the available time.

To take care of such emergencies, primarily on transmission substations, there have been designed and constructed for one system, the system with which the author is associated, portable emergency transformers permanently mounted on specially designed railroad cars and arranged with a considerable number of voltage, tap, and phasing combinations to cover practically all of the transmission-substation requirements on the system. The capacity of these transformers was made as large as railroad clearances and other limitations would permit, and the entire equipment includes lightning arresters and all necessary auxiliaries mounted on the cars. With the exception that lightning arresters must be dismantled during transportation, the entire transformer is carried complete with bushings and oil in place ready to operate as soon as it reaches its destination.

Because of the extreme range of requirements to be covered by such transformers, two complementary units of approximately equal capacity and physical size were used. One of these, with a three-phase capacity of 15,000 kva, was designed for stepping down from 132 kv and 110 kv to any of the lower voltages down to and including 11 kv. Transformations from 132 kv to 110, 88, and 66 kv were obtained by autotransformer connections, while other voltages were obtained by two-winding combinations.

The other unit, having a three-phase capacity of 17,000 kva, was designed to cover the intermediate step-down ratios from 88 kv, 66 kv, and 44 kv down to lower voltages from 44 kv to and including 11 kv.

The size and weight of these transformers, approximately 85 tons each, requires each unit to be permanently mounted on a special 100-ton, drop-frame-type railroad car, which is designed, however, to meet all the requirements of the Interstate Commerce Commission and the Association of American Railroads. The cars are registered with the latter

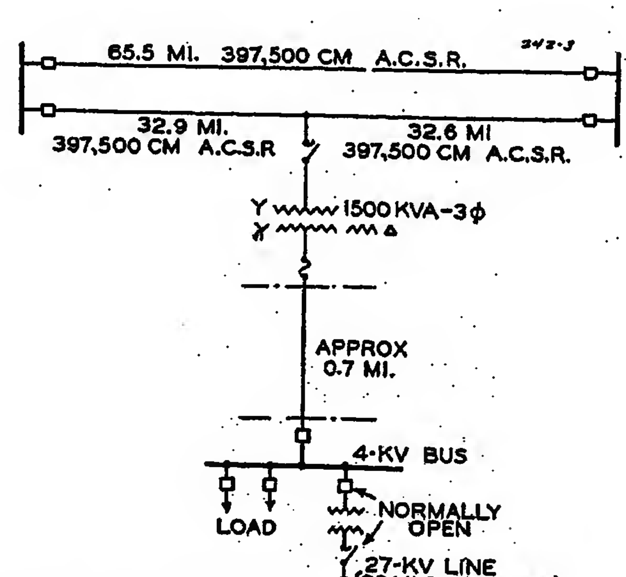

Figure 3. Small-capacity transformer tapped to 132-kv transmission line with minimum protection

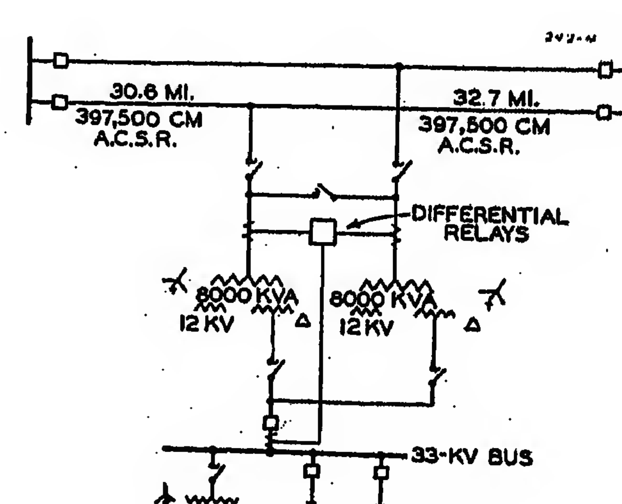

Figure 4. Medium-capacity three-phase transformers tapped to transmission line with automatic air-break switches

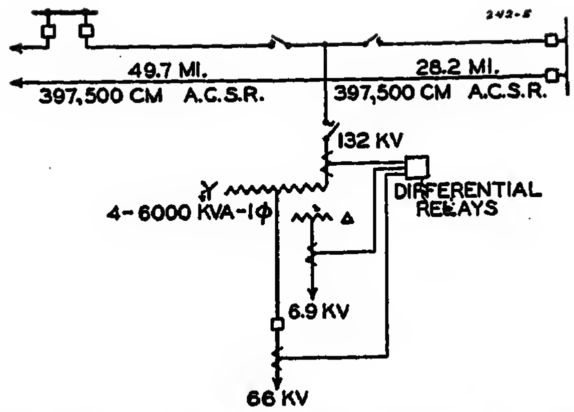

Figure 5. Large-capacity transformer bank tapped to transmission line with automatic line sectionalizing

and subject to the same obligations and privileges as any other railroad freight car.

Inasmuch as railroad sidings are not or cannot be made available at all of the transmission substations or other possible locations where it might be necessary to use these portable "universal" transformers, it will be necessary at such locations to unload a transformer from its car and transport it over highways, using special highway trailers owned by local contractors. For this purpose the weight can be materially reduced by removing the oil and some other equipment from the transformer.

Switching Equipment

As in the case of distribution stations themselves, as pointed out in a companion paper, the rapid expansion of electric systems now taking place, and which will undoubtedly continue to a large extent during the war emergency, creates a serious problem in connection with the interrupting capacity of circuit breakers at transmission stations. In many cases the growth of systems far in advance of expectations has brought about circuit-breaker duties in excess of capacity at stations fairly recently built, or where circuit breakers have recently been modernized. A number of procedures may be suggested for taking care of this circuit-breaker problem.

Probably the most economical solution, where it is applicable, is the rebuilding or modernizing of circuit breakers to increase their interrupting capacity; this, of course, can only be done in certain cases where the breakers are of older design, and where an increase in capacity can be brought about in the rebuilding process. Such a program should result in a substantial saving in material and labor and generally also in cost over the complete replacement of the circuit breakers.

A second solution, which, in many cases, may permit the necessary expansion of the station and, at the same time, hold down the interrupting duty on the circuit breakers to avoid the necessity of replacement, will be to split the bus into two or more sections, either with or without reactors to tie the sections together. Unless the system is designed on a well-balanced basis for operating independent bus sections, it will probably be necessary to use reactors to tie the sections together. In some cases it may be necessary to employ both of these procedures, that is, to sectionalize the bus and to rebuild the circuit breakers as well.

The third, and perhaps final alternative, will be to install new and higher-capacity breakers where the existing breakers are hopelessly inadequate. This, of course, does not save either cost or material, except where it may be possible to make use of the existing breakers at other locations for which new breakers otherwise would have to be purchased. This "shuffling" of breakers, with the purchase of only larger sizes wherever possible, and the shifting of smaller breakers to lesser locations, is sound practice from an engineering and economic standpoint, not only during emergencies but during normal times as well.

Disconnecting switches and air-break switches should not ordinarily present a problem in connection with increased loading on transmission substations but should be carefully checked and maintained, along with other equipment in the station, to be sure that adequate carrying capacity is available. Overheating of such switches will lead to progressive weakness and eventual failure if not taken care of.

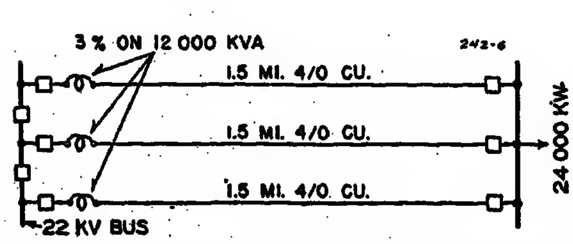

Figure 6. Original layout for 24,000-kw load

3. Tapping Transmission Lines With Low-Cost Transmission Substation

It has been generally believed in the past that important transmission lines should be used only to carry relatively large blocks of power between generating sources and major transmission stations, and that such lines should not be tapped to supply relatively small loads, because of the additional hazard imposed on the transmission lines. However, the economies made possible by occasionally tapping transmission lines with a relatively inexpensive step-down transformation have been so great that more and more installations have been made. Experiences with these installations, and the development of methods for installing and protecting such equipment, as well as the transmission lines themselves, have brought this practice to the point where it is now considered a very practical and successful means of providing service at many suitable locations. If a transmission line is available near the desired location, a tap on the line may be the logical and economical means of supplying loads directly, or reinforcing the supply to an overloaded subtransmission system. The alternative means of supplying a load by extending and reinforcing the subtransmission system may be much more expensive both in material and labor.

Many such installations have been made on the systems with which the author is associated, particularly for stepping down from 132,000 volts to various voltages all the way from 66,000 to as low as 4,000 volts. These transformer installations vary from the very small ones as low as 1,500 kva in capacity for serving a 4,000-volt load, to as high as 18,000 kva for reinforcing a 66,000-volt subtransmission system. The smaller installations, for obvious economic reasons, are made as simple as possible with a minimum of protective equipment. For this reason it may not be feasible to provide for clearing the transformer in case of fault in the transformer, so that it is necessary in this case to take the risk of transformer damage. Experience for a number of years, however, has been quite satisfactory in this regard. Figure 3 shows a typical installation of a small 1,500-kva three-phase transformer tapped to a 132-kv transmission line.

For larger stations and loads, more elaborate protective equipment is justified, although not the expense of high-voltage circuit breakers. Figure 4 shows a typical medium-capacity station with automatic air-break switch protection for the high side and with a differential-relay scheme for clearing the transformers in case of trouble. The two main functions of the protective equipment in this case are as follows:

1. For a transmission-line fault, the transformer is disconnected by means of its low-voltage circuit breaker from the subtransmission system, which would, otherwise, feed into the transmission-line fault through the transformer. To provide positive relaying of the transformer switch in case of line-to-ground fault on the transmission line, it is necessary that the transformer be wye-connected on the high side with neutral grounded.

2. For a fault in the transformer itself, the

transmission line is opened by its own relaying and the transformer disconnected from the low-voltage side by its own differential relays. Immediately thereafter, during an interval of approximately one minute while the transmission line remains de-energized, the transformer high-voltage air-break switch is opened up automatically from the operation of the differential relays. Following this the transmission line is restored to service.

The desirability of providing a grounded wye-connection on the high side of such a transformer may add slightly to the cost of installation:

1. By necessitating a delta-winding on the transformer if it results in a wye-wye connection.

2. By requiring the installation of a grounding transformer for the low-voltage bus if it results in a wye-delta connection, and it is also desired to establish a neutral ground at that point for the low-voltage system.

This additional cost, however, is usually considered well-justified to obtain the more complete relay protection which it affords.

While carrier-current relaying is actually employed on the transmission lines to which this station is connected, its use is not essential to the carrying out of the protective functions described above, except with regard to the ultrahigh-speed reclosing on the transmission lines. The operation of the transformer-differential relays provides a carrier impulse which stops the line from reclosing in case of a transformer fault; otherwise, the line would reclose on the transformer fault the same as for a fault on the line itself.

A still larger station with the most complete automatic protection obtainable without using high-voltage circuit breakers is shown in Figure 5. Here the transformer installation is large enough to justify the use of three single-phase units with a fourth as a spare. The manner in which transformer-differential protection, as well as transmission-line sectionalizing, is accomplished in this station, using automatic air-break switches only, is described as follows:

1. For a permanent transmission-line fault on either side of the station, the entire line is cleared, along with the low-voltage transformer breaker, and remains open for an interval of approximately one minute during which the two line-sectionalizing air-break switches are opened. Following this, both line sections reclose, the good one remaining closed, and the faulted one tripping and locking out. The sectionalizing air-break switch, on the line which remains energized, then recloses, restoring service to the transformer bank. The final step is the reclosing of the 66-kv circuit breaker on the low side of the transformer bank.

2. For a fault in the transformer bank, both the line and the transformer low-voltage breaker are cleared, but, in this case, the differential relays act to open up the transformer high-voltage air-break switch instead of the line-sectionalizing switches, after which the line recloses and the transformer bank remains de-energized.

As in the station of Figure 4, carrier-current relaying and ultrahigh-speed reclosing are used on the transmission line, and, for a differential-relay operation on the transformer bank, a carrier impulse is sent out to prevent the instantaneous reclosure of the line into a transformer fault.

The satisfactory operation of these stations, and of many others of which they are typical, has fully established the soundness of this method of supplying power directly from transmission lines at relatively low cost. The use of this device wherever favorable opportunities are presented offers one possibility for supplying power to distribution substations, and, in some cases, to distribution loads directly, with the most efficient use of equipment and labor.

4. Subtransmission Lines, Existing and Proposed

The term "subtransmission lines," as used in this paper, refers to the intermediate voltage systems, such as 22 kv up to and including 66 kv, which are generally used to supply distribution substations. Such lines, of course, may be supplied either from transmission substations or direct from generating plants. The rapid growth of load brought about by the present war emergency has posed the problem of getting more capacity out of existing lines, or of providing increased capacity in one way or another with a minimum expenditure of material and labor. While a most favorable solution of the problem will, of course, depend upon the particular factors and limitations in each situation, an attempt will be made to suggest methods of obtaining increased capacity in a number of typical situations that may come up.

Short Lines—Thermal Limits Controlling

For lines that are relatively short with respect to the amount of power and voltage, the capacity limitation may be almost entirely a matter of the thermal limits of the conductors themselves, rather than limitations due to voltage regulation. In many cases, however, both of these limitations must be taken into account. Typical ways of obtaining capacity increases in situations of this kind may be suggested as follows:

1. Where several circuits with conductors of moderate or small size are already operated in parallel, the most economical and efficient method of obtaining an increase in capacity may be the rebuilding of such circuits with a considerably larger conductor, on the assumption, of course, that the existing conductor can be salvaged for needed use elsewhere. This method offers certain substantial savings in that

1. No additional terminal switching is required.

2. No additional right-of-way is required.

3. In the case of wood-pole lines in good condition few if any structures will have to be replaced.

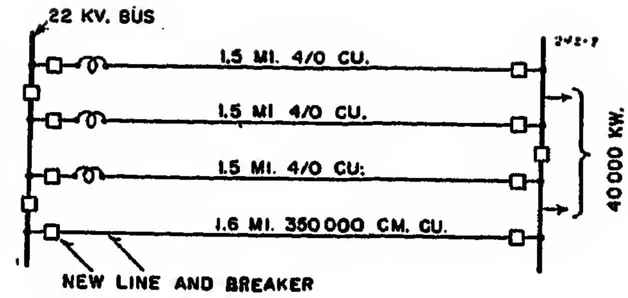

Figure 7. First step to increase capacity of lines to serve 40,000-kw load

If the use of larger conductors alone is insufficient to provide the necessary increase in line capacity, it may become necessary to construct additional circuits which, because of right-of-way difficulties, will usually be at least as long if not longer than the existing circuits. In such an event, the use of a larger conductor on the new circuit will be of little advantage, unless the conductors on the original circuits are enlarged at the same time. In other words, if the existing circuits are not changed, any attempts to load up the new circuits in proportion to their larger conductor capacity would result only in exceeding the thermal limits of the existing circuits.

As an illustration, Figure 6 shows a typical case of three parallel 22-kv lines serving a 24,000-kw steel-mill load. The reactors in these feeder circuits were originally installed to limit the interrupting duty imposed on the feeder circuit breakers. Two steps of increased capacity were required, first about a 50 per cent increase to a load of 36,000 kw, and later an increase to more than double, or approximately 70,000 kw. In carrying out these steps, the procedure outlined above was actually reversed because of the presence of the reactors in the original feeder circuits. Figure 7, therefore, shows the first step, which consisted of building a new circuit of 350,000 circular mil of copper to operate without any reactor and in parallel with the three existing circuits. As a result of this arrangement, the new circuit, both from the standpoint of thermal limit as well as actual impedance, had a capacity of approximately $1^1/_2$ times that of the old circuits, and thus provided the necessary 50 per cent increase in over-all capacity.

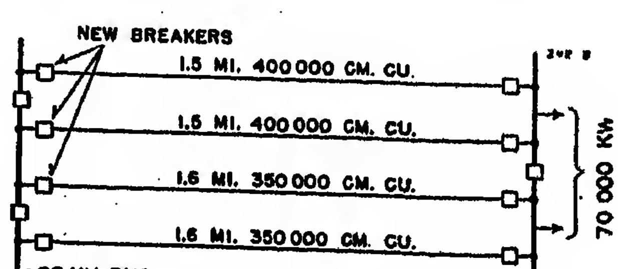

Figure 8. Final layout to serve 70,000-kw load

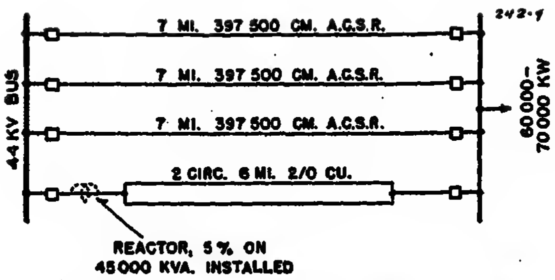

Figure 9. Unequal impedances of lines in parallel—resulting in bottleneck

The final arrangement of the setup, to increase the capacity to approximately 70,000 kw, was then obtained as shown in Figure 8. Here the reactors in the original three circuits were removed, new circuit breakers of adequate interrupting capacity were installed, and the existing number 4/0 copper line conductors were replaced with 400,000 circular mil of copper. Both the breakers and line conductors removed in this process were used elsewhere.

In this case at least three new circuits of the same capacity as the original circuits would have been required to handle the final load increase so that the method of changing conductor size resulted in a net saving of two circuits with all the terminal equipment, line construction, and so on, pertaining thereto. At the same time, voltage regulation under the final setup was quite satisfactory.

2. In other cases of relatively short heavily loaded lines, it may not be feasible to change existing conductors; for example, where steel tower lines are already carrying the maximum physical load. Such a situation may be further aggravated by the necessity of taking a longer route for new circuits.

Figure 9 shows a typical instance where one number 2/0-copper double-circuited line constituted a bottleneck when operated in parallel with other circuits of larger conductor size. Here the installation of a reactor in the number 2/0 copper circuits eliminated the bottleneck and allowed all of the circuits to carry load commensurate with their actual thermal limitations. At the same time, with the fairly short lines involved, no voltage regulation problem was introduced by the use of the reactor.

Medium Length Lines—Both Thermal Limits and Voltage Regulation Involved

In some situations, it may be necessary to increase the capacity of an existing system, consisting of a number of circuits of medium or small conductor size, which cannot readily be changed for physical and economic reasons. Because of increasing right-of-way difficulties, as in the cases mentioned above, it is often necessary that any new circuits constructed to relieve the old circuits be of longer length which immediately defeats the purpose of using larger conductor size or even the same conductor size. At the same time, the use of reactors in the existing circuits would be undesirable from the standpoint of voltage regulation as well as from the standpoint of the number of circuits involved.

For a typical situation of this kind, shown in Figure 10, it was desired to construct two new circuits of relatively high capacity to operate in parallel with four existing circuits of medium capacity, but right-of-way conditions necessitated a longer route for the new circuits. A solution was found in the use of a series booster transformer of simple design connected in each of the two new circuits and operated as part of the line. Using a 60-degree series voltage, obtained from an adjacent phase of a wye-connected transformer as in the zigzag transformer connection, these transformers introduced both a voltage boost and a phase-angle shift to force the line to carry a heavier share of both kilowatts and reactive kilovolt-amperes. The desired results in loading, as shown by Figure 10, were obtained with only $2^1/_2$ degrees angle shift and the corresponding voltage boost of about $2^1/_2$ per cent, which required a series winding of only five per cent. Such an installation, even allowing for a maximum angle of five degrees for future contingencies, can be made relatively inexpensively, as it does not require additional switching facilities or a transformer designed for changing taps under load. Taps, of course, should be provided, but can be changed by momentarily de-energizing one circuit at a time. The amount of phase angle required is so small that it should not be necessary to remove it under light load conditions.

Longer Subtransmission Lines—Voltage Regulation Controlling

In some situations, the length of lines and loading is such that voltage regulation rather than thermal limitations is the determining factor. If the system is laid out with sufficient circuits to give reliable loop service, the use of some means for voltage regulation is probably the most efficient and economical way of increasing system capacity. If not too many stations are involved, individual regulation such as load-ratio-control transformers might be used. Where the need for regulation is quite extensive, it may be more economical and otherwise more advantageous to install one or more synchronous condensers for power factor and voltage control. The beneficial effect of synchronous-condenser operation, particularly if installed at the proper load point on the system, extends over the entire system and even permeates all the way back through the transmission and generating systems. The increase in capacity provided thereby is usually greater than that obtainable from other types of voltage-regulating devices.

If systems such as these are traversed by high-voltage transmission lines, transformer installations tapping directly to the transmission lines may offer the most economical means of increasing the system capacity and at the same time solving the voltage-regulation problem. Even with a synchronous condenser installation, the problem remains of providing the necessary transformer capacity at the transmission substations or other points of supply for the particular system involved.

Increase in Capacity by Revised Concepts in Operating Practice

In addition to the ways and means discussed above for obtaining increased capacity in subtransmission systems by actual physical changes in these systems, there is also the possibility of getting more out of existing systems merely by a change in prevailing conceptions as to what constitutes feasible operating practice. In other words, during the present emergency situation, it may become necessary to revise existing standards as to the combined requirements of service continuity and voltage regulation. For example, in cases

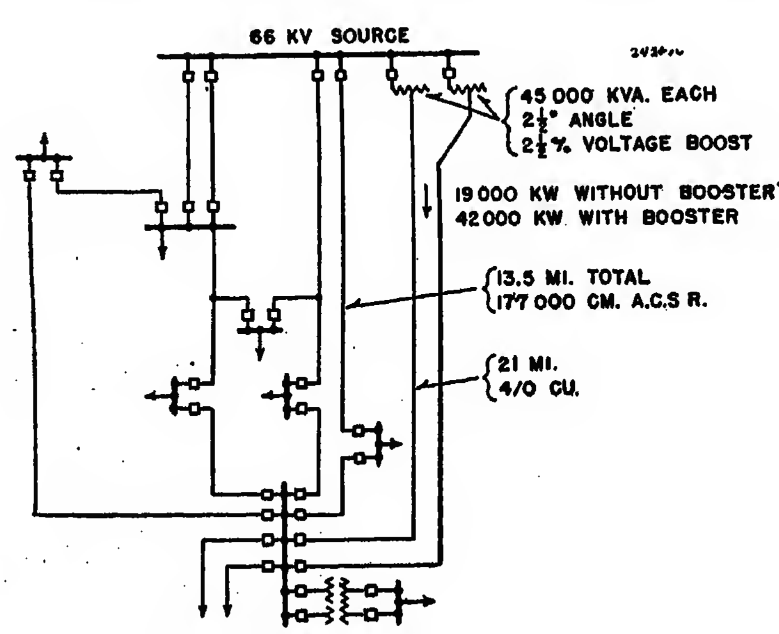

Figure 10. New circuits with larger conductor but greater length compensated to pick up load

where thermal capacities have not been reached but where voltage regulation is the limiting factor, it may be quite proper to dispense with the common criterion of being able to handle the peak load within prescribed regulation limits with one line out of service, and rather to load all of the lines to the point of permissible regulation and accept an emergency reduced voltage if one line goes out. This, of course, cannot be carried to an extreme such as where the load is supplied by only two lines, since the loss of one such line would result in practically no service at all. It should be feasible, however, where three or four circuits are operating in parallel. Such a situation, of course, is not the most desirable and should be avoided if possible but it may be a necessary sacrifice during the emergency to dispense with the luxury of perfect voltage regulation under all expected line-outage conditions.

In other cases, where thermal capacity limits do enter into the problem, it may be necessary to allow an appreciable encroachment on the normal thermal limits on a short-time basis during the outage of one line, so that a larger loading can be carried with all of the lines in service. In defense of such loading, it may be pointed out that line outages of long duration are relatively infrequent and, furthermore, the simultaneous occurrence of a long-time outage during both a high ambient temperature and a low wind-velocity condition would be relatively improbable.

5. Conclusion

It is realized that only a few of the many possibilities that exist for more efficient handling of the problems of power supply to distribution substations have been touched upon in this paper. It is obvious that for such ideas to be utilized at their fullest potentialities, a substantial background of system planning and studies is needed. But even in such cases knowledge of possibly new but tried methods of approach should help.

It is hoped that the suggestions and examples which have been given in this paper will be of value not only as direct suggestions but also indirectly as an incentive to further thought and discussion on this important subject.

Distribution Substations and Wartime Necessities

F. C. POAGE
MEMBER AIEE

M. W. REID
NONMEMBER AIEE

Synopsis: Requirements of war will impose unprecedented demands upon many distribution substations. Equipment will be overloaded before extensions can be built, if at all. New construction must be simplified to the bare essentials. Substitute materials must be used. Protection and maintenance must be intensified and operating personnel must be educated to new responsibilities and skills. These are discussed and means are suggested to meet these needs.

LIMITED to that very important part of the whole power system indicated by the title, that is, the "distribution substation," it is the purpose of this paper to make suggestions, to stimulate thought, and to invite discussion of means available under wartime conditions to serve increased loads, to preserve and protect existing equipment, to provide for restoration of service when outages occur, and to employ the available materials, equipment and man power economically in the necessary extensions to existing substations and in the construction of necessary new substations.

The authors do not here presume that they have exhaustively treated the subject, and they confidently expect that in addition to their suggestions many other means will occur to engineers and operating men and will be developed from time to time under the varying requirements of individual situations.

More Intensive Use of Existing Equipment

The three principal functions for which distribution substations are established are: transformation, voltage regulation, and switching. Usually, apparatus for all these three, together with accessories such as line entrances, potheads, cables, lightning arresters, busses, instruments, meters, and control equipment are grouped together in assemblies of varying capacity and complexity, depending upon local needs and the preferences of designers and users.

Bottlenecks limiting the load which may be carried from a given substation may appear in many items of the equipment mentioned. Their correction or removal often can unlock substantial increments of vitally needed capacity.

Transformers

In general, power companies do not load main power transformer banks to the limit of their capabilities. However, as loads continue to increase during this emergency, in advance of the possibility of obtaining equipment, many transformers will have to operate far above manufacturer's rating.

The idea that a transformer name-plate rating is a limit beyond which load must never go dies hard. Transformers may be operated without distress at loads well above kilovolt-ampere ratings upon the basis of temperature. There is considerable material published on this subject which can be re-examined with profit at this time.[1–4] To carry load on transformers beyond the limit fixed by temperature under self-cooling, some form of artificial cooling must be used. For this purpose, artificial air circulation and water jets are most common. Under emergency conditions, almost any form of fan will circulate the moderate volume of air required if there is a sufficient number of these fans properly disposed to reach the greater proportion of radiating surface of the transformer. The use of water jets is more effective than air circulation but is, of course, confined to those locations where supply of water can be made available. Forced circulation of the insulating oil through separately-mounted radiators or water-cooled heat exchangers is also possible. This scheme is particularly adaptable to indoor installations. By use of these methods of cooling, loadings may be increased, often 50 to 200 per cent over name-plate kilovolt-ampere rating, depending upon the daily load cycle, prevailing ambient temperatures, the scheme of artificial cooling adopted, and liberalness of design of the transformers themselves.

Paper 42-61, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 15, 1941; made available for printing December 17, 1941.

Voltage Regulators

Voltage-regulator loadings may be increased in precisely the same manner as transformer loadings, except that in step-type regulators, the tap-changing switching equipment must be considered. In some instances, induction-type regulators having series parallel windings can be doubled in current capacity by connecting windings in parallel but at a sacrifice of half the range of regulation obtainable when operated in series. It has been too often observed that the "bucking" half of the available regulating range is unused. In such cases, this reduction of range will entail no hardship if the bus voltage is adjusted on a scheduled cycle. Booster transformers may be installed in conjunction with regulators connected in this manner to maintain voltage at locations where its level at peak otherwise would be objectionably low.[5]

Circuit Breakers

Increases in current-carrying capacities of circuit breakers can be obtained in some instances through silver-plating of contacts and bushing studs, and by frequent careful inspection and adjustment to assure maintenance of contact pressure. Switching arrangements can be adopted which place two circuit breakers in parallel, but care must be exercised that the impedances of parallel leads are equal, lest the resulting current unbalance overheat contacts and other current-carrying parts of one of the breakers.

When adding to transformer kilovolt-ampere capacity, either by replacement of an existing bank with larger units or installation of additional units, the increase of transformer capacity may increase fault current sufficiently to exceed the interrupting capacity of the circuit breakers. In such a case, if the substation has two or more transformer banks installed, the main bus may be separated into two or more sections, thereby limiting fault current to a value within the capability of the circuit breakers. This method introduces an element of inflexibility into the operation of the substation and to that extent may be objectionable, but it may be the only practical solution to meet the situation at hand. Another solution is to arrange to trip one or more of the transformer breakers or a bus-sectionalizing breaker a few cycles ahead of the feeder breakers in cases of high-current faults, thereby reducing the current to be interrupted by the feeder breakers.

Reactors may be inserted between bus sections normally fed from different transformer banks. A method of limiting short-circuit current applicable where bus sectionalizing is not possible is the insertion of series reactors in the supply circuits. Such reactors will introduce additional regulation and losses into the supply circuits. This effect, where objectionable, may be overcome by normally short-circuiting the reactors through a breaker or fuses co-ordinated with the time characteristics and interrupting capabilities of the feeder breakers.[6] Series reactors may, in emergencies, be "homemade" and constructed from materials that are stock items, that is, bare copper cable and concrete.

If a circuit breaker of adequate current-carrying and interrupting capacity is available, it may be used with appropriate relaying as a group breaker to open a group of feeder circuits when fault current exceeds the interrupting capacity of individual feeder breakers. The analysis of individual situations will often indicate that the impedance of only a few hundred feet of overhead line is required to reduce the fault current to a value which can be safely interrupted by the feeder breaker. By carefully adjusting relay settings, unnecessary operations of the group breaker can be held to a minimum and consequently only a very small percentage of the total tripouts will involve interruptions on feeders in the group which are not in trouble.

Finally, in some cases, the risk will have to be assumed that such faults as do occur will not be of maximum magnitude, and hence breakers will continue to be used at locations where their interrupting ratings are exceeded. This forced decision will unquestionably be reached frequently in the days ahead.

It seems hardly necessary to point out the increased need for thorough and frequent inspection of circuit breakers during this emergency and of keeping them in even higher state of operating efficiency than has been the practice in the past. When apparatus so necessary for protection of vital equipment becomes difficult, if not impossible, to replace, its preservation assumes great importance and reasonable added expense to assure that preservation is warranted.

Other Switching Equipment

Air-break switches and disconnecting switches, particularly those of earlier manufacture, may have capacities increased through the silvering of contact areas and increase of contact pressure. In some cases, this may involve the use of clamps installed over the jaws of contacts. However, it is fortunate that this apparatus as installed is generally of liberal current rating and is seldom a bottleneck in the system.

Cables and Duct Lines

Forced ventilation of cable tunnels, manholes, and duct lines may be required to reduce ambient temperatures and increase capacity of cable circuits. Such

Parallel facilities together with such sectionalizing facilities as are usual and desirable for transfer of load and isolation of faulted sections are provided at points A, B, and C

ventilation must be directed so that, in case of failures, fires will not be spread to other parts of the substation or operators driven away from their posts of duty.

Busses and Connections

Drastic restrictions in use of copper have been imposed by the Office of Production Management. Copper as a conductor of electricity is recognized as necessary, and power companies undoubtedly will continue to obtain the metal, but in reduced quantities and after much delay. This delay may even become the equivalent of no deliveries at all in the cases of special sizes and shapes of bars and fittings.

Busses and equipment leads are usually of ample current-carrying capacity without exceeding the usually accepted temperature rise of 30 degrees centigrade. This rise, however, may be materially exceeded without deleterious effects on buses, leads or equipment attached to them. Increase of current in the bus of the order of 20 per cent above the limit fixed by present standards seldom will raise bus temperature more than an additional 10 degrees centigrade, if there is reasonably adequate opportunity for dissipation of heat. Higher operating temperatures may require additional provision for expansion, some contact surfaces may require silver-plating to reduce local heating, and soldered joints may need to be replaced by brazed or welded joints. Forced ventilation may be required to protect adjacent apparatus and cables from heat generated within enclosed bus structures. In special cases, temperature of bus bars may be lowered where one section of the bus carries all or a large proportion of the total current, through rearrangement of incoming and outgoing circuits to reduce the current carried in any one section.

Obtaining Additional Circuits and Releasing Switching Equipment

Many substations are in operation which have duplicate equipment not essential to normal operation. Some of this may have to be "borrowed" for more active duty elsewhere. This often can be accomplished without introducing serious operating handicaps. Figure 1 and Figure 2 illustrate one example of this procedure. Figure 3 shows how, in some instances, this may be carried further, still retaining reasonable operating flexibility.

Where duplicate bus and switching facilities are used primarily to permit regular maintenance work on the usual 40-hour-week basis, the rescheduling of this work on a three-shift 24-hour-day basis will often permit these changes and simplifications.

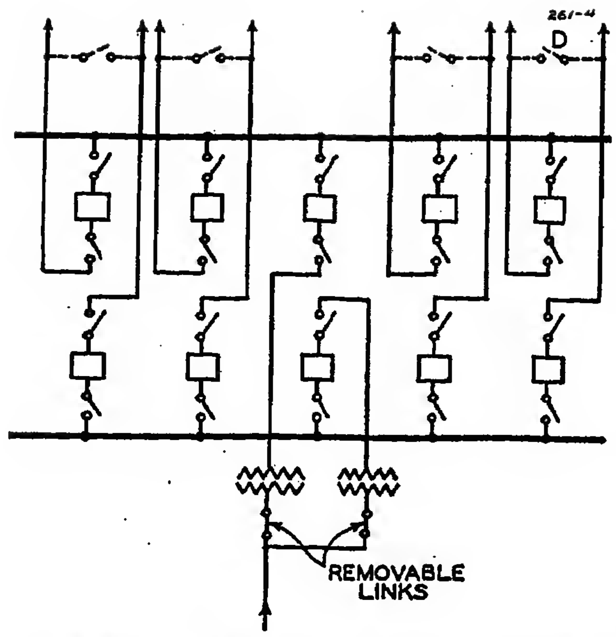

Figure 4. Suggestions for doubling number of circuits and transformer capacity with no additional switching equipment

One-line diagram of double-bus substation of Figure 1 converted to a dual single-bus substation with doubled transformer capacity and number of circuits

Parallel facilities similar to those shown in Figure 3 are provided at point D

Interrupting duty on oil circuit breakers is not increased by this increase in capacity

Figure 4 illustrates a means of doubling the number of circuits and the transformer capacity of the substation of Figure 1 without either increasing the number of breaker positions or the interrupting duty on the breakers.

Automatic high-speed reclosing has been advanced in recent years as a working substitute for duplicate service. Where this would result in saving new construction in the distribution system, the rebuilding of older low-speed breakers may be avoided in substations arranged as in Figure 1 and Figure 2 by the following relay scheme, reference being made to Figure 2. To effect this operation, an auxiliary relay is connected to the trip circuit and auxiliary switches of breaker A, such that completion of the opening cycle of breaker A energizes the closing circuit of breaker B_2. With disconnecting switches a_1, a_2 and a_3 and b_1, b_2, b_3 and b_4 closed, tripping of breaker A will then automatically close breaker B_2 and re-energize feeder A.

Static Capacitors

Where static capacitors are installed on distribution systems, consideration should be given to their proper location on feeder circuits for relief of substation equipment and apparatus that may be severely overloaded.

Installation of capacitors at substations, although not usually as productive of over-all system economies as when installed near the load centers on feeders, may still relieve overloaded condensers, transformers, subtransmission circuits, and system generating equipment. Switching groups of capacitors to control the reactive load and bus voltage can effectively take the place of synchronous condensers or extend the regulating range of existing synchronous condensers.

Customer Co-operation

The co-operation of power customers in scheduling as much of their operations to off-peak periods as practicable offers possibilities for releasing capacity in all current-carrying facilities. There are many industries and commercial enterprises where this off-peak use of power can be effected without difficulty and others where it may be accomplished after careful study and planning. It seems likely, in the emergency, that such co-operation will not be too difficult to obtain where off-peak operation is at all practicable. Co-ordination of the maintenance schedules of customers and power companies should be developed to minimize interference with wartime production and the burden on reserve facilities.

Equipment Capabilities

Operating men will be able to meet load changes and utilize the maximum capabilities of equipment only by keeping themselves more than ever intimately informed of load conditions and the actual capabilities of equipment available, and by using utmost ingenuity in applying that knowledge. Transformers, regulators, circuit breakers or other equipment may become heavily loaded at one substation, and replacement by larger more lightly loaded units from another substation may be indicated. However, only through a thorough knowledge of the equipment itself and what it may be expected to do, can the operating man know whether or not the transfer is justifiable. By keeping information up to date, the need for rearrangement may be anticipated, planned in advance, and changes effected with a minimum of delay.

Equipment and materials in stores should be inspected and, if necessary, reconditioned for immediate use. Thereafter, these should be maintained in readiness in the same manner as those already in service. Many units of equipment and items of material that in more normal times would be looked upon as obsolete or unsuitable for further use can

be reused, either by the company, a sister company, or a customer. It is a reasonable prediction that reserve equipment will be depleted and older equipment outmoded or formerly considered inadequate will be found highly useful in the days ahead.

Intercompany Co-operation

Consideration should be given to the exchange of information among power companies as to the availability of equipment that may no longer be needed for use by the one, but invaluable perhaps for service by another. There should also be merit in a tool-lending and exchange service, similar to that which is understood to be in operation among some of the Canadian utility companies, and in expansion of such service to include replaceable equipment and materials.

Power companies, in the past, have co-operated fully in times of need, and in this emergency period the utmost co-operation is required that all may together better perform a difficult job.

Economies and Conservation in New Work

Planning and Design

In the design of substations to serve wartime loads, a very large "factor of ignorance" must be dealt with in the preliminary stages. Experience has indicated that actual demands may vary up to several hundred per cent from preliminary figures.

As scarcity and priority restrictions both operate to make materials and equipment difficult to obtain, initial orders should cover the full requirements of the work. To run short of materials needed to finish construction may seriously postpone operation of the facilities. To insure against omission of materials required for complete construction, plans must be prepared in greater detail than heretofore considered necessary. This greater detail will also assist erection in view of the lesser skill and experience of the available labor. Extreme care should be exercised in obtaining accurate material lists from the plans. Construction work must be carried out with fidelity to plans, as small changes may call for materials not on order and procurable at best only after long delay.

The scarcity of competent men applies with double force in the engineering and drafting groups, where the detailed planning of new work is done. Simplification of layout, use of standard or semistandard groups of equipment, and elimination of "special" items are all essential to keep down the burden of detail and to prevent mistakes.

Structures

Structural steel is, at the time of writing this paper, a shortage material, and its conservation is imperative. This may be accomplished through use of substation structures of greater flexibility and lighter weight, simplification of bus layouts and the substitution of wood.

In the design of steel substations, it has been more recent practice to provide rigid structures. This rigidity could be relaxed materially in distribution substations by providing for only slack-span attachments of lines to structures without sacrifice of needed strength or safety. There are many earlier structures of this lighter design in service throughout the country which continue to stand as evidence that these lighter, more flexible structures are adequate.

Wood can be substituted for steel in the majority of jobs. Where insulation is equal to that which would be used on steel structures, and where hardware is thoroughly bonded and grounded, wood structures are electrically equal to steel. Many wood structures long have been in every-day operation. There is no question but that they can be built to operate satisfactorily for all usual voltages, will last through the war period, and will conserve materials sorely needed elsewhere.

Bus and Circuit Arrangement

Many of the plants recently established for producing war material provide for power supply to at least half of the load from each of two sources, including separate substations. The practice of providing transfer-bus, inspection-bus, or other duplicate-bus arrangements for new distribution substations should be abandoned for the duration of the conflict in the interest of conserving needed materials and equipment. To serve loads for which separate feeds are already provided, this practice is inexcusable. To serve loads not vital to prosecuting the war, in view of the impelling needs of the times, the omission is amply justified. Substations, if expected to be permanent, may well be designed to permit future elaboration and installation of additional facilities when conditions will permit.

For high-voltage moderate-current bus bars and connections, structural steel shapes or steel pipe may be substituted for copper tubing or bar so long as copper continues to be a shortage material and more difficult to obtain than steel. It may be necessary to use copper cable as bus in lieu of copper tubing or bar, as it seems likely that copper in such form will be more readily obtainable and requires less labor for production and installation. Busses may be reduced in cross section at a saving of material through design to operate at higher current density and through reducing bus current by locating the supply transformer connections as closely as possible to the load center of the substation bus.

Fuses in Lieu of Breakers

Fuses can be substituted for high-side breakers in substations of simple layout. One precaution may be needed, that is, phase-failure relays may be needed to open the low-side breakers to prevent damage to customers' polyphase equipment in case the supply to the high-voltage side is single-phase due to blowing of one fuse. With this precaution and with proper fuse co-ordination, the installation of high-side breakers may be eliminated, and indeed has been eliminated under normal practice in many situations with satisfactory results.

Insulation Levels

Insulation levels and insulation co-ordination should not be sacrificed in the case of simplified substation layouts. The cost of protecting service by providing adequate insulation strength is very little compared with that of duplicate facilities, throw-over switches and other provisions, which are usually installed to permit continued service in case of apparatus failure. In one case, the cost of the next higher level of impulse insulation in an important unit of substation equipment accounted for only five per cent in the cost of that one item. This might well be considered as representing the insurance necessary to permit elimination of permanently installed duplicate or spare equipment with accompanying switches, bus, and cables.

Transformers

The power companies which in the past made a consistent effort to standardize transformer voltages and taps are in position to reap large benefits from this past effort during the present emergency. One of the advantages of this standardization is, of course, that such companies are in position to "play checkers" with their transformers, moving them about between substations to meet the shifting demands. In this connection, it would be well to emphasize the economy of buying new transformers only in the larger sizes in current use by such a company and installing these at locations where smaller transformers are overloaded so that they

in turn can be released for installation in new substations.

The three-phase transformer is more economical than three single-phase units of equal rating from the standpoints of material and labor that enter into its manufacture. It requires a single foundation of lesser volume, shorter and more simple bus connections, and fewer man-hours of labor to install. The modern three-phase transformer is reliable in operation and its use in substations of moderate capacity should be carefully considered as a measure of material and labor conservation.

New substation transformers, whether single-phase or three-phase units, should be obtained with blowers or at least with provision for their addition later. Additional capacity may be obtained in this way at a very small cost per kilovolt-ampere, and the economics of losses and regulation can well be neglected "for the duration."

Unit Substations

The limit to which substation capacity may or should be expanded at a given site should be very carefully considered with respect to the cost in dollars, materials and man power of transmission and distribution facilities immediately associated with it. The development of the factory-built single-unit-type substation consisting of transformer, regulator, circuit breaker, and auxiliaries in a single case offers a very attractive means of increasing capacity to serve a given area without adding to either feeder capacities or substation capacities at an existing site. These unit substations are particularly adapted to installations where it is necessary to reinforce feeder circuits by installing such units close to the load and breaking up heavily loaded feeders to keep load within the capacity of existing substations and their outgoing circuits. The fact that such unit substations may be installed quickly and moved quickly to new locations is a decided advantage in meeting unexpected shifts or additions to loads.

Unit substations are economical in material and labor required in manufacture and require less material and labor of erection for foundations, structures, and bus work than equivalent conventional substations. Their use is of advantage also in that labor required for installation may be largely of lesser skill.

During the trying days ahead, the use of unit substations may prove to be worth while even in instances where such use in more normal times might not be considered economical. Many of the substations erected to serve war loads or loads incidental to war activities will be idle after peace returns. Salvage of a conventional substation involves a considerable write-off, whereas the salvage value of a unit substation is high, there being little unrecoverable material and equipment, and a minimum of labor is required to move it to another point of use and to place it in operation there.

Restoration of Service

Reserve Equipment

Difficulty of obtaining priorities for additional equipment and the continuing growth of load will inevitably bring about active use of much of the reserve equipment of power companies. Restoration of service after equipment failure will then present a different problem than when spare facilities were more plentiful. It has been rather general practice to provide a spare transformer at every important substation. With increasing need for transformer capacity to carry the growing load, and the impossibility of obtaining new transformers in any reasonable time, it is likely that more of this reserve equipment will be placed in operation. It may then be that one transformer will have to serve as a spare for several transformer banks, probably at substations located some distance apart. Such a spare unit should be centrally located with respect to the substations where it may be required for service and kept in readiness for transporting and placing in service in minimum time. Skids should be in place and the unit cribbed to a convenient height for loading on the transporting vehicle. Flexible leads connected to the bushing studs and provided with clamps at the free end will save time in placing such a transformer in operation promptly. Other heavy equipment reserved for use as spares should be similarly prepared.

Transportation facilities for moving a spare transformer are, of course, necessary but there seems to be little justification generally for permanent mounting of spare transformers on special trailers. Transformers of modern design are reliable, and it does not appear that the delay occasioned in loading will justify the cost of transportation equipment that would be reserved for a single service and would remain idle over extended periods of time. In these times, we must recast our notions of what is necessary and what may be only desirable.

Portable Substations

In this period of emergency, portable substations in general do not seem to offer outstanding advantages as compared with separate units of spare equipment. Portable substations must be used as an entity and cannot be separated so that each component part can operate apart from the others. With spare equipment at a premium, it would seem to be the better policy to have spare units of equipment so that these units can be used at different locations as needed. For example, a spare transformer can be used in one substation and at the same time, a spare circuit breaker used for emergency service at a second substation. There may be certain systems where portable substations will have advantages over separate units of equipment, but in the majority of instances during the present emergency at least, spare units of reserve equipment offer a greater degree of protection to service in having a wider diversity of use, although the time element for restoring service may, in some cases, be slightly in favor of the portable substation.

Storage of Reserve Materials

Spare parts and materials held as reserves against substation outages may in some instances be stored at the substation of probable use or they may be stored in a central location. In the first case, the number of spare parts and quantities of materials required will be greater than would be necessary if centrally located. Central storage is preferable in offering the maximum availability of minimum quantities of reserve materials and in many cases permitting better maintenance and care. With either plan, spare equipment should be covered by careful up-to-date inventories both as to specifications and locations.

Protection and Preservation of Equipment

Inspection and Maintenance

Greater attention must be given to the operating equipment to observe or anticipate distress and thereby forestall failures in service. Equipment should be inspected more frequently and maintained at a higher degree of precise operating condition than has in many cases heretofore been considered adequate. Moreover, when inspection reveals the need for even minor adjustments, repairs, or replacements, they should receive appropriate attention at once. Failure to act in these minor instances does not necessarily mean that the equipment will fail to continue to operate satisfactorily, but it may and certainly will in some instances shorten the period before major replacements will be required. It should be kept

in mind that an ounce of preventive maintenance is worth a ton of replacement, especially when replacement is beset with present uncertainties.

Fire Protection

With the prospect of continuing intensive operation of equipment, it is not only vital to preserve that which we have but to protect it from loss. Fires are not frequent but when they occur in a substation, the damage to the equipment where the fire originates is all too often extensive. Moreover, except as precautions have previously been taken, damage to adjacent equipment is the rule. Any fire, even though it does no major damage, diverts man power from the primary function of operation and absorbs materials needed elsewhere. Often the incidental damage to other equipment and the interruptions to service necessary to clean up and make final repairs are of greater consequence than those involved in the immediate failure. Consequently, careful consideration should be given to protection against fire hazards.

Probably the most economical and effective protection available at this time against fires resulting from oil ignition in outdoor substations is obtained from water spray apparatus. Its use is, of course, limited in application to those locations where water may be made available. Transformers installed at important substations where water can be obtained may be protected by fixed or portable spray nozzles or by a combination of the two. Perhaps the most satisfactory over-all method is the combination of the fixed and portable apparatus. A moderate number of fixed nozzles properly installed will tend to prevent the spread of fire and reduce its intensity until such time as portable apparatus can be brought into action by trained men.

Where water is not available, dry-compound apparatus is quite satisfactory as are carbon-dioxide extinguishing devices, although at present the latter are costly and not always effective for outdoor use. Carbon-dioxide apparatus has its widest application indoors and for this use is most satisfactory in that there can be no deterioration of equipment resulting from its use.

Foam is effective for extinguishing oil fires under some circumstances but its use around electrical equipment is open to objection because of the work required to remove the caked foam after the fire is out.

Arrangements should be made for co-operation with local fire departments in the study of fire-fighting problems, in co-ordinating power company fire-fighting equipment with the department apparatus, and in joint drills and rehearsals. The most important element in minimizing damage is the adequate training and drilling of personnel in the proper use and limitations of use of whatever apparatus may be brought into action.

Lightning Protection

There is considerable divergence of opinion as to the need for lightning arresters, particularly for voltages above 66 kv. Experience of many operating companies in numerous widely separated parts of this country and Canada, under diverse operating and climatic conditions, has established the value of spill-gap protection for substation apparatus.[7] The valve action of the lightning arrester, by limiting the time and magnitude of power-follow current, reduces the number of interruptions from lightning surges, but evidence is lacking that the lightning arrester protects substation equipment more effectively than the spill gap. Conservation of material and labor dictates that serious considerations be given to the use of spill gaps in place of arrester installations at new substations or where replacement of arresters may be necessary.

Personnel Training

Of equal importance to protective equipment in the protection of property is a trained staff of operating men who in case of trouble or incipient trouble know what to do, how to do it, and can act promptly as a well-co-ordinated team. The time taken and money spent to educate and continue the education of these men in this important function will be amply justified. In view of conditions that confront the industry, each one should be induced to feel the added responsibility resting upon him. He should be instilled with an enthusiastic desire to do his full part in providing and maintaining the power supply for war and should be thoroughly trained to do that part well.

Conclusion

Difficult problems will arise in the days ahead due to scarcity of materials, equipment, and suitable man power, which problems must be solved by the engineer and operator in the struggle to serve the rapidly expanding war loads. The manner in which these men meet their more unusual problems will be of interest to all who have similar problems to solve. It will be of benefit if these solutions are passed on to the industry as a whole through publication currently in the technical press.

Experience may indicate that some of the needful practices of rigid conservation established during the present emergency will earn recognition as standard practices in the peaceful days that are to come.

Overhead Distribution Systems in Wartime

HAROLD COLE
MEMBER AIEE

Synopsis: An overhead electrical system makes use of large quantities of materials which are also very vital to the nation's wartime program. This paper seeks to point out the most practical ways of conserving these vital materials, thereby releasing them in greater quantities for use in wartime production. In general, this can best be accomplished by keeping to a minimum the quantities used to make the line extensions and system reinforcements which will be required to supply electric service to the new industries and military establishments, and to the increased housing facilities which must accompany them. A number of effective tools are available which may be utilized to reduce the quantities of conductor material required to give satisfactory service. There are also possibilities of rearrangement of existing facilities so as to use them more effectively.

Critical Materials Involved

THE critical materials which are used to the greatest extent in the construction of overhead distribution lines are copper, aluminum, steel, and zinc. Of these copper is by far the most important. Aluminum has been making considerable headway in recent years as a conductor material when provided with a steel reinforcement, but, while it has many good features to recommend its use, particularly for long span rural lines, competing materials of copper-steel composite have been made available which can be used to build these lines. The fact that aluminum has been practically unobtainable for some time was not a serious handicap as long as we were still able to get copper-steel composites. These materials, however, are now being greatly restricted in their availability, and the problem, so far as copper is concerned, is, therefore, to find ways to minimize its use, since no substitute material other than aluminum is available. Various possibilities of accomplishing this purpose will be discussed later.

Steel is used in considerable quantities in overhead-distribution-line construction, principally for line hardware and fittings. It would be difficult to find a substitute material which would be nearly so suitable for such important items as bolts and nuts. For certain uses, however, such as insulator-pins, crossarm-braces, platforms, and other fixtures requiring a considerable proportion of the steel tonnage used in overhead-lines construction, wood is quite a satisfactory substitute.

Zinc is important in overhead-lines work, mainly as a coating for steel to prevent rust. The tonnage used for galvanizing of line hardware is not very great, however, and it is to be hoped that its use, particularly for bolts, nuts, and so forth, may be continued. On the materials of larger size it will be possible to use coatings composed of less vital materials which, while less permanent, will be effective through the present emergency and can later be replaced with more lasting materials.

The need for materials, other than metals, used in the construction of distribution lines is not immediately critical but there is a good chance that it may be unless their consumption is curtailed. Poles and crossarms are the most important of these items. Due to increased consumption of these materials in connection with military and emergency housing, stocks of seasoned material have been seriously depleted, and it is reported that unfavorable weather conditions in pole-producing areas have resulted in a subnormal output of new poles, especially in the larger sizes. Conservation in the use of poles and the avoidance of large stocks not immediately required will help keep to a minimum the amount of substandard materials used in the construction of lines which will need early replacement.

Means of Conserving Materials

In general, the conservation of vital materials can best be accomplished in four ways:

1. By using the minimum possible amount of material on all new line extensions.

2. By using the minimum amount of vital material for bolstering up existing lines when overloaded or under-voltage conditions result from increased loads.

3. By rearranging existing facilities so as to use them more effectively.

4. By salvaging needed materials from existing lines where they are not immediately required to give adequate service.

New Line Construction

The most effective way to save material is, of course, not to use it. To the extent, therefore, that restrictions are applied to the extension of lines to serve potential consumers, there will be an almost proportionate reduction in the amount of material used for overhead-line construction. This is for the reason that in periods of expansion the greater proportion of material used goes into the construction of lines to serve new areas. Unless a real effort is made to concentrate housing facilities in compact groups, this will still be the case. It is not within the scope of this paper to discuss the restrictions to be placed on new line construction by those in control of the allocation of material. Of one thing we are certain, and that is that extensions will be made to serve new projects vital to the emergency effort. It would seem almost equally imperative that the necessary extensions be made to serve new housing facilities which are, in a great many cases, essential to the war effort.

In the building of such new lines as are permitted, every effort should be made to keep the material used to a minimum. The most obviously beneficial expedient is to use the least possible amount of copper. The size of the wire used should be the minimum to give reasonably satisfactory service to the initial customers, unless increased loads are known to be coming in the immediate future. For most distribution engineers this will be a reversion to obsolete practices, since it is the way things were done before the adoption of system-planning methods. We can well remember the frequent and costly reconstruction, replacement, and revamping of lines which were necessary in those days. It must be admitted, however, that building to an ideal ultimate plan sometimes results in the installation of line capacities which are much more than adequate for a large part of their useful life when load growth is slow. In the light of present shortages, we would be justified in returning to the old-fashioned method of using the smallest size of wire which would do the initial job, even if, in some instances, it may require changing to a larger size in a year or two.

It may also be possible to justify some modifications of the pole layout so as to conserve material. Temporary short-cut routings of line extensions may be resorted to in some cases to reduce the

Paper 42-45, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted December 1, 1941; made available for printing December 17, 1941.

HAROLD COLE is distribution engineer for The Detroit Edison Company, Detroit, Mich.

length of line required. The use of longer spans in the initial stages of residential development will conserve poles, crossarms, hardware, and insulators. The ultimate spacing of poles in residential areas is invariably fairly close, because of the necessity of keeping customers' service drops reasonably short, but, if poles can be so spaced that the later installation of intermediate poles as the area builds up results in a good layout, an initial saving in material can be made. In many cases, where the building-up process is not rapid, an over-all saving in investment results. The use of bare primary wire, if permissible, will favor the adoption of this "double-span" construction.

Increased Loading of Existing Facilities

The second objective of the conservation program, namely, the devising of ways and means of carrying increased load on existing lines and equipment with the minimum use of vital material offers the greatest opportunity to the distribution engineer for contributing to the war effort. As loads increase on the electrical distribution system, two limitations operate to cause need for increased capacity in lines or equipment. These are:

(a) Excessive heating which may cause damage or possibly failure.

(b) Excessive voltage drop which may result in decreased efficiency of utilization equipment and even make its operation impossible.

The current-carrying ability of wires and line devices is affected by many widely variable factors, and, in general, the commonly accepted current ratings are arbitrarily conservative. In arriving at these ratings, a combination of conditions is selected which very rarely occurs in practice, and tests made under actual field conditions show that loads considerably in excess of these ratings may be carried for long periods without resulting in any appreciable damage to overhead lines and associated equipment.

Limitations to Wire Loading. The heating of overhead conductors, for example, is greatly affected by air movement, and yet the limiting ratings are often based on temperature rises in still air with high ambient temperatures. As there is practically always some air movement past conductors in overhead-line construction, the effect is to very materially reduce the actual temperature rise. Furthermore, even at the assumed limiting temperature, the effect on the wire or equipment would be serious only if continued for long periods of time. Very seldom will a condition hazardous to service or persons result.

Limitations to Transformer Loading. The loading of distribution transformers is a good example of the ability of equipment to successfully carry so-called overloads. This subject has been discussed at considerable length in recent technical publications* and will be treated only briefly here. The factors which make it possible to carry peak loads greatly in excess of the name-plate rating are:

1. The thermal capacity of the iron core, the insulating oil, and the tank, absorb heat from the windings and greatly reduce the resulting temperature rise on short-time peaks.

2. The loads of highest peak values and longest duration usually occur in winter when ambient temperatures are low and the resulting temperature in the windings is correspondingly reduced.

3. The limiting temperatures assumed in the rating would cause failure of the transformer only after continuous operation over a period of years.

The greatest problem in the proper loading of distribution transformers, of course, is to know what the character of the loads is on individual transformers, both as to yearly peak value and as to the shape of the load curve throughout the year. However, the general characteristics of residential loads are sufficiently well established that, with any one of several methods of determining transformer peak loads, it will be conservative to allow estimated winter peaks of the order of 150 per cent of name-plate rating. Under this procedure, experience shows that transformer life should be reduced very little, if any, over that which would be obtained by more conservative loading. However, before proceeding to materially increase transformer loading beyond this point, it is particularly important to have adequate information on load characteristics and values, since a large number of damaged transformers on a system would be a serious detriment to good service in later years.

Limitations to Voltage Regulation. Excessive voltage drop, causing wide variation in voltage regulation to customers, will probably be a more frequent cause for system reinforcement than current limitations. Here, again, it would seem that present accepted good practice could be modified somewhat during the emergency. Fairly narrow ranges of voltage regulation may be largely justified by economic considerations in normal times, although by the same consideration we cannot afford to maintain as high standards on rural lines as in thickly settled urban districts. When, in the face of serious material shortages, economics is no longer the ruling consideration, it would seem that standards of voltage regulation which apparently are giving satisfactory service to the farmers should not be too poor for the city dweller to put up with for the period of the emergency. This should apply, not only to the long-time variations, but to the sudden fluctuations commonly known as "flicker."

Improvement of Power Factor. In spite of increased current ratings and more liberal voltage limitations, the time will be reached, as loads increase, when something will have to be done to bolster up the supply. But, this need not always take the form of adding new facilities or replacing old ones with like kind of larger capacity. One of the most promising expedients which is available, not only to improve voltage regulation on overhead lines but to decrease the line current capacity for the same load, is the use of shunt capacitors to improve the power factor of the load. An extensive use of this device has been justified under the normal economic conditions of the past few years, and it offers a very effective means of conserving vital material under present conditions. It is true that capacitors require for their construction an appreciable amount of aluminum foil, but the amount of copper which could be saved by their intelligent use should recommend them very highly to the authorities having to do with the allocation of all of these materials.

The use of shunt capacitors will find its best application in the densely loaded parts of our systems, where the reduction of current will often be as important as the reduction of voltage drop in the circuit. In rural areas where conductors are small, loads are light, and power factors high, shunt capacitors are not quite so effective a remedy, although they may still be justified in many cases. The effect of the capacitors is to cause a constant voltage rise in the circuit which will, if too many capacitors are installed, cause too high voltage at light-load periods unless provisions are made to cut out portions of the capacitance. So far, no economical method has been devised for this purpose which is applicable to small installations.

Series capacitors should also be useful devices for improving the capacity of long lines serving individual customers, although they will not have as wide an application as shunt capacitors by reason of the lack of flexibility in their application.

Voltage Regulation and Boosters. Another very economical expedient avail-

* See list of references at close of paper.

able to improve the regulation of long rural circuits is the use of line-type voltage regulators or step-voltage boosters. These are now manufactured in a wide range of sizes and steps of voltage change. The simpler forms of step-voltage boosters are quite satisfactory for rural or suburban line regulation, and their use produces an improvement of voltage regulation which would require many times the amount of material in conductors to produce like results.

Standard distribution transformers, if they have the proper turn ratio, may be used very effectively as a booster to produce a better range of voltage in a circuit at a very low cost. A small amount of fixed voltage boost at a point fairly well out on the circuit will result in a considerable improvement in peak load voltage to the customers on the tag ends without causing too high voltage at off-peak periods. Booster-transformers connected to give a larger amount of voltage boost, used in connection with automatic regulators to permit the better use of the full range of the regulator, will also prove to be a useful expedient where conditions are favorable. For a slight increase in cost, standard transformers may be purchased with increased secondary-to-ground insulation which will insure their satisfactory operation as booster transformers.

Rearrangement of Existing Facilities

In any well engineered electrical-distribution system there will always be an appreciable amount of wire and equipment which will be capable of carrying much greater loads than they are at the time called upon to carry without exceeding either current or voltage limitations. This is partly the result of the planning of system development to follow a layout of facilities which will be adequate to serve an area after it has become completely built up without too much replacement and rearrangement of the initially installed material. A critical shortage of materials, however, may make it desirable to do a certain amount of rearrangement of these materials at this time, so as to use them more effectively and thus reduce the amount of new materials required. Line wire and transformers are the items of overhead-line construction which offer the best possibilities of such treatment.

Removal or Replacement of Wire

Expedients to conserve the use of conductor material which should be given most consideration are as follows:

1. Replacement of the larger sizes of wire with smaller in locations where the load has not yet developed or has been greatly reduced by system rearrangements, and the transfer of the larger wire to locations where the load is increasing rapidly. This will in turn release, for the relief of other circuits, an amount of wire nearly equal to that originally used, if proper salvage methods are used to prevent the scrapping of any large part of the material in the process.

2. Building new sections of line which will shorten feeds to increasing loads rather than replace or add wire on existing routes. This will frequently be practical in suburban or rural areas where piecemeal extensions often result in a poor layout. In many cases, when this is done, sections of line of lengths equal to that installed can be salvaged.

3. Removal of wire which is not required to maintain service except in case of the failure of some other source of supply. Throwover connections, ring feeds, stand-by lines are frequently installed to improve reliability of service to customers. Perhaps, if material shortage becomes really critical, a lowering of service reliability standards would be justified, and some of these facilities could be removed in situations where no consideration of public safety is involved.

Since most of these expedients will release more material than they will require, it is hoped that some method will be found to make it possible either to secure blanket approval of their use or to set up some very informal means of securing approval of individual projects. Otherwise, the volume of paper work and the delays entailed in securing approval may be so great as to seriously discourage any attempt to adopt them. This is particularly true in the case of overhead-lines work where individual projects are small and their number very large. The volume of paper work necessary for specific approvals could easily become so great as to seriously interfere with more important projects.

Conservation of Transformer Capacity

In parts of many overhead-distribution systems, the ratio of demand on a circuit to the total installed transformer capacity on the circuit will be found to be low. This would seem to indicate a large surplus of transformer capacity, which it should be possible to utilize to serve new loads, and reduce, if not eliminate, the necessity of purchasing new transformers for some time. Actually, the possibilities of doing anything very helpful with this situation are not very good. In rural or suburban areas, one of the locations where this ratio of circuit demand to installed capacity is very low, the widespread use of electric ranges, refrigerators and other types of appliances causes high short-time load demands which make it necessary to provide larger transformers than would otherwise be required, in order to give satisfactory voltage conditions. Also, the demands on the individual transformers are not coincidental, and, because of this diversity, the demand on the circuit is much less than the sum of the demands on the individual transformers. The ratio of the circuit demand to the total installed capacity is, therefore, not a proper measure of the loading of the individual transformer and the surplus capacity is more apparent than real.

In urban areas also, during the initial stages of development, this ratio of circuit demand to transformer capacity is low. It might be thought that, in this case, an increased spacing of transformers would reduce the number required with no increase in initial size, but very few liberties may be taken with the spacing of transformers without producing intolerable voltage conditions. Larger secondary wire would be of very little help in this connection and its use would only increase the use of vital material. It would also be unwise to go too heavily into the use of very small transformers for the initial stages of urban area development. The reduction in vital material would not be anywhere near the ratio of the reduction in size, and, in the future, it would probably be impossible to find economical use for them anywhere on the system. Indeed, many of us, with the extensive development of rural lines in our territories, are already having difficulties in finding use for the smaller transformers removed from the farm lines by reason of increased demands of customers on these lines requiring replacement with transformers of larger capacity.

It should be possible to utilize some of the surplus transformer capacity already installed by making interchanges of transformers as some become loaded up and others do not. This will be particularly true if full advantage has not already been taken of the possibilities of loading transformers to the limit of their thermal ability. By this means it should be possible to reduce appreciably the total kilovolt-amperes of transformer capacity required on the system. It will still be necessary to buy new transformers if extensions are made to new areas since, for the reasons given above, it will be difficult to release any large number of transformer units from existing lines.

Salvaging Operations

In addition to conserving new materials for line construction, a great deal can be done toward the same end by the maximum use of material removed from the lines, of which there is usually a considerable amount in any large organization.

Highly profitable salvage operations have already been organized in a number of companies for this purpose, and in the present emergency it is imperative that this practice be adopted by all operating utilities.

Salvage operations which are most productive in the conservation of line materials are the following:

1. Cleaning, straightening, and splicing together into standard lengths all wire suitable for reinstallation.
2. Removing weatherproof covering from wires not suitable for reinstallation, and splicing in lengths suitable for recovering or use as bare wire.
3. Cutting up very short lengths for use as tie wires, ground-rod pigtails, and so forth.
4. Reconditioning hardware, fuse carriers, lightning arresters, and all articles of line equipment not hopelessly obsolete.
5. Cutting off rotted sections of poles and retreating them for use as shorter poles or guy stubs.

Conclusions

It is to be hoped, of course, that some of the expedients suggested in this paper will not be necessary as they involve burdensome operating costs and much additional labor. In some localities now, and probably generally later on, labor will be difficult to obtain. Other expedients involve a lowering of standards of service to our customers and should be adopted only in moderation unless the situation becomes quite critical, and then only with the approval of the authorities charged with regulation of service standards. Failure, however, to adopt some of the practices, which are in the interest of the conservation of materials and are at the same time favorable to the economical design and operation of the electrical system, would be called unprogressive at any time. In the present national emergency, it should be considered unpatriotic.

THE machinery manufacturers are being required to solve many design and production problems in connection with our national-defense program. All electrical manufacturing companies are exerting maximum effort to produce generators, motors, conversion apparatus, and other electrical equipment which are needed in meeting the requirements of a large and rapidly expanding industrial activity. There is a further need for machines of greater capacity, new combinations of apparatus and control devices, and more information on machine characteristics to accomplish new and difficult objectives.

The new wind tunnel of the United States Army Air Corps at Dayton, Ohio, which is scheduled for operation in the early part of 1942 is an example of this type of problem. Wind velocities of 400 miles per hour and greater are to be obtained for testing large size airplane parts and models. The air is to be circulated by two propeller assemblies mounted on a common shaft and operated in series to produce the necessary high pressure. The propeller assembly is driven by a 40,000-horsepower, variable-speed, wound-rotor-type induction motor, which has a top rotational speed of 300 rpm (327 rpm synchronous speed) and is the largest unit of this type built to date. It is essential in this application to obtain close speed regulation over a wide speed range. This paper discusses the problem associated with the design and operation of the equipment required to meet wind-tunnel specifications. The role which the wind tunnel will play in the race for air supremacy in the present world war is a subject of great interest and national importance, but it will only be discussed briefly in this paper as an introduction to the requirements of wind-tunnel drives.

Paper 42-63, recommended by the AIEE committees on electrical machinery, industrial power applications, and air transportation for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 12, 1941; made available for printing December 19, 1941.

A. D. Dickey is with the United States Army Air Corps, Wright Field, Dayton, Ohio. C. M. Laffoon is manager of the a-c generator engineering department, and L. A. Kilgore is section engineer, large a-c motor section, transportation and generator department, both of Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

Wind Tunnels

The principles of aerodynamics and hydrodynamics are neither sufficiently well-known nor subject to sufficiently exact mathematical analysis to permit the accurate calculation of the performance of a body moving through the fluid at high velocities, except for simple cases. It has been the practice of designers for many years to obtain performance characteristic data on equipment and apparatus such as ducts, channels, blowers, waterwheel runners, ship-propeller screws, and ships from the performance of models operated under controlled conditions in laboratories. The same condition is true to an even greater extent in the case of airplanes due to the fact that the plane velocities are extremely high, and materials and structural members must be worked nearer the ultimate limits in order to reduce weights and increase the power per unit of weight. During the early development of the airplane, the Wright brothers used low-power wind tunnels to check plane models rather than resort to the more dangerous and costly method of full-scale flight tests. This condition exists at the present time, and a vast amount of large-scale experimental work will be required to obtain the essential data so that still higher efficiency and flight speed can be reached.

Model tests are quite reliable at low speeds due to the fact that the air-flow lines produced by the full-size unit are similar to those existing in the model test. In some cases, the effects of air viscosity can be determined by varying the density of the air in the tunnel. In other cases, it is necessary to make empirical corrections in extrapolating from the model to the full-size unit. For plane speeds at 400 miles per hour, the air velocity around different parts of the plane may approach the speed of sound. This introduces effects of both the mass and elas-

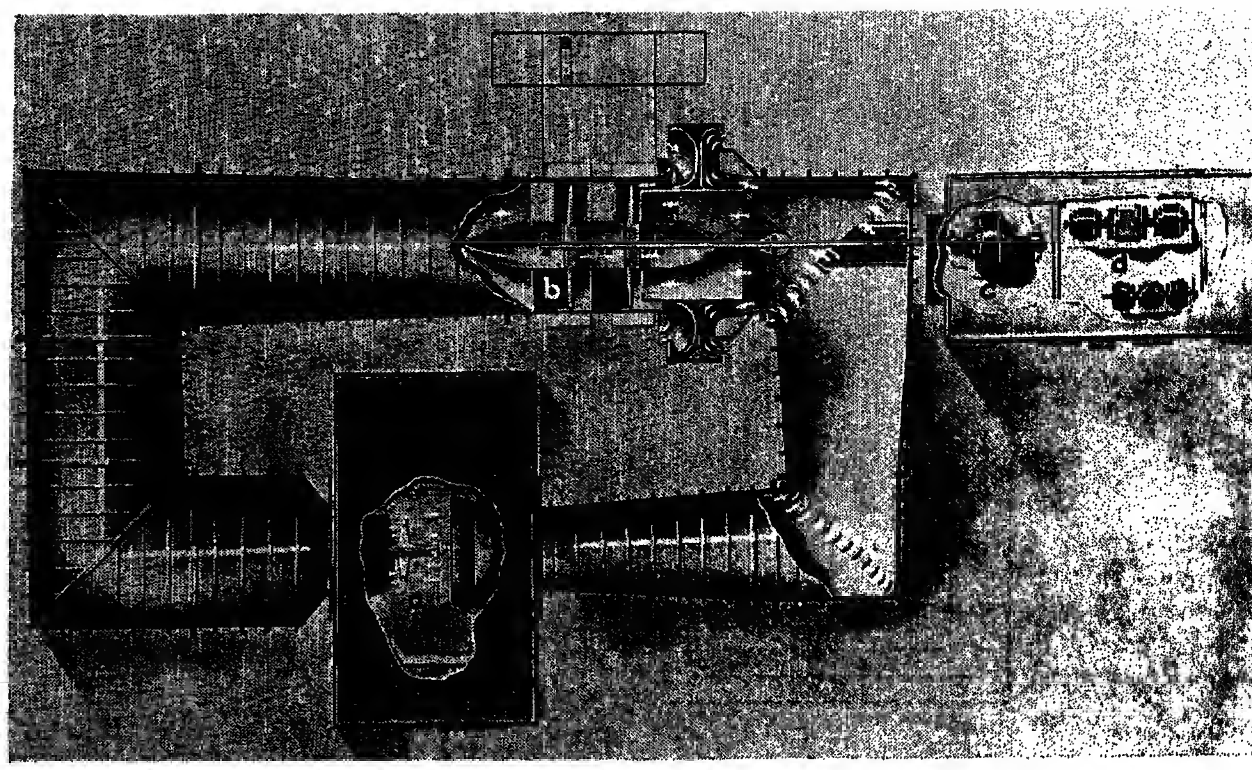

Figure 1. Plan view of wind tunnel and driving apparatus

ticity of the air. In the present state of the art, large-scale models and full-size parts must be checked in wind tunnels at full speed to get reliable data for building high-power superspeed planes. Fortunately, it is not necessary to use full-size planes, due to the fact that basic data can be obtained for large or full-size parts and the constants for the parts combined for application to the entire plane. It is interesting to note, in connection with wind-tunnel operation, that the power required to circulate the necessary large volume of air around a complete wind tunnel is several times greater than the power required to drive the model through the air at the same speed. Since the power required to circulate the air varies as the cube of the speed, it is not surprising to find that a 40,000-horsepower motor rating is required for the largest high-speed wind tunnel.

Wright Field Wind Tunnel

The Wright Field wind tunnel is designed with a cross section sufficiently large to accommodate full-size plane sections or parts, and large-size complete models, with wind velocities of 400 miles per hour or greater. Since the output from the motor is eventually absorbed by the circulating air, it is obvious that the temperature of the air would continue to rise until the rate of heat loss dissipated by the tunnel became equal to the rate of input to the air, if complete recirculation were used. When operating under full-speed conditions with 40,000-horsepower motor output, the air temperatures would become excessive, and it is thus necessary to resort to partial circulation. Sufficiently large inlet and outlet openings are provided at appropriate sections of the tunnel so that approximately 30 per cent make-up air is provided and the gas temperature kept down to tolerable values. Each of the two stage propellers which circulate the air have 16 wooden blades, which are approximately 40 feet in diameter at the tips. The propeller assemblies, including rotating blades, supporting hubs, and stationary guide vanes, were designed by the Air Corps engineers at Wright Field. The general arrangement of the tunnel and propelling equipment is as shown in Figure 1.

Driving Equipment

The largest wind tunnel in operation at the time the Wright Field wind tunnel was originally planned, had two 4,000-horsepower driving motors (8,000 horsepower total). A wind tunnel requiring five times as much driving power was a large step forward. It was also desired to use a single driving motor in order to avoid possible difficulties in assembly and complications in the operation of the equipment. Although a 40,000-horsepower wound-rotor induction motor had not been heretofore contemplated, the electrical manufacturers had no misgivings in regard to the feasibility of building it, on account of the fact that synchronous motors on much greater capacity had been built for both 300 and 600 rpm. The motor characteristics—power factor, starting kilovolt-amperes, and speed control—were influenced to an appreciable degree by conditions associated with and requirements of the main power-supply system. In order to maintain speed practically constant at any value over a wide speed range with minimum energy requirements, a speed-control system was chosen which provided for returning the power from the rotor of the main induction motor to the a-c supply system. The main rotating auxiliary equipment required to accomplish this result is shown in Figure 2 and consists of two motor-generator sets. The a-c elements of both sets are salient-pole synchronous units with d-c excitation.

In one set, the a-c motor receives its power supply from the rotor of the main drive motor, and operates as a synchronous machine at the slip frequency over the entire speed range of the main motor. The second set has the a-c generator electrically connected to the 60-cycle main supply system, and operates at constant synchronous speed. Table I shows the speed and frequency for the main motor and auxiliary sets.

A qualitative interpretation of how the main and auxiliary equipment perform can be readily obtained by analyzing the power, voltage, current, torque, and speed relation that exist under given operating conditions.

Starting and Operation of Equipment

It is apparent by reference to Figure 2 that the unit can be started either from the main driving motor or from the a-c element of the constant-speed motor-generator set. When starting from the main motor, no excitation is to be pro-

vided for the d-c and a-c elements of the auxiliary sets. When power is applied to the stator of the main motor, the rotors of the main motor and variable-speed set start to roll and accelerate in speed. The speed reached by the rotor of the main motor will be relatively low, due to the fact that the output of the main-motor rotor winding is limited primarily to the losses of the variable-speed set. The speed of the variable-speed set will be relatively high, for its speed is determined by the slip frequency of the main driving motor. If excitation is applied to the field of the a-c element of the variable-speed set, it will pull into synchronism with the rotor of the main motor. The constant-speed set can then be started from either the d-c or the a-c end. If started from the d-c end, it will be necessary to synchronize the a-c end with the main power supply. When the constant-speed set is started from the a-c end, it is necessary to adjust the excitation of the d-c elements of both sets, so that there will be no appreciable interchange of d-c power. When starting the main drive from the a-c end of the constant-speed set, the stator of the main motor should be left on open circuit, the connections for the remainder of the equipment should be normal, and the excitation of the two d-c units adjusted so that the d-c element of the constant-speed set delivers power as a generator to drive the d-c element of the variable-speed set as a motor. Both sets are then brought up to full synchronous speed in the conventional manner. The rotor of the main motor remains at standstill, and the voltage induced in the stator has the same frequency as that supplied to the rotor. The excitation of the a-c and d-c elements of the variable-speed set are then adjusted so that the voltages of the main-motor stator are in synchronism with the voltage of the supply system. When the voltages have the same magnitude, frequency, and have approximately correct phase position, the main-motor supply switch can be closed without the interchange of an appreciable amount of power between the main motor and the supply system.

There is thus no flow of power between the rotor of the main motor and the stator of the a-c element of the variable-speed set, and hence no torque is produced to accelerate the rotor. By increasing the excitation of the d-c end of the variable-speed set, its speed will tend to decrease and its voltage increase so that it functions as a generator and supplies power to the d-c end of the constant-speed set. This power is then returned to the supply system by the a-c element of the constant-speed set. At the instant the speed of the variable-speed set starts to drop, the initial angular displacement between its voltage and the voltage of the main-motor rotor winding produces a secondary current which reacts with the magnetizing flux to produce a motor torque to turn and accelerate the rotor. As the speed of the variable-speed set decreases, the speed of the main rotor increases and both elements maintain synchronism at the slip frequency of the main motor.

Either of the two methods of starting are practical and satisfactory. The method of starting from the relatively small constant-speed set was adopted due to the fact that less complication is involved in the starting equipment and less shock to the supply system occurs.

It is apparent from the above discussion and through a knowledge of the characteristics of a-c and d-c motors and generators that the amount of electric power supplied by the rotor of the main motor and its slip frequency can be determined and controlled by varying the excitation of the d-c elements of the two motor-generator sets and controlling the flow of power between them. The amount of wattless power returned to the supply system can be controlled by varying the excitation of the a-c generator element of the constant-speed set. The amount of wattless kilovolt-amperes supplied to the main motor can be controlled by varying the excitation of the a-c element of the variable-speed set. The curves in Figure 3 show the slip, mechanical-power output, and rotor-electrical-power output for the main driving motor, and the d-c voltage and current of the auxiliary sets as a function of the speed of the main motor.

The elementary power relations in any induction machine are best understood by first considering an ideal machine without loss. In this machine the same

torque is developed on the stator and the rotor by the fundamental flux and current. The product of this torque and the rotor speed represents mechanical power output (P_m). The product of the torque and synchronous speed represents power input (P_i), and the secondary power at the slip rings (P_s) is represented by the product of torque and slip speed.

Expressing the slip as a decimal fraction (s) of the synchronous speed, the secondary power can be written in terms of the mechanical power as $P_s = P_m[s/(1-s)]$. For a fixed propeller and a given air density, the power P_m varies as the cube of the speed, which gives a maximum secondary power at $s = 1/_3$.

The accurate power relations are obtained by adding the friction and windage losses to the mechanical power (P_m) and subtracting the secondary I^2R from the secondary power P_s to obtain the net power at the slip rings. To trace the power flow from the slip rings through the auxiliary machines back to supply line, it is necessary only to subtract the losses of the various auxiliary machines at each step.

The variable-speed set operating from the slip rings of the induction motor will have a speed proportional to slip. Neglecting the losses, the variable-speed set must handle the secondary power (P_s) which is then equal to the product of its speed and torque. The torque could be written as $P_s/s = P_m/(1-s)$, and from the curves of Figure 3 it will be seen that although the secondary power is maximum at $s = 1/_3$, the maximum torque will be at minimum slip. The product of this maximum torque of the variable-speed set and its synchronous speed is approximately equal to the full rating of the main motor, and this determines the size of the variable-speed set. The fact that the maximum current is required only at the minimum speed is of advantage in designing the d-c generators for large capacity.

The constant-speed set must handle the same maximum d-c voltage and current as the variable-speed set, but the maximum voltage occurs at about four times as high a speed requiring a correspondingly smaller machine for the d-c motors. The a-c generator feeding the power back into the line must handle only the maximum secondary power minus the auxiliary machine losses. While the total capacity of the auxiliary sets is great, the speed can be kept high and the physical size is not so large as might be expected.

With the power-speed relations in mind, it becomes apparent that it is desirable to keep full field on the d-c generators over the upper range of speed where the torque is high, and to control the speed by the field of the d-c motors. In the lower range of speed the d-c voltage is held constant and the flux reduced in the generator. The rheostats for the motors and generators are mounted on one shaft, but arranged so that they are changed one at a time.

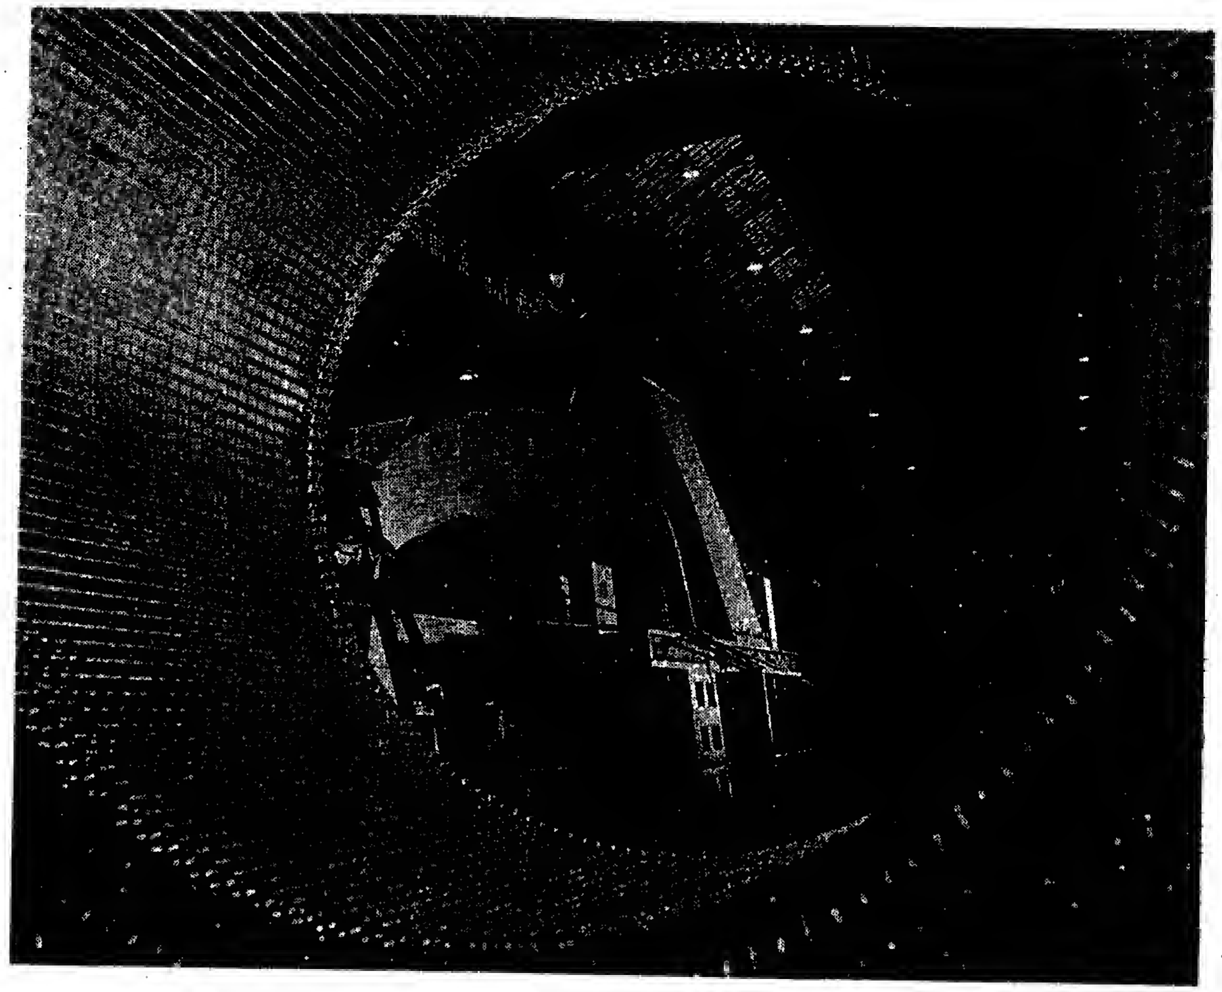

Figure 4. View of main induction motor looking through the stator of the synchronous motor for the variable-speed set

New Problems

In addition to the problems in designing the largest induction motor yet built, there were a number of other problems which had to be solved in the application of this system of speed control. These problems included the steady-state stability, and the dynamic stability or the reaction of the system to oscillating torques either impressed by the propeller or self-excited.

The usual induction-motor criterion of stability that the torque should increase with increased slip is readily met since, even with fair regulation of the d-c machines, the secondary power taken by the variable-speed set, with fixed fields, would increase much faster than the slip frequency. The synchronous motor which is fed from the secondary of the induction motor, must stay in synchronism with the slip frequency, and this presents a stability problem with new conditions. However, it can be shown that the induction motor can be treated as a high reactance transformer with high magnetizing current so that the problem is resolved into the conventional two-machine synchronous-stability problem.

The possibility of self-excited torsional oscillations mentioned above arises from the fact that at low slip frequencies, the reactance-resistance ratio is much lower than in large machines of normal frequency. This tendency to oscillate is the same general phenomenon of hunting encountered in small synchronous machines but is complicated by the addition of the induction motor in circuit. This tendency to establish self-excited oscillations has been termed negative damping, since it is due to a torque in phase with the velocity, or opposite in sign to the usual damping torque. Negative damping may exist in this system for relative angular motion between the induction and synchronous motors. Fortunately, the synchronous-motor damper winding and the speed-torque characteristics of the d-c machines, as well as the fan load, all contribute to the positive damping of the system, so that by proper attention to these factors it is possible to get a net positive damping. Hence it is possible to avoid any tendency to hunt. Methods of analysis of this problem have been written up and proposed for presentation at the winter convention.

A model system was set up using a 100-horsepower wound-rotor motor with two synchronous d-c motor-generator sets. The propeller was represented by a d-c generator with an added flywheel. The starting and control features were tested and the tendency to hunt at low-slip values investigated. With small machines, it was not possible to represent the

large units exactly, but the test did serve to prove that the methods of analysis were adequate.

Since there are torsional impulses on the propeller resulting from slight irregularities in the air flow caused by guide vanes, it was necessary to determine their effects on the entire system. The fan, the main induction motor, and the various auxiliary machines, all represent inertias tied together either by shafts or electrical ties. This complicated system has many modes of vibration and many natural frequencies. These were solved by setting up a complete equivalent circuit representing the electrical analogue of the mechanical system, along the well-known principles of representing torques by voltages, velocities by currents, inertia by inductance, torsional flexibility by a capacity, and damping by a resistance. Solving for the natural frequencies of this electrical analogue was difficult due to its many branches. The a-c calculating board was used to represent the system and the approximate frequencies found which could then be checked by direct calculations in complex numbers. The torsional impulses are low, and the net damping is found to be adequate to keep any oscillations low.

The same electrical analogue was found to be very useful in calculating the stability of the speed-regulating system. Since the speed variations must be measured on the motor and the corrections applied through the d-c auxiliary machine fields, the regulating problem is not simple, and careful consideration had to be given to the amplification and antihunting features of the speed regulator.

Conclusions

The type of drive adopted for this largest wind-tunnel application is found to be very efficient to give low starting currents. Also this system lends itself to full automatic control and accurate speed adjustment.

The solution of the many problems associated with this drive have led to some advances in the analysis of machines and in the design of very large motors. This knowledge should prove valuable in the future, on other variable-speed drives, on ship drives and other applications involving systems of machines.

Progress in Design of Electrical Equipment for Large Diesel-Electric Locomotives

GERALD F. SMITH
ASSOCIATE AIEE

DURING the last eight years, as the result of development of the Diesel engine, Diesel-electric locomotives have come into wide use for heavy switching, passenger, and freight service. There has also been a rapid development in the electrical equipment going back about 15 years.

The primary function of the electrical equipment is to transmit the power from the Diesel engine to the rail, and also change the relation of engine to locomotive speed. In modern high-speed equipments, the weight of electrical equipment somewhat exceeds the weight of the Diesel engine with radiators, and so forth, and is of the order of 20 per cent to 25 per cent of the locomotive weight. This may appear to be out of proportion, but it must be realized that the propulsion output of the Diesel engine is all converted to electrical energy and then converted back to mechanical output at the rail over a very wide range of speed.

Modern high-speed passenger and freight locomotives operate under the widest range of conditions. They traverse the plains, rolling country, and mountainous ranges.

Definitions

In order to understand clearly the operating conditions affecting equipment design, it is well to define several items:

1. *Maximum Test Speed.* This is the speed in rpm defined by the rules of the A.S.A. for a stand test of the motor for two minutes and is 120 per cent of the rpm corresponding to:

2. *Maximum Safe Service Speed.* This is the highest locomotive speed permitted in service with minimum size wheels (worn wheels) on down grades.

3. *Balancing Speed on Straight, Level Track.* With normal trains, this is generally somewhat less than the maximum safe service speed, and is of interest chiefly for comparative purposes since stretches of straight, level track long enough to permit reaching balancing speeds are not frequently encountered.

4. *Balancing Speed on Prevailing up Grades.* In rolling country, these grades may be of the order of 0.2 per cent to 0.4 per cent. In hilly country, they may be in the neighborhood of one per cent. In mountainous country, long grades of 1.8 to 2.2 are common and helper grades up to 3.5 exist

5. *Unloading Speed.* This is the speed above which the full power of the Diesel engine is not utilized. It should be sufficiently high so that the full power of the Diesel engine can be used on the prevailing up grades in *each* district.

6. *Continuous Rated Speed.* This is the lowest speed which can be maintained with full engine power for prolonged periods with unworn wheels without exceeding the temperature limits of the motors and generators, and should closely correspond to the speed with maximum train weight on the ruling and helper grades unless the time spent on these grades is fairly short and is preceded by a run at light load or a very definite and effective cooling period.

7. *Maximum Tractive Effort.* This is the maximum tractive effort which can be developed for short periods during accelerations. In high-speed passenger locomotives it may be limited by the commutating capacity of the generator, otherwise by the slipping point of the driving wheels. In very powerful freight locomotives, driver slippage is the usual limit, but the strength of freight car draft gear may make the practical limit lower than the slipping point.

8. *Maximum Weight Per Driving Axle at Rail.* This is the weight as limited by stress in rail and depends on the minimum (worn) wheel size and maximum safe service speed.

Chronology

Prior to 1927, standard 600-volt self-ventilated railway trolley-type motors, designed for suburban and subway service, were used. About 1928, motors designed primarily for operation from limited power supply were introduced. These power plants were of 300- to 400-horsepower capacity, with one generator and two motors. In 1932, 600-horsepower equipments were introduced using

Paper 42-23, recommended by the AIEE committee on land transportation for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 13, 1941; made available for printing December 19, 1941.

Gerald F. Smith is engineer in the transportation engineering department, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

semiforced ventilated motors, class B insulation; with multiple windings and four brush holders instead of the conventional two-circuit winding and two brush holders; with wedges on the core, nonmagnetic bands on the end windings and with roller bearings. In 1936 a further increase to 900-engine horsepower was made. At present, motors are available which can use 1,500-engine horsepower per pair of motors. These motors are only 17 per cent heavier than the motors used with a 400-horsepower engine in 1928.

Motors

Design

This increase in capacity has resulted from improvements which may be listed:

1. Increased peripheral speed of armature. The armature peripheral speed has been increased from 8,500 to 12,500 feet per minute. This has been the result of improved methods of insulating and wedging the coils in the armature slots and better methods of banding the end windings with predetermined band tension and multilayer nonmagnetic bands of high-tensile strength.

2. Increased peripheral speed of commutator; from 7,000 to 10,000 feet per minute. This has resulted from the more detailed study of stresses in the commutator copper and steel parts and of the characteristics of mica, the use of an increased number of brush holders to keep down the over-all length, the seasoning of the commutator and the use of better grades of carbon brushes.

3. Forced ventilation. A definite supply of ventilating air from a source relatively free from snow, water, oil, brake-shoe dust and dirt of all kinds is provided.

4. Better insulation and processes in applying the insulation. Mica tapes and wrappers with a lower per cent of combustible material, glass, and asbestos are used. Coils pressed to exact size exclude air and give high percentage of copper in the coil with good heat conducting characteristics and avoid shrinkage and consequent loosening in service. Also improved sealing compounds exclude oil, moisture and air, thus permitting higher temperatures. It is also good practice to connect all motor and generator field coils on the negative side to reduce the voltage stress in the field coils.

5. Micarta wedges which are capable of standing higher temperatures.

6. Nonmagnetic high-strength multilayer bands on the end windings. In addition to permitting higher peripheral speeds, the elimination of magnetic bands on the armature core and end windings reduces the commutating voltage materially.

7. Multiple armature windings permit higher speeds with low commutating voltage.

8. Armature coils are designed to reduce eddy current loss.

9. Roller bearings.

10. Better gearing.

Overload and Commutating Capacity

With the increase in capacity, the loss in per cent of input is lower; however, with better ventilation the loss in watts per motor is increased. Since the motor weight has not materially increased, the thermal capacity in proportion to motor capacity has materially decreased. Hence much greater care must be used in applying motors to a given service to avoid overloads that produce high temperatures, which by forcing expansion and contraction will damage insulation. This is particularly true of armature windings which are much less free than field windings to expand and contract. When the motor is operating at its highest ampere load, the speed is low and also the commutating voltage is low. Its overload capacity is determined by heating. When the motor is operating on weakest field with full engine power and highest voltage, its commutating voltage is highest.

Generators

Main

The capacity and speed of the main generators is determined by the capacity and speed of the engine. The generator differs from the motor in its speed, mounting and overload capacity. When the generator is operating at its highest ampere load, full speed is obtained, hence its maximum capacity is determined by its ability to commutate heavy ampere loads as well as by heating. Compensating windings, often used on high-capacity generators, are not generally used on railway Diesel-engine generators. This is due to the space taken and the higher resistance of such windings. The main-pole air gap is tapered to reduce the maximum volts between bars and also to reduce the load core loss.

Mechanical connection of the generator armature direct to the engine shaft gives a substantial rigid connection using the weight of the generator armature in place of an engine flywheel. The generator stator is also usually direct connected to the engine frame.

Auxiliary

It has become general practice to drive auxiliary machines such as compressors, radiator fans and main motor fans, and so on, from the engine. An auxiliary generator need be of only small capacity, sufficient to charge battery and supply power for headlights, cab lights and miscellaneous small auxiliaries.

Control

The differential exciter of special design has been developed to give full engine loading over a wide range of locomotive speed under usual conditions. To provide for unusual conditions and to secure the very maximum utilization of engine power, the field of the exciter is put under control of the engine governor. When fuel rack exceeds a predetermined setting, the exciter field is decreased, and when the fuel rack goes below this setting the field is returned to its normal maximum value. This avoids overload on the engine and keeps the fuel rack at full load without sacrificing the inherent advantages of the simple differential exciter. By operating on the exciter field, the physical size of the device is kept low. Since the time constant of the exciter field is much more rapid than that of the main generator field, this does not slow up the operation.

Conclusion

For present high-speed passenger locomotives, electrical equipment is available with a weight between 20 and 21 pounds per engine horsepower, with continuous rated speed 33 per cent of maximum service speed of above 100 miles per hour and with sufficient maximum tractive effort to slip wheels at 33 per cent adhesion. For freight locomotives with double the number of motors per power plant, the weight is between 30 and 31 pounds per engine horsepower, and the continuous rated speed 16 per cent of maximum rated speed.

Distribution-Type Lightning-Arrester Performance Characteristics

AIEE COMMITTEE ON PROTECTIVE DEVICES

Lightning Arrester Subcommittee*

THIS report presents the results of work by the lightning arrester subcommittee to bring up to date and make available to the industry the performance characteristics of present day valve-type distribution arresters having a maximum rating of 3 kv to 15 kv. Distribution arrester characteristics were given in a report by the lightning arrester subcommittee in ELECTRICAL ENGINEERING, volume 56, May 1937, page 576. Since that date there have been changes in the arrester. The subcommittee felt it desirable to present up-to-date values and also to include values at higher discharge currents than those previously given.

Table I includes the arrester gap breakdown values—maximum, average, and minimum—from tests on the arresters using the rates of voltage rise specified in the Lightning Arrester Standards Bulletin 28, ASA Standard *C-62*. Table I also shows maximum, average, and minimum *IR* discharge voltages for all arresters at discharge currents of 1,500, 3,000, 5,000, 10,000, and 20,000 amperes, all on a 10x20 current wave.

To enable rapid interpretation, the data have been plotted in curve form.

Figure 1 shows the relationship of arrester gap breakdown for the AIEE rate of voltage rise versus arrester maximum rating, with maximum, average, and minimum values.

Figure 2 shows arrester gap breakdown for other rates of voltage rise as well as for the AIEE standard rates. The breakdown values cover a range of 0.25 microsecond to 6 microseconds.

Figure 3 shows the spread found in *IR* discharge voltage values for a discharge current of 1,500 amperes, for the several voltage ratings.

Figure 4 shows average *IR* discharge voltage for the different discharge currents from 1,500 amperes to 20,000 amperes and the different voltage ratings 3 to 15 kv.

Four lightning-arrester manufacturers supplied the data from which the characteristics in the report were tabulated and plotted. The values are for arresters of present day manufacture and do not necessarily apply for older types.

While the total spread for all manufacturers is of the order of plus or minus 40 per cent, the tolerance permitted by any one manufacturer does not exceed plus or minus 25 per cent for arrester gap breakdown voltage, or plus or minus 20 per cent for arrester *IR* discharge voltage from the average performance values which are published in his literature.

The 60-cycle spark potential of the arresters referred to in this report will not be less than 150 per cent of the arrester maximum line-to-ground rating.

By comparing the volt-time characteristics of the insulation to be protected with the volt-time characteristics of the arrester, an evaluation can be made of the margin of protection.

Hot-Spot Winding Temperatures in Self-Cooled Oil-Insulated Transformers

F. J. VOGEL
MEMBER AIEE

PAUL NARBUTOVSKIH
ASSOCIATE AIEE

IN recent years operators have wanted to know how much overload a transformer would carry for a given length of time without exceeding a safe temperature. This knowledge would enable them to obtain the most from available equipment or to install equipment which would provide reasonable overload capacity in case of emergency. In order to do this, it is necessary to be able to calculate the temperatures within windings, and to know safe operating temperatures.

It is not easy to calculate the temperatures within windings, and rough rules which are extremely conservative have been used. For example, it was recognized that there were places in the windings hotter than the average temperature, and an arbitrary 10-degree hot-spot allowance was made.

It is shown in this paper, that the hot-spot allowance for many transformers is less than five or six degrees centigrade, and that the gradients do not increase as fast as previously supposed, due to the effect of decreased oil viscosity at higher oil temperatures. This makes it possible to recommend much higher emergency overloads than in the past. In an example it is shown that 200 per cent load could be carried for one hour, without exceeding what appears to be a conservative temperature limit, as against previous recommendations of 138 per cent load for the same duration of time.

Variation of Temperature With Load

In presenting this subject, it is thought that it will be easier to follow if we take a specific transformer as an example and carry through calculations for a given overload. Comparison of the calculations and actual test results will show whether the method is accurate or not.

Paper 42-59, recommended by the AIEE committee on electrical machinery for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 12, 1941; made available for printing December 22, 1941.

F. J. VOGEL is division engineer, and PAUL NARBUTOVSKIH is engineer in the transformer department, both with Westinghouse Electric and Manufacturing Company, Sharon, Pa.

The authors acknowledge the help of C. W. Penney, Westinghouse research department, in the preparation of this paper.

Test Data

Full-load heat run, 2,000-kva single-phase transformer, 44,000 high voltage, 2,300 low voltage, 60 cycles.

Actual copper loss	9,450 watts
Iron loss	5,200 watts
Total losses	14,650 watts
Ambient temperature	27.5 C
Rise by resistance,	
High voltage, winding	34.8 C
Low voltage, winding	33.8 C
Top oil rise	30 C

An overload run was made at 135 per cent load. The copper losses at the 100 per cent run were at an average copper temperature of approximately 34 degrees centigrade rise, plus $27^1/_2$ degrees centigrade ambient, or $61^1/_2$ degrees centigrade. If the winding on the 135 per cent run was at about 75 degrees centigrade, the copper losses would be:

$$\frac{9{,}450 \times 1.35^2 \times (234.5+75)}{234.5+61.5} = 18{,}000 \text{ watts}$$

The total losses would then be 18,000+5,200 or 23,200 watts. If the oil rise at full load was 30 degrees, the oil rise at 135 per cent load should be $30 \times (23{,}200 \div 14{,}650)^{0.8}$ or 43.4. This is based on the assumption that the hot oil rise above ambient varies as the 0.8 power of the total losses. The gradient between the high-voltage average copper and the hottest oil is 4.8 degrees centigrade, at full load. If the gradient varies as the 0.8 power of the copper losses, the new gradient should be $4.8 \times (18{,}000/9{,}450)^{0.8}$ or 8 degrees centigrade. This would give an average copper rise of 43.4+8 or 51.4 degrees centigrade.

The actual temperatures at 135 per cent load were 43 degrees centigrade oil rise, and 46.6 degrees centigrade copper rise, compared to 43.4 degrees and 51.4 degrees centigrade, respectively for calculated values.

In order to check this further, several transformer test records were examined where overload runs had been made, and the results are tabulated in Table I, below.

The interesting part of this tabulation is found in the fact that the oil rises seem to follow, within a few degrees, the values obtained by calculation, but it will be noted that there is a considerable discrepancy in the gradients. In general, they change much less than might be expected. It will be noted that so far as the temperature rises at overloads are concerned, values calculated in this way from full-load data are apt to be higher than those obtained in actual runs.

There are several reasons why these approximate methods give the results they do. The laws of convection and radiation of heat losses from the tank surface and radiators seem to be well established, and the average temperature rise above ambient air varies very closely as the 0.8 power of the losses. This would apply with a small error to both the hottest and the average oil, if the difference between top and average oil is not great.

For example, suppose we have an average-oil rise of 26 degrees centigrade, and a top-oil temperature rise of 30 degrees centigrade, at full load. We can refer

	135	12,900	15,600	45	34.7	34	34	11	+0.7	12.7	*

*Not calculated because of apparent "negative" gradient.

back to the first example given. The calculated top-oil temperature rise using the 0.8-power rule at 135 per cent load is 43.4 degrees centigrade, and actually was 43 degrees centigrade. If the same rule is applied to the average-oil rise, which is 26 degrees centigrade, at full load, the calculated value would be 37.6 degrees at 135 per cent load. The difference between the top-oil and average- or effective-oil temperature is assumed to be 4 degrees at full load. Suppose it varied anywhere from 4 to 6 degrees at the overload. The calculated top-oil temperature rise would range from 41.6 to 43.6 degrees versus 43 degrees test. This indicates that where the difference between top oil and average oil is not great, both of these rises may be assumed to vary as the 0.8 power of the losses.

If we follow along this reasoning, the difference between the average copper and average oil adjacent to the coils will be 8.8 degrees centigrade at full load, and 14.7 degrees centigrade at 135 per cent load. This assumes that the gradient, copper to oil, varies as the 0.8 power of the losses. The difference between the top oil and average copper might then be, at 135 per cent load, 14.7−6.0 degrees or 8.7 degrees centigrade, compared to 3.6 degrees centigrade measured. This indicates that there are other factors than those considered, or that the factors used are in error. These factors are oil flow or convection, and the effect of changes in oil temperature on the gradients between the copper and oil.

Effect of Convection Currents

The convection currents within windings and in the radiators are not easily estimated from the dimensions, and no effort to provide methods for such calculations is to be made in this discussion. However, it is possible to consider the variation of convection currents and their effect on temperature rise. Table I contains some interesting material. For example, there are variations in the test gradients of the low-voltage and high-voltage windings at different overloads which do not look consistent. Part of this may be due to experimental error. The corrections for "time to shut down" were made according to AIEE test standards. The largest factors in these variations are undoubtedly the difference in length and area of the oil paths through different windings and the variation in the watts loss per-unit area in the windings. This is particularly true in the case of the last unit. The low-voltage winding has a relatively large area of ducts, and a very low

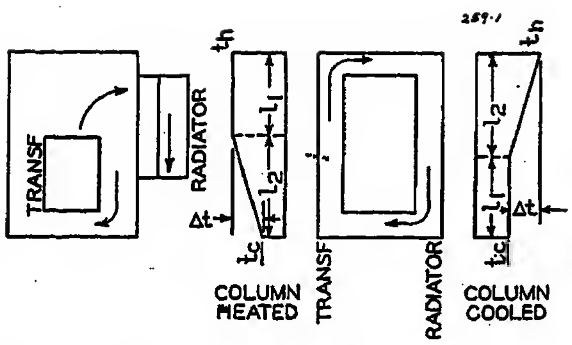

Figure 1. Sketch showing main convection current in transformer and equivalent circuit, with oil temperatures at various points

value of watts per square inch, compared to the high-voltage winding. The result is that the oil flows more easily through the low-voltage winding and is relatively cooler when it leaves the low-voltage coils than the oil leaving the high-voltage winding. If the watts per square inch of coil surface on both windings were the same and the length and area of the oil paths were the same, then both windings would behave more nearly alike.

If both windings are about alike, it is possible to replace them thermally with a heating and cooling circuit as shown in Figure 1.

The density of the oil at $t_h = D_{t_h} =$

$$\frac{1}{(1+0.00074\,\Delta t)}\,D_{tc}$$

The pressure of the liquid in column 1 will be

$$l_1\left(\frac{D_{t_c}}{1+0.00074\,\Delta t}\right)+ l_2\left(\frac{D_{t_c}+\dfrac{D_{t_c}}{1+0.00074\,\Delta t}}{2}\right)$$

and in column 2

$$l_2\left(\frac{D_{t_c}+\dfrac{D_{t_c}}{1+0.00074\,\Delta t}}{2}\right)+l_1D_{t_c}$$

The difference between these quantities represents the "head" available to cause oil flow, or

$$l_1D_{t_c}-l_1\left(\frac{D_{t_c}}{1+0.00074\,\Delta t}\right)=H$$

$$H=l_1D_{t_c}\left(\frac{1+0.00074\,\Delta t-1}{1+0.00074\,\Delta t}\right)\alpha K\,\Delta t$$

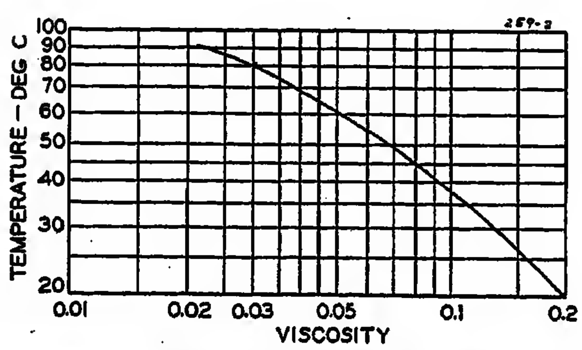

Figure 2. Variation of kinematic viscosity of transformer oil with temperature

The conclusion can be drawn that the pressure head causing thermosyphon flow is practically proportional to the difference between the hot and cold oil temperatures. Although this is derived for a specific case, it is generally true as long as the temperature gradients in each leg remain proportional.

If the flow is slow enough, and is streamline in character, not turbulent, the rate of flow is proportional to the head, and inversely proportional to the viscosity. This can be expressed as—

$$\text{Rate of flow}=K\frac{\Delta t}{v}$$

Also the losses which are dissipated are equal to the rate of flow times the specific heat (S.H.) times the temperature difference—

$$\text{Rate of flow}\times K_2\times(\text{S.H.})\times(\Delta t)=\text{losses}$$

$$\therefore\ \text{Losses}=K\frac{\Delta t}{v}\times K_2\times(\text{S.H.})\times\Delta t$$

$$\therefore\ (\Delta t)=K_3\sqrt{\text{losses}\times\text{viscosity}}$$

Figure 2 shows the relationship between oil temperature, in degrees centigrade, and the kinematic viscosity of a transformer oil. In order to show the effect of these factors, a transformer was tested at overload, and top and bottom temperatures noted, as shown in Table II.

Table II

Transformer Rating—1,667-Kva Single-Phase 60-Cycle, 13.2 to 2.3 Kv. Copper Loss at 75 Degrees Centigrade—11,308 Watts. Iron Loss 3,850 Watts

	80% Load	100% Load	120% Load
High-voltage rise	42.1	56.7	68.5
Low-voltage rise	42.4	56.9	69.8
Ambient	27	31	29.5
Top-oil rise	36.5	49	60
Top of radiator, rise	34	45	56.5
Bottom of radiator, rise	22	34	43.5
Difference in radiator temperatures	12	11	13
Bottom-oil temperature	49°	65°	73°
Viscosity	0.070	0.045	0.036
Copper losses	7,100	11,750	17,500
Total losses	10,950	15,600	21,350
√Losses × Viscosity	27.7	26.5	27.6

The following conclusion may be reached:

The difference between the top oil and average oil does not change greatly with load at constant ambient temperature, due to the nature of the oil flow and viscosity changes. If the velocity is sufficient to

cause turbulence, there is the possibility that some increase in temperature difference will occur.

Effect of Oil Temperature on Gradient Between Copper and Oil

Tests have been made on circular coils wound with 0.009 thickness of paper insulation at various oil temperatures, both in a vertical and horizontal position. In the case of the vertical coils, the oil temperature and copper temperature were measured at the top of the coil. In the case of the horizontal coils, the oil temperatures were measured both 2 inches from the coil horizontally, and also, in the duct between the coils and the tube inside the assembly. The oil temperature was found to be essentially the same in both places. The results of these tests are shown on Figures 3 and 4. It is of interest that the gradient for the vertical coils varies very closely to the 0.8 power of the watts per square inch for a given oil temperature, and that the gradient is higher for lower oil temperatures. It will be noted that low oil temperatures affect the gradient for horizontal coils very much, but at 80 degrees, the curves for both horizontal and vertical coils are substantially the same. This is very reasonable, as the viscosity of the oil at 80 degrees centigrade is very low, and permits nearly as easy flow into the horizontal ducts as in the vertical ducts.

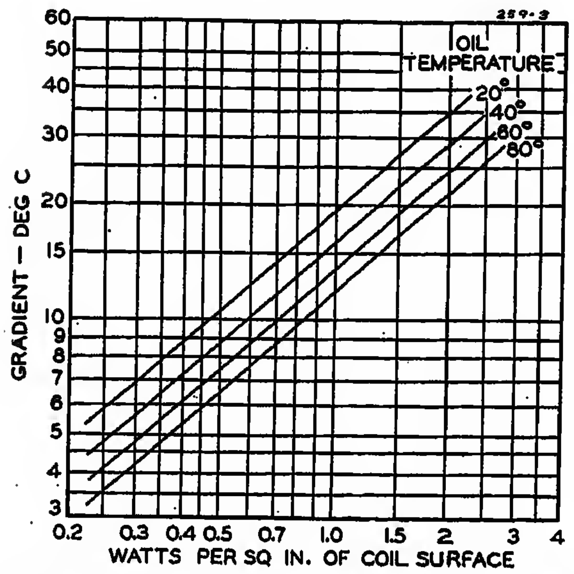

Figure 3. Gradients between oil and copper for model transformer coils—coils in vertical plane

There is one interesting fact that can be derived from Figure 4. If a transformer had an average of one watt per square inch dissipated on the coil surface at 60 degrees centigrade, the gradient would be 15 degrees. At 80 degrees centigrade, the watts per square inch would be increased to be approximately $(234.5+95)/(234.5+75)\times 1$, or $329.5/309.5$ equals 1.07. With 80 degrees centigrade oil, the gradient would be about 12 degrees. A change in ambient temperature of 20 degrees centigrade, therefore, would make the temperature rise 3 degrees centigrade less. This effect is less pronounced for transformers with vertical coils.

Temperature Rises Under Transient Conditions

In order to determine how the temperatures varied during short-time overloads, a test was made at varying loads for different lengths of time on a 600-kva, three-phase transformer. The hottest spot temperatures were also measured by thermocouples in the second coil from the top.

Figure 5 shows the transient conditions between the oil and the copper, and since this is a fairly representative case, shows that this transient for most transformers will be completed in fifteen minutes, more or less, depending on the design and the current density in the copper. After this transient has ended, the determination of the hottest spot would be reduced to determining the difference between the average and top oil, and the gradient between the top oil and the hottest copper.

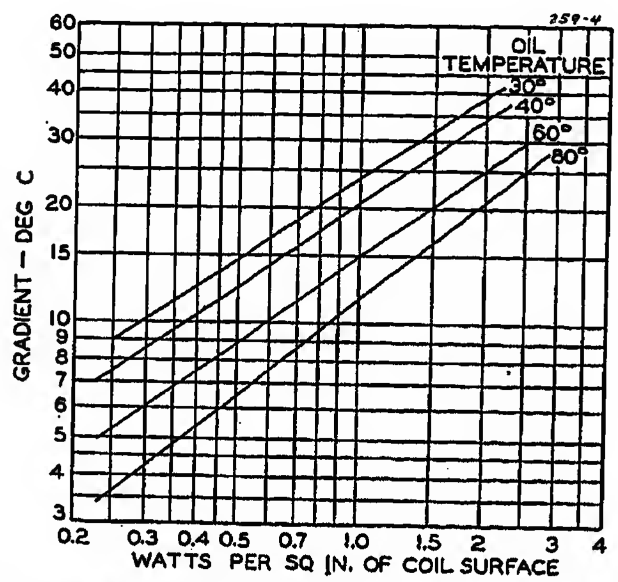

Figure 4. Gradients between oil and copper for model transformer coils—coils in horizontal plane

Since the top oil and the average oil have the same difference, or gradient, between them on overloads of long duration, it would follow that this might also be true on shorter-time overloads. To satisfy this condition, the difference between the average rise by resistance and the hottest copper rise should also be constant, since the gradient between the copper and oil, adjacent to it at any place in the column of coils, should be substantially a constant. This would not be true if the conductor insulation, ventilation, and so forth, were not the same for the top coils as for the body coils. Figure 6 shows the temperature gradients found between the top oil and both the hottest copper and the average copper. On the average, the difference between the hottest copper and the average copper was 8 degrees. The variation is within the limits of reasonable experimental error, and indicates that there would be no serious error in calculating hottest-spot temperatures using this assumption.

Table III

Time—Hours	Hot-Spot Temperature—Degrees Centigrade
1/4	140
1/2	135
1	130
2	125
4	120
8	115
24	110

Application of Calculated Hot-Spot Temperatures

The data obtained above are of interest because they can be applied to practical transformer design and operation. The most interesting application is in the determination of safe short-time overloads for transformers. In order to do this, a table of safe temperatures must be established. To illustrate the point, assume the temperature-time table, Table III.

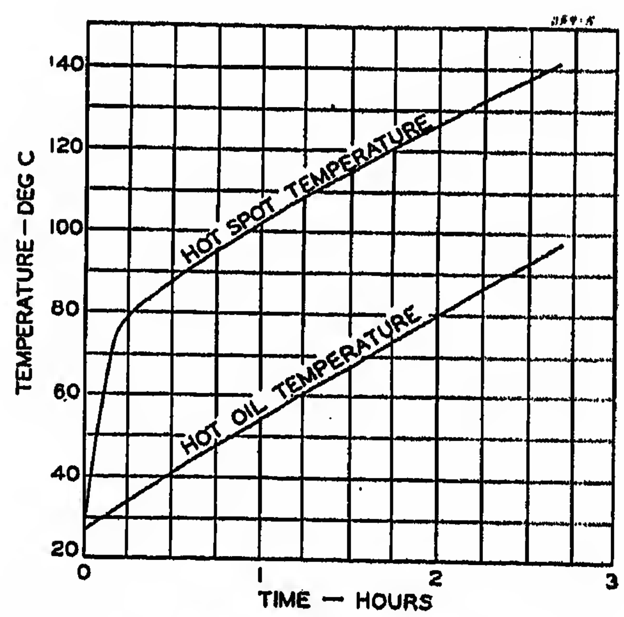

Figure 5. Transient temperatures in 600-kva transformer at 300 per cent load, starting cold

The values for hot-spot temperature and the times associated with them are a matter of judgment, and are based on tests of insulation under oil at various temperatures.[1] These values are very conservative, and higher values probably could be used when the present operating recommendations are revised. If we are to make a general application of these values, it is next necessary to establish average transformer characteristics. Such a study

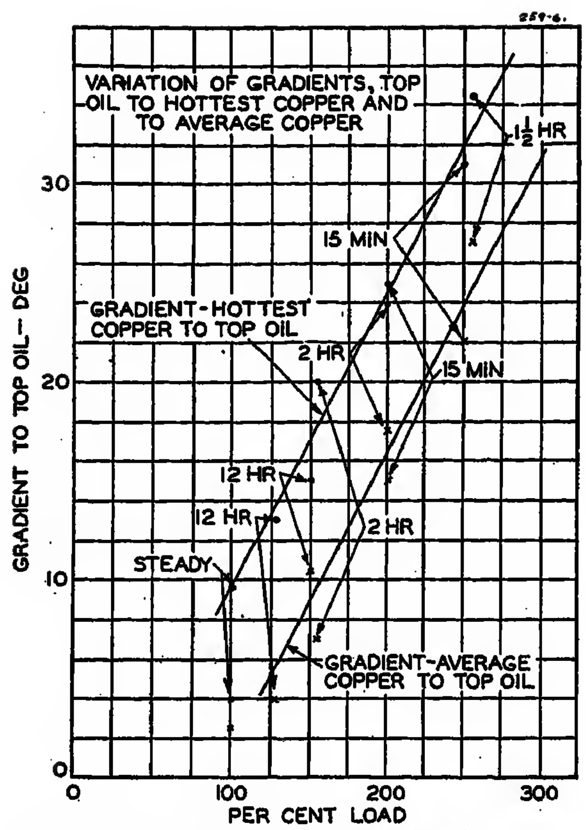

Figure 6. Variation of gradients, top oil to hottest copper, and to average copper

has led to the tabulation for power transformers shown in Table IV.

From other authors,[2] the approximate formula for transient oil rises has been derived as follows:

$$T_t = T_f(1 - \epsilon^{-t/B}) \qquad (1)$$

where

T_f = Final temperature rise
t = Time, hours
B = Time constant $= \dfrac{T_f \times C}{L}$
C = Heat capacity
L = Losses

Table IV

Ratio of losses, copper to iron, full-load	2:1
Time constant	4
Temperature rise—copper*	55 degrees
Hot-oil rise*	50 degrees

*Maximum allowed, not average values. Gradients of 5 degrees between copper and hot-oil rises are common.

The formula 1 can be shown to hold for any abrupt change in loading, so that if the transformer is fully loaded and at a steady state, a sudden increase in load will result in a transient determined by the difference between the final condition, under the overload, and the full load condition.

It appears that for many transformers the actual hottest-spot temperatures are in the order of 6 degrees or less above the average copper temperature. In this case, the actual hottest spot should not exceed 61 degrees. Also, the average oil rise will be $50-6$ degrees or 44 degrees centigrade. It is now possible to calculate the overloads which can be applied for the times and temperatures given. As an example, let us pick one hour, and 130 degrees centigrade. Cut and try methods are simplest, and we will assume the load to be 200 per cent.

At full load the total losses are equal to $3X$, where X equals the iron loss.

At 200 per cent load the copper loss will be $8X$, not correcting for temperature change. Correcting for copper temperature change, assumed to be 124 degrees centigrade, it would be $8X \times (234.5+124)/(234.5+85) = 9X$. The total losses would be $10X$. An ambient of 30 degrees centigrade is assumed.

Since the average oil rise is 44 degrees at 100 per cent load, at 200 per cent load, and with losses at 124 degrees centigrade, the ultimate rise would be $(10/3)^{0.8} \times 44$, or 115.0 degrees centigrade.

If the original rise was 44 degrees centigrade, the change in temperature rise is $115-44$ or 71 degrees centigrade.

In one hour, the oil rise will be:

$$71(1-\epsilon^{-1/4}) = 71 \times 0.223 = 15.9 \text{ degrees centigrade}$$

The actual top-oil temperature will be $15.9+50+30 = 95.9$ degrees centigrade.

If no allowance for the reduced oil viscosity is made, the winding gradient is obtained by multiplying the gradient at 100 per cent load (=11 degrees centigrade) by the ratio $(9/2)^{0.8}$, which takes in account the increased losses, due to the change in copper temperature. There is an appreciable change in oil temperature, however, and Figure 4 and the previous discussion indicate that it should be safe to assume that the increase in resistance loss at higher temperatures is compensated for by the reduction in gradient, due to reduced oil viscosity. On this basis, the computed gradient for this case will be $(8/2)^{0.8} \times 11 = 33.3$ degrees centigrade.

The total rise is then 95.9 plus 33.3, equals 129.2 degrees centigrade, which indicates that 200 per cent load for one hour following full load will meet the temperature limits.

By using similar methods, all of the values can be calculated. Figure 7 shows such a table and curve, giving values of overload slightly below the computed values. Comparison of this with Figure 17, Proposed Recommended Practices of the American Standards Association, page 86, indicates the conservatism of the older table.

Summary

A more accurate method than previously used for calculating temperature rises in transformers has been derived, and applied both to steady and transient conditions. This latter application, along with the recognition that newer transformers have both lower gradients and better oil protection, give the possibility of recommending much higher emergency loads than previously given to such apparatus.

Electropneumatic Brakes for High-Speed Trains With Particular Reference to Their Electrical Features

JOSEPH C. McCUNE
NONMEMBER AIEE

ELECTROPNEUMATIC brakes for main-line high-speed passenger trains are a recent innovation. Electropneumatic brakes have, however, been known and used for many years. The first steam road tests were made in 1887. The results were quite gratifying, but improvements in the pneumatic apparatus resulted in such satisfactory performance that the added expense and complication of electropneumatic control was clearly not warranted. Electropneumatic brakes have been used, however, in subway and elevated service, and in considerable quantity, for more than 30 years.

To understand why electropneumatic brakes have so generally been adopted for modern high-speed trains requires some comprehension of the limitations of a strictly pneumatic system and some grasp of the part played by the brake in modern transportation. The importance of the brake, as a factor in the expeditious movement of trains, is not generally appreciated. The brake system suffers, in a consideration of its influence upon the maintenance of high schedule speed, because its work seems entirely negative. That is, the purpose of the brake is to retard or stop trains, a result which can be attained, after a fashion, without any brake at all. Since the brake appears to be only assisting in an event which would take place anyway, its potentiality as a means to move trains faster over the road is not apparent at first glance. In fact, it seems anomalous to assert that a brake, which stops a train, has anything to do with covering ground, which obviously implies motion, but that this is actually the case will become apparent later.

Because the work done by the brake is of a negative character, it frequently happens that the technical difficulties involved in producing a satisfactory brake and the power embodied in it are not fully visualized by those who are not directly in contact with the braking situation. Many engineers are confronted with the problem of transferring heat energy into mechanical energy, as in steam or gas engines. Electrical engineers change, in motors, electrical energy into mechanical energy. Engineers, in general, are mainly preoccupied with obtaining mechanical energy from some other form of energy, whereas brake engineers, as a very special group, deal with the transformation of mechanical energy into heat. Although this transformation is the reverse of that ordinarily encountered, it is evident that many technical problems must be met with, a consideration of which is not pertinent to this paper.

It is believed, however, that some mention should be made of the power requirements of the modern brake. Neglecting friction, wind resistance, and so forth, it is obvious that, measured at the rail, the motor torque and the brake torque must be equal if a train is to be accelerated or decelerated at the same rate. But in actual practice, the brake torque is greater than the motor torque since the rate of deceleration exceeds the rate of acceleration. Furthermore, this higher brake torque is produced at the highest speeds. Consequently, since horsepower is proportional to the product of torque and velocity, the horsepower involved in deceleration is many times as great as the horsepower involved in acceleration. Thus, to decelerate a 1,000-ton train, at 100 miles per hour, at the rate of 2.2 miles per hour per second, involves the dissipation of 53,500 horsepower.

Horsepower may be used to indicate the rate at which a brake dissipates energy, since it is a less cumbersome expression than foot-pounds or Btu's per second and is also a concept familiar to engineers. But it should be noted that, from the heat viewpoint, the horsepower of a motor is a very different thing from the horsepower of a brake. The heating of the motor, caused by I^2R loss, friction, and so on, has a low value, expressed as horsepower, since it is but a small percentage of the output horsepower. The entire output of the brake, on the other hand, is heat. When expressing the energy dissipated by a brake in terms of horsepower, therefore, it must be remembered that the quantity of heat involved is many times the heat found in a motor of similar horsepower.

It is clear that in braking trains, mechanical energy is transformed into heat at a very rapid rate and that very quickly tremendous quantities of heat are generated. Fortunately, since a brake can be installed at each wheel, this heat does not have to be dissipated in some localized area, but instead can be dissipated at each wheel in the train. The problem of heat dissipation is thereby made much easier of solution. In addition, a brake at each wheel makes possible the shortest stop, because it enables the maximum retarding force to act upon the train. It is evident that since a brake has to be provided at each wheel, both in order to handle heat satisfactorily and to produce the necessary retardation, the air brake must provide for remote control of all these brakes from the head end.

Electrical engineers will recognize a certain similarity between a multiple-unit control system and an air-brake control system. In the electrical system, each car is fitted with a control group or box; in the pneumatic system, each car is fitted with a triple valve or its equivalent of universal or control valve. In the electrical system, the controller is moved from its off to its on position by remote control from the head end; in the pneumatic system, the triple valve is moved from its release to its applied position, again by remote control from the head end. In the electrical system, the controller progresses or notches up under remote control from the head end; in the pneumatic system, the triple valve graduates on or applies the brake fully, also

Paper 42-55, recommended by the AIEE committee on land transportation for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted November 12, 1941; made available for printing December 19, 1941.

JOSEPH C. McCUNE is director of research with the Westinghouse Air Brake Company, Pittsburgh, Pa.

under remote control from the head end.

If there are certain similarities between a multiple-unit control system and an air-brake control system, there are three striking dissimilarities. The first of these is that the electrical system employs several control wires, whereas the pneumatic system employs but a single control pipe, the familiar brake pipe. The second dissimilarity is that the control wires of the electrical system transmit control current only and do not carry the main motor current; the single pipe of the pneumatic system handles not only air for control purposes, but also the air for charging the brake cylinders, which involves substantial volumes of air. The third dissimilarity is that current flows through the control wires with the speed of light, whereas air flows through the brake pipe with the velocity of sound as the limit.

It is well-known that car brakes are caused to be applied by reducing the pressure in the brake pipe, but this operation should be examined in some detail in order that the reasons for electropneumatic control may be better understood. It is a comparatively simple matter to move a car controller from its off to its on position by remote control from the head end, but a somewhat more difficult operation to move a control valve from its release to its applied position, the equivalent of from off to on with the controller. This difficulty arises because the brake pipe is used, not only as the control medium, but also as the means of transporting large quantities of air to the car supply reservoirs, from which the brake cylinders are charged. Because of this function, which means that the feed grooves are open, the control valves, in release position, are not in a condition to respond to slight reductions in brake-pipe pressure occurring at a relatively slow rate.

To move the control valves from their off to their on position, it is necessary, therefore, to make a slight reduction in brake-pipe pressure throughout the train rather rapidly. This reduction cannot be made too rapidly, however, because then an emergency and not a service application would develop, not to mention certain other undesirable results. In order that this reduction in pressure may occur quickly throughout the train and with minimum pressure gradient from head to rear, control valves are provided with a quick-service feature which causes the pressure to be vented locally, at each control valve, at the same time that a reduction is being made at the brake valve. With this arrangement, the control valve on the last car of a long train can be moved from its off to its on position in a few seconds. It has been found that the time is roughly proportional to the linear length of the brake pipe; that is, in long trains about one second is required for each 300 feet of brake pipe. In other words, if a train were of such length that the control valve on the last car was 1,000 feet from the brake valve, this control valve would move from its off to its on position about 3.3 seconds after the brake valve had been placed in service position.

It should be noted that 300 feet per second applies to the last car only. The combined action of the quick-service feature and the flow of air from the rear is such that the first car does not apply until shortly before the last car. In consequence, at the expiration of a brief interval proportional to the length of the train, control valves, from head to rear, move from their off to their on positions with a fair approach to simultaneity.

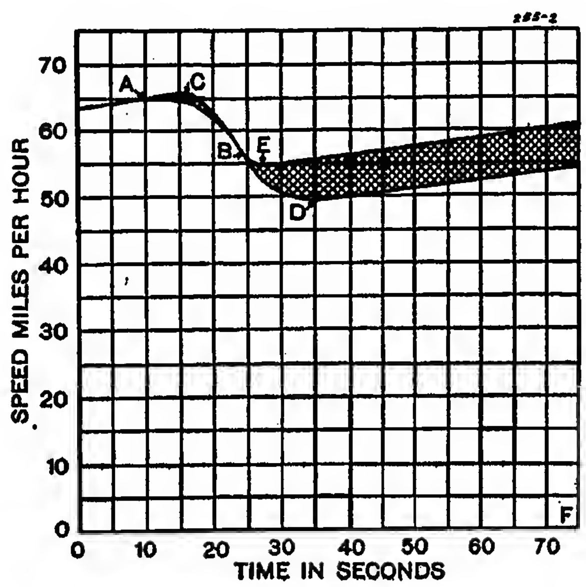

Figure 2

The operation just described covers the movement of the control valves throughout the train from release to application position, in which position the brake cylinders are charged with compressed air from the car reservoirs. In order that the brake cylinders may be charged to full-service pressure, the brake-pipe pressure must be reduced, on each car, 24 pounds or, say, from 110 to 86 pounds. It is clear that the pressure in a long pipe, commencing at the head end, cannot be lowered 24 pounds throughout its length, except when an appreciable time is available, and particularly when the gradient in pressure, from head to rear, must be held to a minimum. With the most modern pneumatic equipment, including continuous quick-service valves, it takes roughly 15 seconds, after placing the brake valve in service position, to build up full-service cylinder pressure on the last car of an 18-car train.

The release of the brakes, or the movement of the car control valves back to off position, is accomplished by building up pressure in the brake pipe. After a full service application, as stated above, the brake-pipe pressure throughout the train, is roughly 86 pounds, and this pressure must be restored to about 110 pounds before all pressure can be completely released from the brake cylinders. Since the brake-pipe pressure is restored from the head end and against the drain of car reservoirs which are, at this time, recharging themselves from the brake pipe, a substantial time element is involved, although this time is still a matter of seconds and not greatly different from the time to apply all brakes fully.

It is clear that the operations just described involve transient pneumatic phenomena. Electrical engineers appreciate the difficulty attached to understanding and controlling transient electrical phenomena. They probably will not dissent from the statement that transient phenomena in a gas, or elastic medium, present technical problems at least as difficult. Many of these problems can be circumvented by utilizing electrical control means.

Since 1887 at least, it has been understood that the time element involved in applying or releasing brakes could be greatly reduced by the use of electricity and since that time many systems of electropneumatic control have been devised, and several types have been placed in actual service. The type used on the modern high-speed train may be called a two-pipe system. That is, a second pipe, termed the straight air pipe, is employed as well as the familiar brake pipe. The straight air pipe only is used during electropneumatic operation.

Each car is equipped with electropneumatic valves. When these valves are energized from the head end, pressure is built up locally on each car, in the straight air pipe, so that the pressure in the straight air pipe throughout the train can be brought up quickly to full service value. Suitable pneumatic relays, controlled by straight air-pipe pressure, charge the car-brake cylinders to the pressure existing in the straight air pipe and in the same time. With this system of control, full-service cylinder pressure can be secured in about four seconds from brake-valve movement on all cars of a train of any length. To release the cylinder pressure, the electropneumatic valves are de-energized, which vents the straight air-pipe pressure locally throughout the train. Brake-cylinder pressure is consequently rapidly released.

With this system, it is evident that in service operation, three results, which

cannot be obtained with pneumatic control alone, are accomplished.

1. Pressure commences to appear in all brake cylinders throughout a train of any length at substantially the instant the brake valve is placed in service position.

2. The cylinders throughout the train can be charged simultaneously to full pressure in a time fixed by the designer's option.

3. Pressure in the cylinders throughout the train can be completely exhausted simultaneously in a time again fixed by the designer's option.

It will be noted that the time saved by electropneumatic control is a matter of seconds. The question arises as to why a few seconds is an item of any great moment in the operation of high-speed main-line trains, which make few stops and few slowdowns. If one of these trains, however, traveling at 100 miles per hour or about 150 feet per second, has to make an emergency stop to save lives and avoid property damage, the importance of saving a few seconds in brake-application time is self-evident. This aspect of electropneumatic control is so well understood that no particular comment seems called for. But since the effect of electropneumatic control on service operation is less widely understood, some comment in this connection may be of value.

Figure 1 illustrates a situation which arises more or less frequently in actual service. A train is moving along the track, still accelerating, when it encounters, at A, an unfavorable signal aspect and under circumstances which indicate that a service-application stop must be made at once. Power is immediately shut off and the brake valve placed in service position. With pneumatic brakes, the train decelerates along the line AB; with electropneumatic brakes, along the line AC. The stop distance with the pneumatic train is represented by the area ABD; with the electropneumatic train, by the area ACD: The cross-hatched area is the saving in stop distance, which, obviously, is far from negligible.

This chart has been prepared to show the gain brought about by a single factor, that is, the use of electricity, and does not refer to any specific train. It assumes that a full service application, with either brake, produces a retardation of 1.25 miles per hour per second, and that this retardation is constant, irrespective of speed or temperature. When the brake is partially applied, the retardation is taken as directly proportional to the cylinder pressure. The cylinder-pressure build-up is assumed to duplicate laboratory tests of an 18-car train. The retardation is supposed to depend entirely upon the car-cylinder pressures, that is, the locomotive brake blends harmoniously with either system of car brakes. Internal and wind resistance is neglected.

None of these assumptions corresponds precisely with the conditions found in actual operation. Notwithstanding, it is believed that the chart fairly indicates the order of the shortening of service-stop distances, on a comparative basis, accomplished by adding electricity to the pneumatic-braking system. The saving reduces as the number of cars in the train decreases but never entirely vanishes, because the pneumatic-application time is always greater than the electropneumatic time, even for a one-car train.

Since signal spacing is based upon service-stopping distances, the situation described above is of considerable practical importance. Another aspect of service-stopping distances was mentioned by R. P. Johnson, chief engineer, Baldwin Locomotive Works (*Transactions* of the American Society of Mechanical Engineers, October 1941, page 614) before the society, namely:

"Modern high-speed operation presents problems in deceleration as well as acceleration, but the paper does not say much about this. On some railroads, such as the New Haven, station stops may be rather close. If, on such a road, the decelerating force were relatively low, the train could not, within the distance, be permitted to attain the maximum speed of which it is capable."

Figure 2, which is based on the same assumptions as Figure 1, illustrates a situation frequently encountered in regular service. The train is proceeding along the track, still accelerating. Suddenly a condition arises which may call for a brake application. This condition may be an unfavorable signal indication which is not clearing as expected, an automobile crossing the track, a track-repair gang somewhat slow to move, or any unexpected interference, of a temporary nature, which may call for a stop. A brake application is deferred as long as possible but with pneumatic brakes, in order to stop short of the interference, the brake valve has to be placed in service position at A and the train decelerates along the line AB. To stop at the same point with faster-acting electropneumatic brakes, the brake valve does not have to be placed in service position until several seconds later or at C. The train then decelerates along line CB.

At C, the temporary interference clears; that is, the signal aspect becomes favorable, the automobile completes its passage across the track, the track gang gets out of the way, and so on. The brake valve is, therefore, immediately placed in a position to release the brakes. The train continues to decelerate, of course, until the brakes are completely released, which occurs at D with the pneumatic brakes and at E with the electropneumatic. Power is then applied and the train accelerates. The cross-hatched area indicates the greater distance covered by the electropneumatic train in the time OF. It will be noted also that at F, the electropneumatic train is at a higher speed than the pneumatic train and is consequently still gaining distance.

It has been stated that in Figures 1 and 2, it is assumed that a full-service application of either the pneumatic or the electropneumatic brake produces the same retardation. The savings discussed above

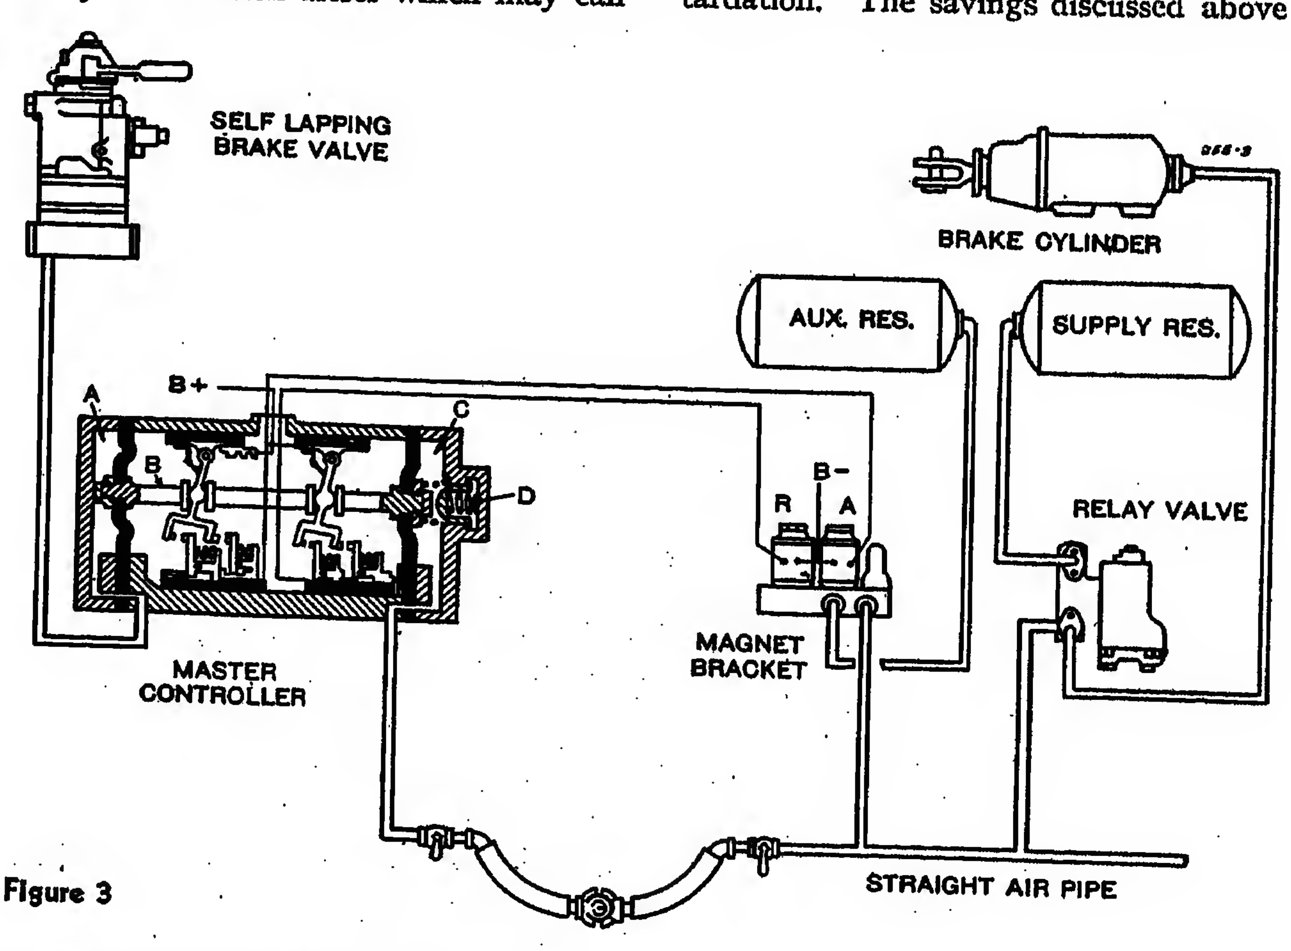

Figure 3

are, therefore, those to be credited entirely to the use of electricity. It will be observed that these savings are obtained in situations where the brake valve has to be placed in service or release position without any prior warning At regular station stops or slow-order curves, the need for a brake application or release can be anticipated, in which event the savings under discussion, with skillful handling, largely disappear. But there are so many occasions in actual operation, apart from emergency stops, when the brake must be applied or released without advance notice that electropneumatic brakes contribute materially to the expeditious movement of high-speed trains.

In this connection, the release function is of particular interest. Since a long time and a considerable distance are needed to accelerate a train to the high-speed zone, it is important that the high speed, once attained, be held as long as possible; that is, that slowdowns and stops be reduced to the absolute minimum. The urgent necessity of such a course can be readily appreciated by anyone who has noted the effect of one or two stops, or a long detour, on the mileage covered in an all-day automobile trip. The railroads, from the beginning of high-speed operation, have fully appreciated this necessity. Large sums of money have been spent to eliminate speed restrictions at curves, track intersections, grade crossings, and so on. Meets have been arranged so that high-speed trains would not be called upon to reduce speed. Steps have even been taken with track-repair gangs so that their presence would not interfere with the maintenance of high speed.

That brake release has an effect upon these improvements is not always considered. But it is clear that since slow orders cannot be completely eliminated, slow-releasing brakes introduce an additional penalty, because the speed of the train, due to slow-brake release, is brought down somewhat below that called for by the slow order. Electropneumatic brakes, because of their fast release, assist greatly in reducing this penalty to a minimum.

That brakes play an important part in maintaining schedule speeds is evidenced by a statement by A. A. Raymond, superintendent of fuel and locomotive performance, New York Central (*Railway Age*, September 20, 1941, page 446) before the American Society of Mechanical Engineers, namely:

"While acceleration only has been shown, getting over the road in the minimum amount of time is affected also by the rate of deceleration, although, in general, more time is lost accelerating than decelerating."

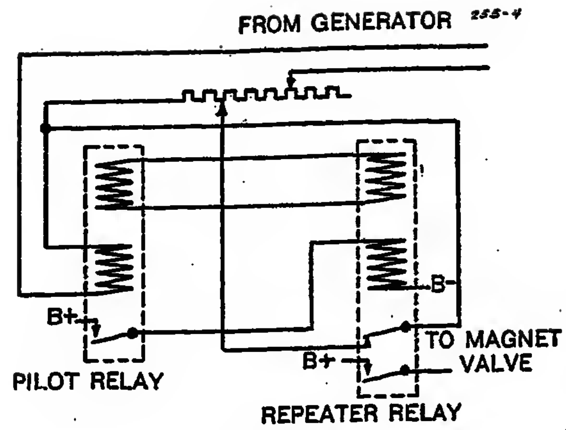

Figure 4

A detailed description of the operation of the complete electropneumatic brake does not come within the scope of this paper. In fact, it appears that such a description would possess only a very limited appeal. It is thought, however, that certain features of the brake involving problems of electrical control, which are not widely, nor ordinarily encountered, will interest electrical engineers in general.

It has been emphasized that electropneumatic brakes can be quickly brought into action, or as quickly taken out of action. In addition, it has been previously pointed out in this paper that a train-braking system comprises a large number of individual brakes, or one per wheel, and that they must all be controlled remotely from the leading unit. The retarding force at each wheel is created by brake-shoe friction; the brake-shoe friction is proportional to the brake-shoe pressure; and the brake-shoe pressure is proportional to the brake-cylinder pressure. It follows that regulation of the cylinder pressure within close limits is essential if the retardation of the train is to be controlled with maximum satisfaction.

Figure 3 shows, in simplified form, the essential elements of the electropneumatic system for controlling cylinder pressure. When the brake valve at the left is moved to service position, pressure is built up in chamber A of the master controller. This pressure causes shaft B to move to the right and close a set of contacts which energize the release wire from the battery. All release-magnet valves R throughout the train are then energized, thereby closing all exhaust ports from the straight air pipe. Continued movement of shaft B to the right closes the application contacts, which causes all the application-magnet valves A throughout the train to be energized and opened, thereby permitting air to flow from the auxiliary reservoirs to the straight air pipe. When pressure is built up in the straight air pipe, the relay valves open and from the supply reservoirs, charge the brake cylinders to the pressure existing in the straight air pipe. Meantime, pressure from the straight air pipe has been building up in chamber C of the master controller. When this pressure almost equals that in chamber A, spring D moves shaft B to the left and opens the application contacts. The application magnets close and the cylinder pressure remains equal to that in chamber A.

To release the cylinder pressure, the brake valve is moved to release position which releases the pressure in chamber A. Shaft B then moves to the left and opens the release contacts. All release-magnet valves are then de-energized and straight air-pipe pressure is exhausted to atmosphere at each magnet bracket. Exhausting the straight air-pipe pressure causes the relay valves to move to a position in which the brake cylinders are connected to atmosphere. The brakes are thereby released.

The very simplicity of this control system tends to obscure the many advantages it possesses. These advantages represent such an advance in the brake art that it is believed attention should be directed to them.

The brake valve employed with this system retains an old name but actually the mode of operation is entirely changed. The self-lapping brake valve is essentially a two-way regulating valve; that is, it regulates the pressure admitted to or discharged from chamber A. When the brake-valve handle is moved to the right, out of its normal or release position, each position of the handle calls for a definite pressure. In other words, when the handle is placed in a certain position, the pressure in chamber A is increased or decreased, depending upon whether it is less or greater than the pressure called for by the position of the brake-valve handle. The pressure can be increased or decreased at will in very small steps. It is independent of the volume of chamber A or the pipe attached thereto and is not affected by any reasonable leakage from volume or pipe. Those who are acquainted with old-style brake valves will appreciate what an advance in the art this self-lapping brake valve represents.

For practical purposes, the master controller moves to its application position, the application-magnet valves are energized and the relay valves are opened coincident with placing the brake valve in an application position. It has been previously explained that several seconds are required to move the control valves of the purely pneumatic system from their off to their on position with trains of

customary length. All this time is eliminated by electropneumatic control.

Furthermore, the time of charging the brake cylinders to full pressure is not contingent upon dropping the pressure throughout a long brake pipe. Instead, the application-magnet valves on each car can charge the small straight air-pipe volume of each car very quickly and the brake-cylinder pressure, through the action of the relay valves, keeps pace therewith. Each application-magnet valve is provided with a choke so that the time of fully charging the straight air pipe is prefixed at about four seconds. It is not necessary to change the size of this choke to compensate for variations in car length, and so on, because the straight air pipe itself averages out variations since it is continuous throughout the train. If a magnet valve should become inoperative, this continuous pipe supplies the necessary air from front and rear. If, during an application, the pressure in the straight air pipe should reduce through leakage, which is probable since its volume is small, the master controller promptly moves to the right, re-energizes the application-magnet valves, and restores the loss in pressure.

Electropneumatic brakes can be applied to one-half their full-service effectiveness in about two seconds. It is clear that if the pressure build-up had to be shut off by moving a brake valve back from service to lap, very considerable skill would be required, if indeed it could be done with reasonable accuracy. With the system shown in Figure 3, the brake valve is moved half way toward full-service position, which produces one-half the full-service pressure in chamber *A*. As soon as this pressure is attained in the straight air pipe, and hence the brake cylinder, the master controller de-energizes the application-magnet valves. It is plain that this system makes it possible to apply and release brakes partially, despite the very short times involved, easily, positively, and uniformly.

It is apparent that with this system, the control of cylinder pressure is not influenced by the number of cars that may be in the train. This is in decided contrast to a purely pneumatic system in which the time to obtain a certain cylinder pressure changes with the number of cars in the train. That brake action should be independent of train length is obviously so desirable as to call for no extended comment.

The action of the relay valve, which directly charges the brake cylinder, is not changed by variable brake-cylinder volume. Variations in brake-cylinder pressure caused by variations in piston travel, a troublesome problem with older pneumatic brakes, are entirely overcome. Moreover, the relay valve automatically maintains the brake-cylinder pressure against leakage.

The net result of this control system is that any cylinder pressure desired, requiring either an increase or a decrease over the pressure previously existing, may be easily, positively, and uniformly obtained in a very short time which is always the same irrespective of train length; and independent of variations in pipe volumes, changes in brake cylinder piston travel, or brake cylinder leakage. Similar results, particularly with respect to time, cannot be attained with a one-pipe pneumatic system.

It is well known that the friction of cast-iron brake shoes, for a given pressure, decreases as the speed increases. If the same retardation is to be obtained in the high-speed brackets as in the low, a greater brake-shoe pressure must be employed at the higher speeds. It has been found empirically that satisfactory results

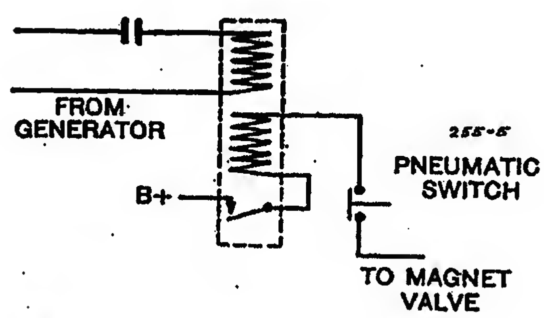

Figure 5

are obtained if 100 per cent of this higher pressure is employed at speeds above 65 miles per hour, 80 per cent between 65 and 40 miles per hour, 60 per cent between 40 and 20 miles per hour, and 40 per cent at speeds below 20 miles per hour. To make these changes automatically, it is evident that a speed-recognizing device is required. For this purpose, a generator, usually axle-mounted, is employed.

A generator to measure speed is a familiar arrangement but such generators ordinarily provide energy only sufficient to operate indicating instruments. The generator here considered has to supply enough energy to operate a system of relays, which means that at 100 miles per hour the generator output is about six watts. Since the relays operate on direct current, a d-c generator is used, and operation in either direction is taken care of by a directional relay.

One problem with relays, of course, is that they pull in with one voltage and drop out with an appreciably lower voltage. This characteristic has to be overcome with the speed-control system, since it is desired that speed recognition be as sharp and definite as possible. The method used is illustrated by Figure 4.

When the generator has built up sufficient ampere turns in the lower coil of the pilot relay to pull in the armature, the closing of the contacts energizes the lower coil of the repeater relay. The flux thereby built up induces a current in the upper circuit which adds to the ampere turns of the pilot relay, so that its armature is pulled in without hesitation or fluttering. Opening of the upper contacts of the repeater relay cuts additional resistance into the circuit of the lower coil of the pilot valve. It consequently drops out on a higher voltage than would otherwise be the case.

The result achieved with this combination is that if the pilot relay pulls in at a speed of 69 miles per hour, it drops out at no less than 65 miles per hour and ordinarily at a somewhat higher speed. This four-mile-per-hour maximum range represents a drop of 5.8 per cent. Despite the fact that this device must be sufficiently rugged to withstand the shocks of railway service, its range approaches that of a household thermostat.

This generator can also be used to prevent wheel sliding. When used for this purpose, the generators are termed "Decelostats" and one is required per axle.

It is obvious that not very much time is available to prevent wheel sliding. When the wheel is rolling freely with brakes applied, a very small portion of the braking torque is devoted to destroying the angular velocity of the wheel and axle assembly, but the greater portion is balanced by the counter torque set up at the rail. But the retarding force set up at the rail cannot exceed the product of the coefficient of adhesion and the pressure actually exerted by the wheel on the rail. If the retarding force is near the adhesion limit, therefore, it is clear that the wheel will slip if

1. The braking torque, for any reason, increases abnormally.

2. The pressure of the wheel on the rail is reduced because of oscillations, and so on.

3. The coefficient of adhesion decreases because a section of bad rail is encountered.

If one or more of these conditions arise, the wheel and axle assembly loses angular velocity with great rapidity because the braking torque is directed almost entirely to arresting the rotary motion of the wheel and axle assembly. The wheels may cease revolving completely in a time which may not exceed 1 second.

A mechanism to prevent wheel sliding, therefore, must recognize wheel slippage

A Control System for Modern Multiple-Unit Rapid-Transit Cars

H. G. MOORE
ASSOCIATE AIEE

MUCH has been accomplished in recent years in the development of refined systems of control for traction motors as applied to buses, trolley coaches and street cars. Chief among the innovations is the extensive use of some form of electric braking—either as a holding brake for limiting speed when descending a grade or as a service brake for retarding the speed of the vehicle each time a slowdown or stop is made.

The latter type of brake is used as the principal means of braking PCC (Presidents' Conference Committee) cars, being supplemented by magnetic track brakes to obtain rates of retardation beyond the adhesive limit of wheels to rail and complemented by some form of friction brake to provide means of retarding the car at speeds at which the electric brake is not effective and to hold the car at standstill on a grade. The electric service brake is obtained by connecting the motors so that they operate as series-excited generators, the output being absorbed by the same resistors used for acceleration. To control this output under widely varying and continually changing conditions of speed and load requires the use of a novel switching and regulating scheme.

The success with which the equipment for PCC cars has met in street railway service has led to its adaptation to multiple-unit service. A notable example of such adaptation is the "compartment car", a number of which have been placed in operation by the New York City Transit System (Brooklyn-Manhattan Transit division). Because of conditions peculiar to operation in multiple-unit and from third-rail supply in subway and elevated service, various modifications and additional features (as compared to PCC car equipment) are provided.

Paper 42-49, recommended by the AIEE committee on land transportation for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted November 12, 1941; made available for printing December 23, 1941.

Characteristics of Dynamic Braking

Methods of determining the accelerating and braking characteristics of d-c series-excited machines and control are well known. For the elementary circuits illustrated by Figure 1 the following relations apply:

In Figure 1a,

$$2I_M R_A = V_L - 2nE_M - 2I_M R_M \tag{1}$$

and, in Figure 1b,

$$2I_M R_B = 2nE_M - 2I_M R_M \tag{2}$$

where V_L is line voltage and R_M is the motor resistance (including effective brush-contact resistance).

Equation 2 is of particular interest, because it illustrates that, since E_M is a function of I_M, the braking resistance is a linear function of speed for any constant value of current I_M. In fact, from equation 2

$$\frac{n}{R_C} = \frac{I_M}{E_M} \tag{3}$$

where $R_C = R_B + R_M$ = total circuit resistance.

If, therefore, the ratio I_M/E_M for each value of field strength used in braking be plotted as a function of I_M as shown in Figure 2, very useful curves for determining braking characteristics of the machine are provided. The curves are the basic form of all constant-resistance braking curves of the machine as, by multiplying the ordinate scale by any value of R_C, the curves become the current-speed characteristics for that circuit resistance. For example, with a circuit resistance of three ohms, the GE-1198 motor (full-field) will generate 200 amperes at 3,000 rpm. By further multiplying the ordinate scale by the proper factor determined by gear ratio and wheel diameter, the speed can be expressed in the more familiar unit of miles per hour car speed.

The curves also clearly show, for each field strength, the critical ratio of speed to circuit resistance below which the machines will not generate appreciable current. At this critical ratio the machines are very sensitive to slight changes in speed and resistance, this condition representing operation in the unsaturated portion of the magnetization curve.

Switching and Spotting

Obviously, in the interests of safety and efficient operation, the response of dynamic braking to the control of the operator or to automatic application for an emergency stop must be prompt but free of surges which might cause discomfort or injury to passengers.

Switching from accelerating to braking connections is facilitated by the use of motors connected permanently in parallel relation as it is necessary only to transfer the location of the resistors in the circuit.

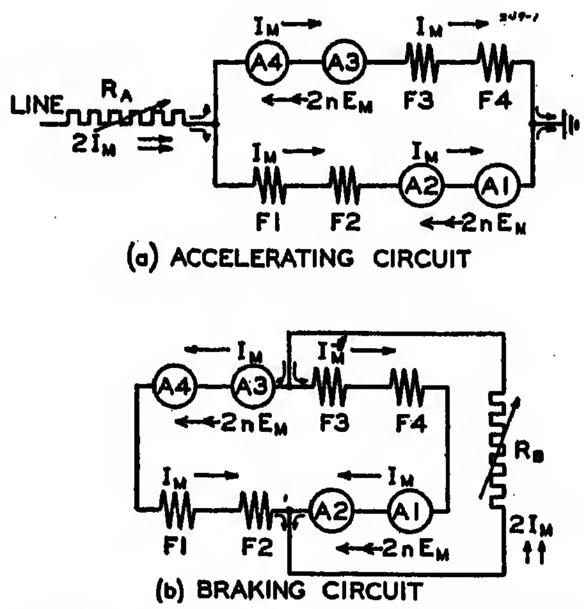

Figure 1. Elementary motor-circuit connections showing relations of current and electromotive force

R_B—Variable braking resistance

---

promptly and must act quickly to release brake cylinder pressure. How this can be accomplished with a generator is illustrated by Figure 5. The generator charges a condenser through a unidirectional relay. If the wheel is losing angular velocity at an abnormal rate, as it does when the wheel slips, the generator voltage drops at an abnormal rate. The condenser then discharges a current sufficient to trip the sensitive relay, which causes a magnet valve to be energized and pressure to be released very rapidly from the brake cylinder.

In conclusion, it should be pointed out that electropneumatic brakes involve control of the brake-cylinder pressure from the brake valve and do not necessarily include speed governor or "Decelostat" control. That is, speed governors and "Decelostats" may or may not be used with electropneumatic brakes.

It is not necessary to operate the motor reversers and, in the braking connection, the exciting fields are "cross-connected" to insure equal division of load between the two parallel groups of machines.

It is not enough to merely establish the braking connections, but the circuit resistance must also be quickly adjusted to the value which will give the desired value of braking current at any speed at which the brake may be applied. This operation has been termed "spotting" the control, and various schemes have been used to accomplish the desired results.

One scheme which has been successfully used is to arrange that, regardless of car and motor speed, the braking resistance be at (or near) its maximum value at the time of switching to the braking connections, and then to rapidly reduce the resistance until the current builds up to the desired value. This requires, regardless of the means for controlling the resistance, that the control be capable of rapid operation and that its current-responsive regulating system be capable of quickly stopping operation before the resistance has been reduced to too low a value. The principal advantage of this scheme is that the braking sequence is practically independent of the accelerating sequence, and a "switching step" of acceleration control can be provided wherein the accelerating resistance can be retained at maximum value.

The principal factor governing the correct value of braking resistance is, however, the speed of the car and motors. This suggests, if the acceleration sequence be suitably arranged and controlled in relation to motor speed, that braking current can be obtained immediately upon switching to the braking connection without requiring that the resistance control operate to change the load resistance. Such ideal operation cannot be attained in practice because of the wide ranges of accelerating and braking currents used, but is approximated in the control systems now generally used for PCC cars. Such systems permit the use of a less powerful drive for the resistance controller but requires, even on the "switching step", that the acceleration sequence progress so as to maintain the required relation of resistance to car speed.

Coasting Operation

A refinement of the spotting operation can be provided by utilizing the interval in which the car may be allowed to coast before the application of braking. This is done by automatically switching the motor circuit to the braking connection and allowing the braking sequence to progress immediately after the operator shuts off accelerating power. However, under this condition, the braking current is held to a very low value and the exciting fields are partially shunted to maintain the resulting retardation at a negligible value. The control thereupon operates to establish the circuit resistance at the critical value corresponding to that particular field strength and car speed.

By proper choice of field strength and value of current used for coasting, the equipment may be made to provide immediate response to the application of dynamic braking simply by the operation of unshunting the exciting fields. As an example, from Figure 2, if the coasting current is maintained at 20 amperes with fields partially shunted, a current of approximately 95 amperes will be obtained by full-field operation without change in either motor speed or circuit resistance. Thereafter this or higher values of braking current are obtained by the resistanee control operating automatically in response to a current-sensitive relay to maintain the speed-resistance ratio at the value corresponding to the desired braking current.

Specific Connections and Operating Sequence

Figure 3 illustrates, with some modifications described later as being incident to multiple-unit operation and a particular type of service, a complete motor circuit for a PCC car. The resistor section $R1$-$R2$ indicated as having a tap which can be moved from position A to position B takes the form of a rheostatic, or "commutator", controller as shown by Figure 4. This device is essentially a stationary commutator with 137 active bars on about 330 degrees of the periphery, each connected by copper straps to resistor elements. Each active commutator bar, therefore, represents a tap on the whole resistor section $R1$-$R2$. Six carbon-tipped fingers or "brushes" are carried in constant contact with the surface of the commutator by an arm driven by a small reversible motor so as to rotate in either direction over the active bars. Mechanical stops are provided to prevent rotating the brushes over the inactive commutator bars which, with their slot insulation, serve to insulate resistor terminals $R1$ and $R2$ from each other over the remaining 30 degrees of periphery.

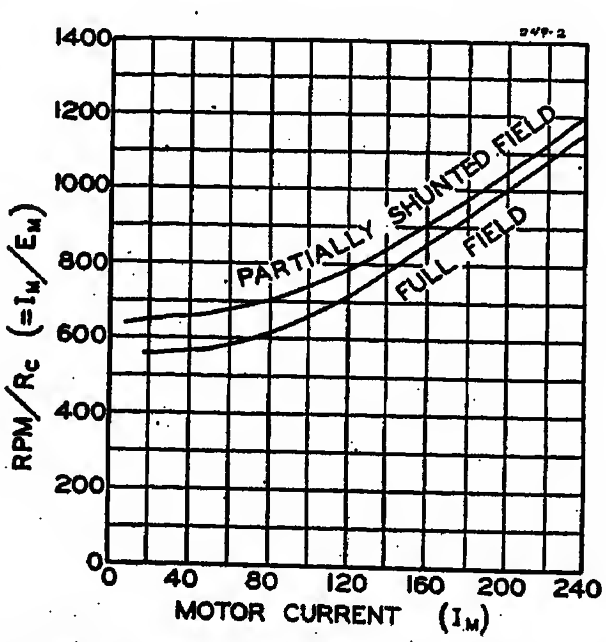

Figure 2. Basic characteristics of GE-1198 motor operating as a series-excited generator

The direction of rotation of the pilot motor and brush arm is controlled solely by the combinations of contactors which may be closed, and the speed is controlled primarily by the operation of accelerating and braking relay ABR.

For an acceleration from standstill to maximum speed, line contactors $LB1$, $LB2$ and $LB3$ close to complete the power circuit with all of rheostatic controller resistance $R1$-$R2$ and resistor sections $R2$-$R3$ and $R3$-$R4$ in series with the motors. The initial value of current and tractive effort so obtained is equivalent to a rate of only about 0.4 mile per hour per second for the usual weight of car.

Contactors $C1$ and $C2$ close in sequence to leave only the rheostatic controller in series with the motors and thus, in two steps, increase the current and tractive effort to approximately the value required for acceleration at the minimum service rate. The rheostatic controller then operates to move its brush arm from position A towards position B under control of relay ABR which, in turn, is responsive to current in its operating coil ABR (a). If a high rate of acceleration is required, relay ABR is made responsive to a corresponding value of current and the rheostatic-controller brush arm is permitted to move rapidly until this current is obtained. Thereafter, the speed of brush-arm movement is closely regulated to maintain constant current through the motors as the car speed increases.

When the brush arm reaches position B, the motors are operating at full voltage and contactor $LB4$ closes to prevent the re-insertion of resistor $R1$-$R2$ when the brush arm subsequently moves back towards position A. At this point in the sequence, transfer switch TS operates to open its contact (a) and close contact (b). This has no immediate effect in the motor circuit but is in anticipation of a following coasting or braking sequence. As the brush arm returns to position A, field-shunting contactors $FS1$, $FS2$, $FS4$ and $FS3$ are closed in sequence by circuits

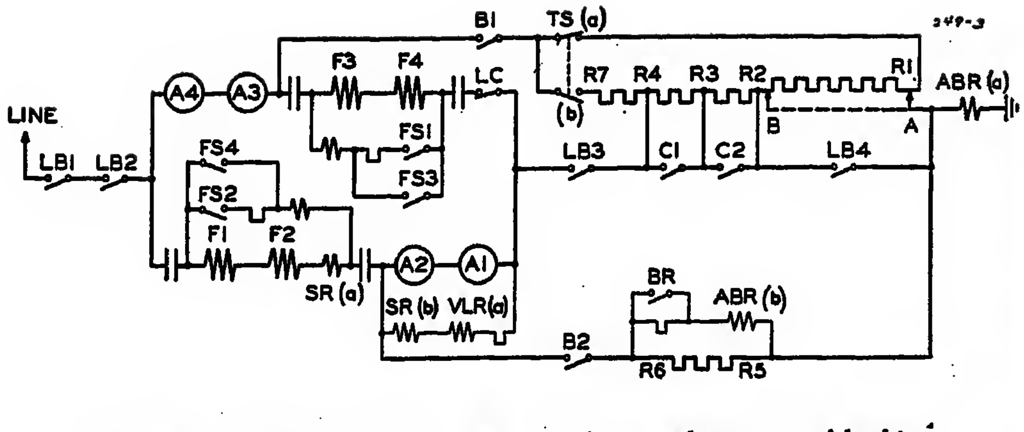

Figure 3. Motor-circuit connections for accelerating and braking

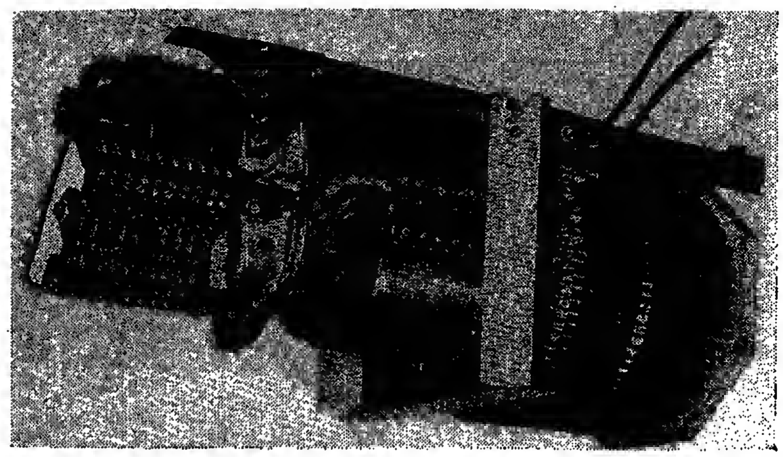

Figure 4. Rheostatic motor controller

controlled by cams mounted on the brush-arm shaft of the rheostatic controller.

The motor circuit may be switched to the braking connections at any time in the accelerating sequence by opening all contactors which may have closed and immediately closing braking contactors *B*1 and *B*2. As transfer switch *TS* and the rheostatic-controller brush arm do not change position during this operation, the value of braking resistance initially obtained in the braking circuit is determined by the status of the accelerating sequence just preceding the switching operation. Thus, if the acceleration sequence had been completed with rheostatic-controller brush arm returned to position *A*, the initial braking resistance would be at a maximum value, or the sum of all resistances shown. On the other hand, if the circuit were switched to braking connections at some low speed such that the brush arm was still moving from position *A* toward position *B*, the initial braking resistance would be only that part of section *R*1-*R*2 which had been cut out during the partial acceleration, plus the resistance of section *R*5-*R*6. This latter section is never cut out of the braking circuit, because it has been found impractical—except by means otherwise detrimental—to automatically regulate the braking current at very low speeds where the response of the motor to changes in speed-resistance ratio is very sluggish.

While either coasting or braking, the speed of brush-arm movement is again controlled primarily by the operation of relay *ABR* which is now responsive to an operating coil *ABR* (*b*) connected so as to be energized by the voltage drop across resistor section *R*5-*R*6. By use of a suitable control resistance in series with this operating coil, the range of operation of the relay in respect to braking current through resistor *R*5-*R*6 can be readily changed from a very low value, corresponding to coasting current, to high values, corresponding to normal service and emergency braking, by allowing contact *BR* to open.

The complete coasting and braking sequence from high speed consists of first moving the rheostatic controller brush arm from position *A* towards position *B*, transfer switch contact *TS* (*b*) having been closed and contact *TS* (*a*) having been opened in the preceding acceleration sequence. When the brush arm reaches position *B*, the transfer switch operates to open contact *TS* (*b*) and close contact *TS* (*a*). Since the resistance of sections *R*2-*R*3-*R*4-*R*7 is essentially the same as the resistance of the rheostatic controller resistor, the operation of the transfer switch re-inserts the resistor *R*1-*R*2 in the braking circuit without surge due to abrupt change of load resistance. As the car speed continues to decrease, the rheostatic-controller brush arm moves back to position *A* until, finally, only resistor *R*5-*R*6 is left in the circuit and the dynamic braking "fades out" at very low car speeds.

As previously indicated, the braking connections may be established at any speed and, therefore, the braking sequence described may be foreshortened by any amount.

The relation of braking-sequence progression to speed of the car also permits the switching to accelerating connections and the reapplication of power quickly and smoothly at any speed. A typical diagram showing the relation of sequence progression to car speed for extreme rates of acceleration and braking is shown in Figure 5.

Cushioned Shutoff

Emphasis has often been given, in the design of accelerating and braking control, to the smooth application of power and brakes, particularly where high rates of acceleration and braking are provided. It is quite as important that if, while accelerating at a high rate, the operator finds it necessary to coast, power be removed in easy steps to avoid passenger discomfort. This is accomplished by introducing sequential opening of contactors *C*2, *C*1, the field-shunting contactors (if accelerating sequence has progressed that far) and, finally, the line contactors. If it is necessary to make a brake application, however, the sequential operation is automatically nullified and the switching of the motor circuit to braking connections is obtained without delay.

A cushioned release of high rates of dynamic braking is obtained by the normal operation of partially shunting the motor fields when coasting. The braking current does not immediately drop to the normal coasting value because of the relative characteristics of braking with full and partially shunted fields.

Control of Rheostatic Motor Controller

Figure 6 shows the complete circuit for speed and directional control of the pilot motor which drives the rheostatic controller brush arm. The motor is provided with separate series-exciting fields for each direction of rotation so as to simplify the reversing operation by contactor interlocks. It should be noted that the direction of rotation is always such as to reduce traction-motor circuit resistance, whether accelerating or braking. No voltage, therefore, appears between the commutator bars of the rheostatic controller and the trailing edges of the carbon-tipped fingers, and the voltage at the leading edge is so low as to preclude any possibility of burning or sparking.

Control of the speed of the pilot motor in response to accelerating or coasting and braking currents is provided through the medium of relay *ABR* which, at a predetermined current determined by tension of a restraining spring, picks up to short-circuit the pilot-motor armature. Besides the operating coils (*a*) used during acceleration, and (*b*) used during coasting and braking, a third coil (*c*) is in series with the circuit controlled by *ABR*. This coil provides a powerful anticipatory response to increasing current in the traction-motor circuit to prevent "overshooting" and, at the regulated value of traction-motor current, causes the relay to operate on one or more of the sequentially closed contacts with a vibrating ac-

tion such that the armature voltage and field excitation of the pilot motor and, therefore, the speed of brush-arm movement is regulated to maintain constant current through the traction motors.

Where service is such that the cars may be operated frequently at maximum speed it is desirable to prevent the repeated use of dynamic braking at loads beyond safe operating limits of the traction motors. As these limits are characterized by an almost constant value of armature voltage, a voltage-limit relay *VLR* may be provided to control the rheostatic-controller pilot motor in a manner similar to relay *ABR*, but responsive to a predetermined traction-motor overvoltage. The effect of voltage-limit operation on braking sequence is indicated by the broken line at the top of Figure 5.

Multiple-Unit Operation

Figure 7 shows one of a number of multiple-unit rapid-transit "compartment" cars to which the electric equipment of a PCC car has been adapted. Each compartment car is equivalent to two PCC cars in electrical equipment, as each car has four two-axle trucks supporting three articulated body sections designated *A*, *B* and *A*1. The outer sections, *A* and *A*1, are identical and carry the major portion of the electrical equipment. The car weight per motor is approximately 15 per cent greater than that of a standard PCC car but, as the car operates in less frequent stop service, is well within the capacity of the motors.

Multiple-unit operation requires that certain devices (controlled mechanically by the operator of a PCC car) be arranged for remote control. The hand-operated reverser of the PCC car is replaced by a conventional electropneumatic reverser, controlled by the energization of either one of two train wires. On a PCC car, the accelerating and braking currents are controlled by varying the tension of the accelerating- and braking-relay restraining spring. For remote control, the spring is fixed at a value which will normally cause the relay to operate at the desired maximum values of current. Lower operating currents are obtained by energizing a separate coil section, *ABR* (*d*) of Figure 6, at various currents to assist the other coils in closing the relay contacts. A variable voltage is supplied the train wire to which the rate coils are connected by a potentiometer incorporated in the master controllers.

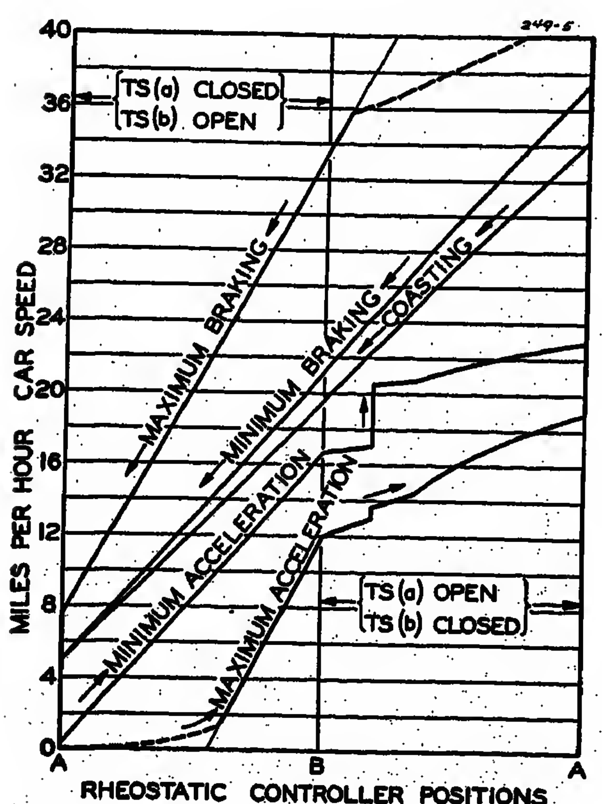

Figure 5. Typical sequence diagram

It is neither practicable nor safe to control all of the circuits directly through train wires from the master controllers, because

(*a*) Some circuits must be energized to obtain dynamic braking sequence.

(*b*) Some circuits associated with undervoltage protection are controlled independently of the master controller.

(*c*) The capacity and number of master controller fingers and train wires would be increased appreciably by direct control.

The control circuits of each equipment are supplied, so far as is practical, from the local battery and its charging generator on each *A* and *A*1 section, through contacts on auxiliary relays which, in turn, are controlled through train wires from the master controllers. Because of the possibility of open circuits or short circuits on these train wires, the circuits are arranged so that it is necessary to energize two or more train wires to release all types of brakes with which the cars are equipped (electric, magnetic track and friction brakes), and also it is necessary to energize two or more train wires to accelerate the cars. Failure of any essential train wire therefore cannot prevent the removal of power and the application of brakes.

Low-Voltage Bus

All control-voltage storage batteries in a train are connected in parallel to provide a reasonable division of load and to insure a reliable supply of power for the master control and train-wire circuits. The battery positives are each connected to the positive bus line through a limiting resistor, which serves the dual purpose of diminishing the effects of inequalities in the setting of the battery-charging generator-voltage regulators and, in case of a fault between positive and negative bus lines, prevents quick depletion of battery charge by limiting the fault current to the full-load capacity of the charging generators.

It is very desirable to ground the battery system to prevent or minimize damage to low-voltage control devices and insulation if a fault should occur between the control circuits and the high-voltage power circuits. Grounding one of the battery bus lines at more than one point in a train, however, invites the diversion of power current from its normal return path through the running rails, if the train should pass over a high-resistance rail bond. In such circumstances the battery negatives, while connected directly to the train wire used as the negative bus line, are also connected to "ground" (car structure) through a resistance such as will limit the current diverted from the rail to the capacity of the bus line and yet pass power-to-control fault currents which may occur.

Remote Battery Disconnect Contactors

To prevent back circuits through contacts in master controllers which are not being operated, all such contacts are usually required to be open when the master controller is nonoperative. But this does not de-energize control circuits local to each equipment which are essential to the operation of brakes. In particular, the magnetic track brakes are fully energized from local batteries and charging generators when all control circuits are opened preparatory to changing control stations or laying the car up in yard or shop. To automatically remove these power loads which are no longer required after the car or train is at standstill, the circuits are supplied through contactors which are closed by energizing a train wire whenever any master controller is operative. Each contactor mechanically latches in the closed position so that the local circuits will not be interrupted if the train wire is subsequently and unintentionally open-circuited. The contactors are automatically tripped open by momentarily energizing another train wire in the sequence of movements the operator must make in making a master controller nonoperative.

Cutting Out Bad-Order Cars

It is of extreme importance that means be provided to permit the continued operation in multiple unit of any equipment in the train which may not be func-

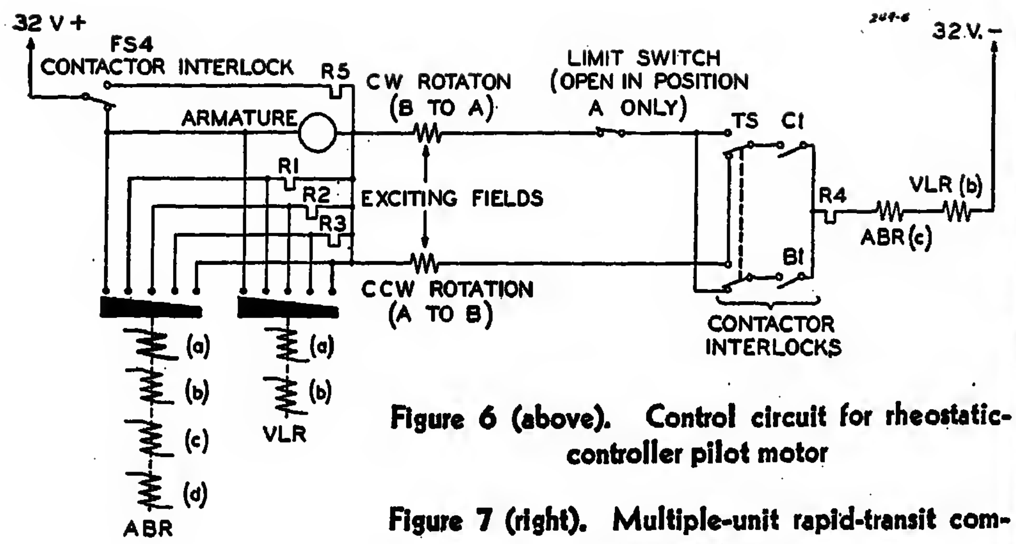

Figure 6 (above). Control circuit for rheostatic-controller pilot motor

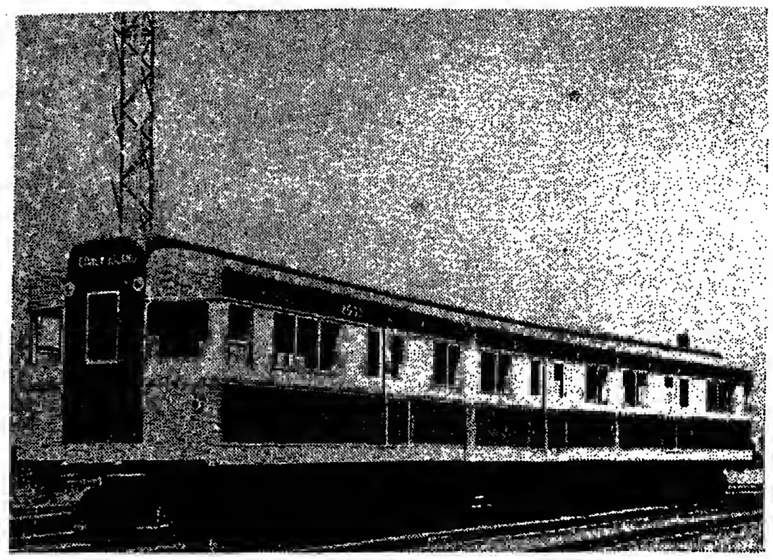

Figure 7 (right). Multiple-unit rapid-transit compartment car

tioning properly. This is particularly true of equipments having motors connected permanently in parallel or having provision for the type of electric braking here described. Failure of a motor reverser to throw to a position in agreement with direction of train movement will cause the motors to build up as short-circuited series generators, the current flowing around the "loop" circuit formed by the motor interconnections. Failure of the braking-circuit contactors to open or the sequence to progress will cause abnormal braking currents to be generated while the rest of the train is being accelerated.

To guard against such contingencies a train-wire circuit is provided which, energized at the rear end of the train, can be completed to the front or operating end to operate a control relay and permit the acceleration of the train, only if all reversers in the train have assumed a position in agreement with the desired direction of train movement, and only if the braking connections of all motor circuits have been interrupted.

Failure to accelerate a train because of operation of this protective circuit requires that the motor "loop" circuit of the defective or "bad-order" car be interrupted by some means. This is accomplished by the operator momentarily energizing a train wire which causes cutout relays in each equipment to operate contacts which, in turn, de-energize the operating coil of a "loop contactor" in the motor circuit of that equipment. The opening of this contactor (designated *LC* in Figure 3) effectively prevents the motors acting as series generators under any condition and, by electrical interlocking, prevents the closing of line contactors on that equipment. The operating coil of contactor *LC* is normally energized directly from the battery-charging generator. As this generator is driven by the motor which also drives a blower for forced ventilation of the resistors and rheostatic controller, loss of ventilation will also cause that equipment to automatically cut out.

The cutout relays, when operated to open all loop contactors, latch in this position. As soon as the operator attempts another acceleration, however, all cutout relays associated with equipments which are functioning properly are tripped out, the loop contactors on all but defective equipments close, and a normal acceleration is made. A cutout relay which remains latched in on a bad-order car also causes a light to burn continuously to assist in location of that car so that it can be readily removed from service for correction of the defect.

Overspeed and Braking Overload Protection

Protection against braking overloads is not desirable or necessary on a PCC car, because loss of dynamic braking due to the operation of an overload relay would mean complete loss of the principal braking means, and, in any case, the current is limited by the loss of adhesion of wheels to the rail.

In the case of multiple-unit compartment cars the loss of dynamic braking on one equipment in a train is not so serious; the greater weight per axle may cause overloads of greater magnitude before the wheels slide on the rail, and the operation of a whole train should not be handicapped by the possibility of repeated overload in one equipment. Accordingly, a braking overload relay is provided which operates to open the loop contactor if a braking current in excess of normal maximum value is obtained. The relay latches in position and may be reset only by hand. The circuits are arranged so that the loop contactor can reclose during each acceleration sequence, and the operation of the braking overload relay, therefore, does not result in loss of accelerating ability.

The possibility of running at sustained high speeds is much more prevalent in rapid-transit service than in street railway service. It is, therefore, desirable to limit (or at least to make less likely) the operation of a train above a predetermined speed which may be determined by any one of several factors. To this end a speed relay is provided which operates when a speed of 40 miles per hour is attained in acceleration. The relay is of the differential type, having a balanced beam attracted to one position by a coil which carries motor-exciting field current, and attracted to another position by a coil which is excited in proportion to motor armature voltage. See Figure 3. At the high motor speed and low current at which the relay is required to operate, the motor is unsaturated, and the ratio of armature voltage to field current is essentially proportional to speed. At the ratio corresponding to 40 miles per hour the relay operates to open the field-shunting contactors and thus reduce the motor tractive effort to a value below the train resistance.

Line Breakers and Overload Protection

The magnitude of fault currents that may occur on circuits connected to the third-rail supply requires extraordinary provisions for interruption of the currents. Line contactors designated *LB*1 and *LB*2 in Figure 3 are each identical in most details with the single line breaker used on PCC cars. They are magnetically operated, and each is provided with an independent overload tripping mechanism. This mechanism not only de-energizes the operating coil of the contactor but also mechanically forces the main contacts open at high speed. Two line contactors are used in series to provide a high factor of safety in interrupting power faults.

The overload mechanisms latch in operated position, but, since they may have been operated by a nonrepetitive occurrence such as an abrupt rise in supply voltage, they may be remotely reset by

the operator momentarily closing a control switch provided for this purpose. Operation of an overload relay does not prevent obtaining normal dynamic braking.

Summary

Operating the series motors of a street railway car as series generators is a convenient way of providing electric braking, but, since the motors are self-excited while braking, they are very sensitive to changing speed and load conditions. This is particularly true of modern small high-speed motors which operate at relatively low-flux densities. Control systems are available and in use, however, which provide a smooth, responsive and flexible electric brake which has replaced the air brake as the principal means of braking modern cars in street railway service.

The use of such a control system with electric braking has been extended to multiple-unit rapid-transit cars by adapting the equipment of the PCC car to conform to the requirements of remote control without sacrifice in safety or reliability, and by providing special features in recognition of the distinctive operating conditions encountered in rapid-transit service.

Utilization Voltages

HOWARD P. SEELYE
MEMBER AIEE

UTILIZATION voltage is usually thought of in terms of the voltage rating of the lamps used, or of a nominal standard voltage announced by the company rendering service. It is probably quite generally understood that the voltage actually appearing at the outlets to which lamps or appliances are connected varies somewhat from time to time. What is not so well recognized, however, is the fact that the voltages delivered at customers' outlets on any power system are normally distributed in a characteristic pattern through a band of voltage of considerable width. It is the purpose of this paper to point out that this voltage band or spread is an inherent characteristic of the system, to discuss its source and its nature, and to indicate the connection between it and the design and rating of utilization equipment.

The voltage which will be treated in this discussion is the "utilization voltage" as distinguished from "service voltage." That is, it is the voltage appearing at wall outlets and lamp sockets rather than that which the utility supplies at the service entrance to the building. The difference between these voltages is the voltage drop in the building wiring, which is an appreciable amount, as will be shown.

While utilization equipment is built for various voltage classes, the major portion is applied at voltages in the 120-volt group. Attention will be given to these first, therefore, but mention will be made later of the special problems encountered with the higher voltages.

Voltage Spread

It would be preferable if the general conception of utilization voltage could be that of a band or spread of voltages between defined limits, rather than of a single voltage such as 115 volts or 120 volts. It is, of course, commonly accepted that a piece of commercial utilization equipment may be called upon to operate at other voltages than the rating stamped on its name plate. There seems to be a tendency, however, to consider such variations as deviations from a normal voltage rather than as themselves normal voltages within a normal voltage band. It should be clearly understood that on any ordinary distribution system such a voltage spread is inherent in its operation. At heavy-load periods, the voltage delivered at customers' outlets will, of necessity, be distributed throughout a band which is rarely less than 6 or 8 volts where close regulation is feasible, and may be as wide as 15 volts in some areas.

With reference to utilization equipment, this means that the equipment is expected to operate satisfactorily to the users through this band of voltage on any individual system, and through a still wider spread of voltage in general when the variations between systems are taken into account. Only a part of this equipment will actually operate regularly at its rated voltage, the rest being used as voltages ranging from the lowest to the highest limits of the spread. It follows, therefore, that, in the design of such equipment, the emphasis must be placed as far as possible on having good operating characteristics over a specified band of voltage rather than at some one voltage. In order that this voltage band be so placed as to be most advantageous to the users, it is essential that a generally accepted standard voltage spread for the industry be fixed and defined.

A considerable amount of work has been done by the transmission and distribution committee and the electrical equipment committee of the Edison Electric Institute during the past few years toward the establishment of standards of utilization voltage, particularly this voltage spread for satisfactory operation. Surveys were made of 45 operating companies to obtain data in regard to the actual operating voltages in use. The data from these surveys, and other information on this subject which has been presented to these committees, have been made available to the author for use in the following discussion.

The reasons for the normal voltage spread will first be described. The numerical order of existing spreads and their limits and the standards which have been proposed will then be discussed. Following that, there will be pointed out for some of the commoner types of equipment, the conditions of operation to which weight should be given in choosing their "best voltage."

Paper 42-69, recommended by the AIEE committees on domestic and commercial applications and power transmission and distribution for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 27, 1941; made available for printing December 19, 1941.

Howard P. Seelye is senior engineer, engineering division, The Detroit Edison Company, Detroit, Mich.

Causes of Voltage Spread

There are, in general, three causes for the existence of a "spread" in utilization voltage. The first two pertain to the variation between different power systems throughout the country. The third is responsible for the deviations in any one system or circuit. All three should be given careful consideration in setting a voltage standard or an apparatus rating.

1. Lamp-Voltage Ratings

It is well known, of course, that lamps are made in several standard-voltage ratings, 110, 115, 120, 125, 130 volts, and so on. This and an even greater variety of ratings came into existence in the early growth of the industry. At first this was largely on account of the inability of the makers of carbon lamps to standardize their product to definite voltage ratings.

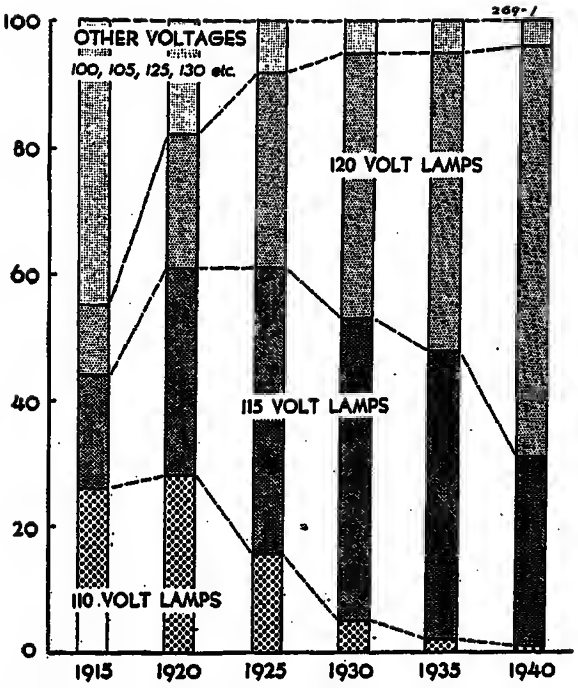

Figure 1. Proportion of incandescent-lamp sales, according to voltage rating

Later, as manufacturing control improved, it was continued on account of the same sort of voltage spread on operating systems which is being discussed here. As time went on there was a tendency toward concentration on a few definite ratings. This was facilitated by the fact that the negative resistance characteristic of tungsten lamps permitted a lamp to be used satisfactorily through a wider spread of applied voltage than was allowable with the positive characteristics of carbon lamps. Figure 1 shows how the lamp sales have varied in proportion to voltage rating since 1915. It is of interest that, whereas 115-volt lamps were in the majority from 1920 to 1930, they are now only 30 per cent of the total, while 120-volt lamps now constitute 65 per cent; 110-volt lamps have become a negligible factor; 125-volt and 130-volt lamps are still insignificant, being more or less special. It is evident, however, that there are a sufficient number of both 115- and 120-volt lamps in use to account for a spread of voltage between different systems which use them, even if the other ratings are not considered.

The shift from 115- to 120-volt lamps has been due to several causes, among them the desire to gain the advantages of higher voltage in distribution and the introduction in recent years of the 120/208-volt three-phase four-wire secondary network. Motor ratings have remained at 110 volts until recently when the standard for single-phase motors has been raised to 115 volts in the National Electrical Manufacturers' Association Standards and in the proposed revision of American Standards Association Standard C50. Other utilization appliances have been variously rated at voltages from 110 to 120.

It is believed desirable to discourage a future repetition of this shift in voltage preference to an eventual predominance of one of the higher-voltage lamps. There is now considerable confusion in the ratings and applications of both lamps and appliances. A continued rise in lamp voltages would add to the confusion, particularly in regard to the appliances. These must attempt to cover the whole field of voltages in use but cannot follow changes so readily, their useful life being much longer than that of lamps. The establishment of a standard voltage spread would tend to restrict further extension of that spread upward, unless the advantages were to become obvious and generally acceptable.

2. Relation of Rating to Outlet Voltage

In addition to the differences in lamp- (and system-) voltage ratings, there exists in the industry well founded differences of opinion in regard to the relation which the utilization voltage should bear to the rating of the lamp used. Figure 2 shows the characteristic variation in lamp lumens, energy consumption, and lamp life with variation in applied voltage. Some operators prefer to have the lamps operate as nearly as possible at their voltage rating. Others believe that the increased life resulting from voltages a little under rating is of more practicable value than the higher illumination, and shorter life which results from operation at rated voltage or higher. Others take the opposite view, that the increased lumens per watt at over-voltage operation are preferable. The question is basically one of

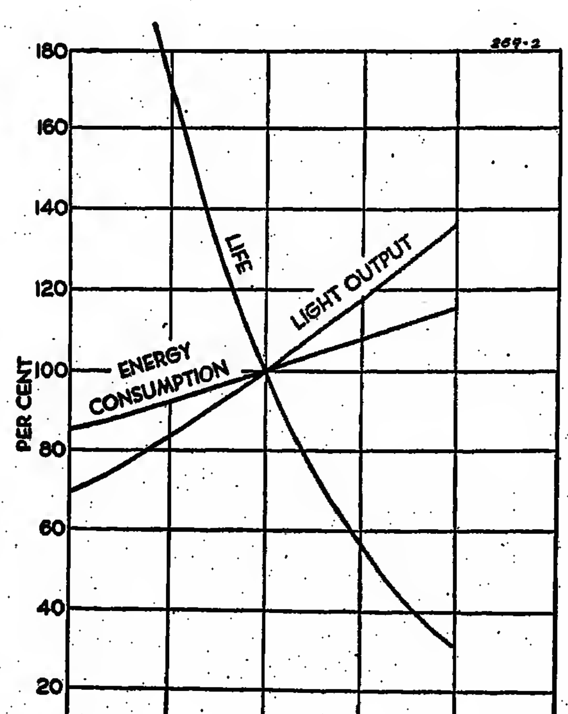

Figure 2. Variations in incandescent-lamp characteristics with voltage

economy, involving the relation between the cost of lamps and the cost of electrical energy. It must be considered, however, that the nuisance of too frequent lamp replacement may outweigh economy in the minds of the general run of customers.

These preferences must, of course, take into account the inherent voltage spread that exists on every system, which will be discussed in detail later. Where, for example, there is a 10 per cent total spread, and this is not uncommon, there will be some customers, even though a small proportion of the total, getting five per cent above the average. If this "average" is held at lamp rating, say 120 volts, these high customers will be getting 126 volts with a lamp life of 55 per cent. If the average is above rating, say 124 volts, the high customers will be getting 130 volts, with lamp life at 37 per cent. The performance of ordinary appliances, such as toasters, waffle irons, and the like, at such voltages must also be considered. Of course, where a smaller spread such as six per cent is feasible, an average of 124 would result in a high of only 127.6.

On the other hand, if the average voltage is low, the customers at the bottom of the spread may be getting inferior illumination and indifferent operation of appliances. It will not be attempted here to state the proper relation between rating and average operating voltage. It is merely pointed out that the voltage spread, including the top and bottom limits, should be taken into account as well as the mid-point or average. The differences in opinion in regard to this relation of lamp rating to voltage leads to a voltage difference even between systems using the same lamp rating. One such system will carry its voltage spread at a higher level than will another.

A confusion in system ratings also results from this source, since these ratings are generally 115-volt or 120-volt, according to the lamp rating used. Some so-called 115-volt systems, with average of outlet voltages above the lamp rating, actually have practically the same voltage spread and at the same voltage level as other systems normally designated at 120 volts but having average outlet voltages below the lamp rating. System rating is, therefore, not a definite indication of the existing utilization voltage.

3. Inherent Voltage Spread in Distribution System

The normal, inherent spread of utilization voltage on an operating system is probably the least understood of the three causes of voltage deviation. Its basis is simple, lying in the elementary fact that

when electric current passes over a wire, there is a corresponding drop in voltage. The energy delivered to customers on a power system passes over many miles of wire in

(*a*) Transmission.

(*b*) Step-up and step-down transformers.

(*c*) Distribution circuit feeders and primaries.

(*d*) Distribution transformers.

(*e*) Distribution secondaries and service drops.

(*f*) Customer's house wiring.

The voltage drop in transmission is usually controlled to considerable extent by variation of generator voltage, transformer taps, and regulators. Since any of these can regulate in bulk only at one point, there will be a variation in the voltage between that regulating point and other points on the system at which load is supplied. This variation can be compensated for at the substation by voltage regulators on the substation bus or on individual distribution circuit feeders.

These substation regulators and supplementary regulators and boosters out on the circuits, can also compensate for *part* of the drop in the outgoing distribution circuits. A fairly constant voltage can be held at *some point* out on such a circuit. Since the circuit may consist of several miles of line, however, it is impossible to have the voltage constant at all points. Some customers will be connected near the regulated point and some far from it. Some will be connected through heavily loaded distribution transformers and some through transformers only lightly loaded. The impedance of the transformers themselves will vary with size, type, and make. Some customers on a secondary main will be near the transformer and some will be at the end of long secondaries. Figure 3 is a schematic diagram indicating these conditions. The result is that, even though the voltage at the circuit feeding point is held practically constant throughout the day and night, utilization voltage at the customer's outlets will vary through a band which is of appreciable width.

In Figure 3 the station bus is, for convenience, assumed constant at 122 volts at all loads. The circuit regulator is compensated to hold 122 volts at an intermediate point on the primary mains, indicated by the middle distribution transformer (*C*). The voltage drops indicated for primaries, transformers, secondaries, and service and house wiring are typical, rather than extreme cases, of those in ordinary practice. It is evident that

Table I

	Maximum Voltage Drop, Per Cent	
	Urban Customers	Rural Customers
In primaries	1.3 to 3.5	3.3 to 10.0
In distribution transformers	2.5 to 4.65	2.0 to 4.4
In secondaries	2.0 to 4.5	No secondaries
In service drops	0.5 to 1.25	0.5 to 1.8
In customer's building wiring	1.0 to 5.0	1.0 to 2.0
Total utilization-voltage spread	7.5 to 12.0	6.87to15.0

customers' outlet voltages at time of heavy load will be distributed through a band whose maximum is about 122 volts at customer (*A*), and whose minimum is something like 112 volts at customer (*B*). At light-load periods, the voltages lie in a much narrower band, of perhaps 119 to 121, while at no load, which seldom occurs, all would be 122, the voltage at the regulating point (*C*).

There are many sorts of distribution circuits, ranging from those in concentrated urban areas where the distances are short, and regulation can be reasonably close, to rural lines with long distances and correspondingly poorer regulation. In many of the latter, the desirability and practicability of giving reasonably good regulation, similar to that in more densely built suburban territory, is recognized, but, on the other hand, there are others where regulating equipment is omitted in the interest of lower first cost. Also, there are various types of circuits, such as networks, ring-main, and feeder and branch. In any case, however, there will be an unavoidable spread in the delivered utilization voltage similar to that indicated in Figure 3. It may, of course, be considerably less in some areas than the amount shown here (networks for example); and in others it will be greater. It will be located at several different voltage levels on different systems.

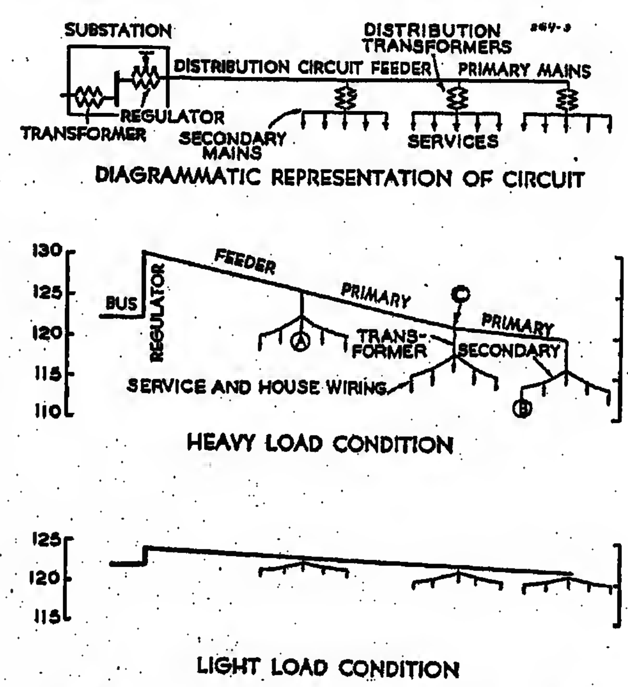

Figure 3. Diagrammatic illustration of voltage spread on a typical distribution circuit

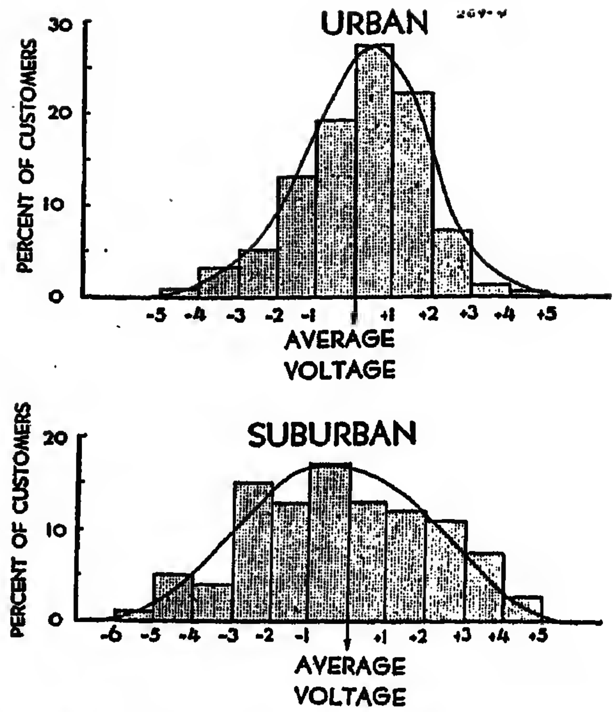

Figure 4. Distribution of customers' outlet voltage

From actual sampling survey of a large system

A survey of 14 companies made by the transmission and distribution committee, Edison Electric Institute, produced results which shed some light on the magnitude of the various elements in this voltage spread. The figures in Table I show the range of values reported. Since these figures were mostly based on design values rather than field measurements, they should be considered only as indicative.

Pattern of Voltage Spread

The outlet voltages on a system are, of course, not distributed uniformly over the voltage spread. The pattern of this distribution is shown in Figure 4. The blocked graphs were obtained from a sampling survey on a large diversified system. While the urban graph is somewhat different from the suburban, their general shape is similar as shown by the smooth, generalized curves. This pattern has been confirmed in essentials by data from several companies and is believed to be typical.

It is evident that comparatively few customers get either the highest or the lowest voltage in the spread, but on the other hand, there are appreciable numbers getting a volt or two higher than the minimum and a volt or two lower than the maximum. The largest number getting any one voltage is about 27 per cent in the urban curve and only about 17 per cent in the suburban.

The average voltage is determined by the shape of the curve and this may vary somewhat between different systems.

Field surveys in several companies have shown, however, that the average as in Figure 4 is near the mid-point, or in some cases even a little higher, up to about 60 per cent of the spread. This distribution of customers' voltage is useful in considering the range for "best operation" of equipment.

Voltage Spread in Practice

Surveys of the industry in general, made by the EEI committees, have indicated existing values for voltage spreads and other related quantities. The surveys covered 45 companies, serving approximately ten million residential customers. Since most of these companies did not have available figures on actual field surveys of voltage conditions, design values were reported. Some allowance should perhaps be made for discrepancy between these and voltages which really exist.

No extensive field data on the voltage drop in building wiring is available. Some estimates are given in Table I. A sampling survey on the Detroit Edison system covering 300 customers, mostly residential, showed a range from about $^1/_2$ volt to 5 volts, with an average of about $1^1/_4$ volts to lamps in the most used room under evening load conditions. There are, of course, some outlets which have less drop than these, and there will be some cases with more. It is believed that a 3-volt drop will cover the maximum for the great majority of customers.

If 3 volts is added to the spread at service entrance resulting from the survey as listed above the following deductions can be drawn:

1. The maximum voltage spread at *utilization outlets* for the industry as a whole is of the order of 20 volts, from 107 volts (110−3) to 127 volts.

2. This whole spread will not occur ordinarily in any one system but takes account also of the variation between systems which has been previously discussed. It is the spread for which utilization equipment in general must be designed.

3. There will no doubt be some outlets outside of this spread, both above the upper limit and below the lower limit. It is believed, however, that the percentage of these will be very small, and that they may be considered as unusual or temporary conditions, for which operation of equipment cannot be expected to be as good as it should be within the normal range.

4. The greater bulk of customers have outlet voltages within the band between 110 (113−3) and 125 volts.

5. On individual systems the voltage spread at utilization outlets ranges from 7 volts to 18 volts, with nearly two thirds lying between 10 and 13 volts, very few above that, and the remaining one third lying between 7 and 9 volts.

Table II. Service Voltage

Drop in building wiring should be deducted

Minimum Service Voltage Reported	110 volts
Maximum Service Voltage Reported	127 volts
Minimum Service voltage for companies serving 77 per cent of the total customers	113 volts
Maximum Service voltage for companies serving 80 per cent of the total customers	125 volts
Voltage spread at service	
Minimum reported	4 volts
Maximum reported	15 volts
Classification of service voltage spreads	
For companies reporting 33 per cent of total customers	4 to 6 volts
For companies reporting 62 per cent of total customers	7 to 10 volts
For companies reporting 5 per cent of total customers	11 to 15 volts

It should be clearly understood that these figures refer to voltage spreads existing on systems as a whole and are not intended to refer to the voltage variations at any individual customer's service. The voltage at such a customer's service will vary from his voltage at heavy-load period to that at light-load. Referring to Figure 3, in the case there represented the maximum individual variation occurs at the customer's service having the lowest heavy-load voltage and is equal to nearly the full spread of some 10 volts. The minimum is at the customer's service having the highest heavy-load voltage and is very small. Referring to the customer distribution curve of Figure 4, it is evident that few customers have the maximum or minimum variation. Most of them get more nearly the average, which in the case of Figure 3 would be about 5 volts.

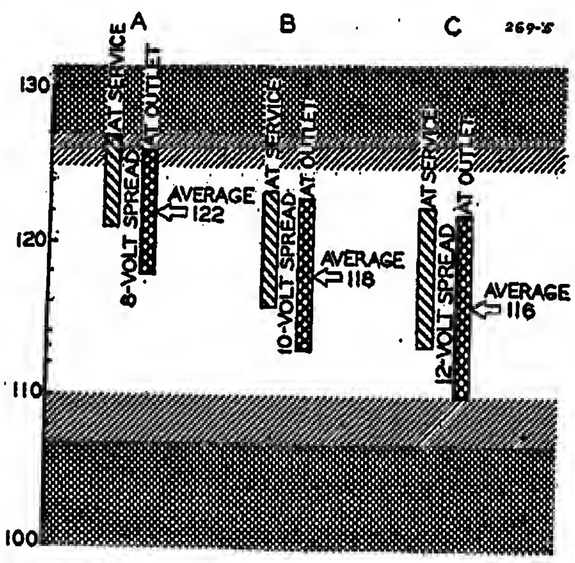

Figure 5. Typical voltage spreads within the proposed standard

A—Urban service, closely regulated, 120-volt lamps

B—Urban service, general, 120-volt lamps

C—Rural service, 115-volt lamps

The figures which have been cited lead to a suggestion of a general standard maximum utilization voltage spread of 107 to 127 volts, with a *preferred* spread of 110 to 125 volts. Figure 5 illustrates how several different typical service conditions can fall within this spread. There are, of course, many other variations which can and will be used on operating systems and still lie within the total proposed spread.

Higher Voltages

The discussion so far has referred only to voltages in the 120-volt group. The same problem exists, however, with the higher utilization voltages, 240, 480, 2,400, and so on. In the 240-volt group, the complication of the "odd-ratio" system is introduced. Network distribution in dense urban territory is now commonly four-wire, at 120/208 volts. The voltage supplied to 240-volt equipment on such a system is only 87 per cent of what it would be on a 120/240-volt even-ratio system, with the same voltage for the 120-volt equipment in both cases.

For the most part, the same standard 240-volt equipment has been used satisfactorily on these odd-ratio systems as on those of even-ratio. Special 208-volt motors are available but have not been widely adopted. This practice has been allowable, largely because the odd-ratio systems usually are found in densely loaded areas where service voltage tends to be relatively high and the voltage spread relatively small, making the minimum voltage high enough for 240-volt equipment. There are several advantages in having one standard line of apparatus so designed as to serve both purposes if feasible. Manufacturing and stocking are obviously simpler for one line than for two; interchangeability is provided between locations where service voltage is odd-ratio and locations where it is even-ratio.

In setting up a standard voltage spread for the industry, it is desirable that it be broad enough to be adequate for both even-ratio and odd-ratio systems, and yet not too broad to allow one line of apparatus to cover it. Taking into consideration the probability that the voltage drop to 240-volt equipment would be somewhat greater than to that at 120 volts, and that the service voltage in general to 208-volt services would be relatively high and well-regulated, a spread of 193 to 250 volts maximum, 197 to 245 volts *preferred* has been recommended.

At the still higher voltages, 480, 600, etc., similar problems of "odd-ratios" are also found, and it is probable that the

voltage spreads for these levels should be multiples of those at the 240-volt level.

Equipment Design

One of the most important objectives in trying to establish standard voltage spreads is the simplification of the design and rating of utilization equipment. If the voltage spread which must be met in practice is fixed between reasonable limits, there will be more assurance that equipment which operates satisfactorily within those limits will be generally satisfactory for the industry. Also, as further knowledge is gained of the characteristics of service voltage within those limits, the designs of specific items of apparatus can be more definitely directed toward the actual voltages at which they will most commonly be operated.

This paper has pointed out the fact that a voltage spread of from 7 to 15 volts is a normal condition on an operating system. The utilization equipment supplied should be expected to operate at any voltage throughout that spread, with satisfactory results to the user. If and when a standard spread for the industry, such as that which has been suggested, is generally adopted, it should be expected that equipment sold would operate satisfactorily *throughout* that spread. Since the bulk of the customers will have voltages within a somewhat smaller spread than the maximum, the preferred voltage spread indicates the range through which *good characteristics* of operation should be maintained. On the other hand, it should be kept in mind that there will be occasional customers on any system where voltage will fall somewhat above or below a recognized spread, and their equipment should still operate, even if not with characteristics which would be considered generally satisfactory.

It would be desirable, if practicable, to eliminate all the variety of voltage ratings on different equipment, reducing them to a uniform rating of, perhaps, the nominal 120-volt designation, with the understanding that they would meet the requirements of the standard-voltage spread. It is realized that there are difficulties in carrying out such a simplification, one of them being the different ideas which are prevalent concerning the proper relation between lamp rating and average voltage supplied, or in other words, between lamp life and illumination. Another is the probability that all types of equipment are not adaptable to as wide a range of voltage as the spreads proposed. These considerations will probably require the retention of more than one rating for some equipment. Other items, such as motors, are probably already pretty well adapted to such a standard range and could be uniformly rated accordingly.

While it is not the province of this paper to attempt to specify the best voltage for which any piece of equipment shall be designed, some of the considerations which could affect such a choice within a standard voltage spread will be suggested.

Lamps

There is probably a distinct need for both "long-life" lamps, and for "high-illumination" lamps. The former would be used where efficient illumination is not the prime requirement, such as for low-wattage lamps for indicating or ornamental purposes. The design voltage should be high in relation to the voltage spread so that they would be operated at undervoltage most of the time. "Long-life" lamps in larger sizes would also be preferred for general use by some operators. For this purpose, however, the design should give somewhat more regard to illumination and less to extreme length of life. "High-illumination" lamps would have a demand where illumination intensity is closely measured, and the application is strictly on a "lumens-per-dollar" basis. The design voltage should be nearer the middle of the spread or below it, giving "normal" voltage or "over-voltage" operation to the majority of lamps.

Fluorescent Lamps

A recent publication states, "The lamps with 'low'-voltage ballast equipment are designed for operation on circuit voltages of from 110 to 125 volts inclusive and, in some cases, may operate satisfactorily on circuits as low as 105 or as high as 130 volts."

These figures correspond well with those of the proposed standard-voltage spread.

Electric-Range Elements

Ordinarily the voltage drop to a major appliance, such as a range, will be fairly large, due to the current it draws. Much of its operation will be during hours which are off-peak for the lighting load, but it will also have to operate on peak. Its maximum, will, therefore be several volts lower than the top of the voltage spread and its minimum near the bottom of it. The suggested standards, published in 1938 by a joint EEI–NEMA committee, have a "preferred standard rating" of 115–120 volts, based on a design voltage of 118 volts, with a maximum operating voltage of 124 volts. There are, in addition, two optional ratings, one at 125 volts with maximum operating voltage of 129 volts, and the other at 110 volts with a 116-volt maximum. The preferred rating corresponds fairly well with the proposed 110–125-volt preferred spread.

Toasters, Waffle Irons, Flatirons, and Similar Appliances

These produce a considerable voltage drop, due to their own relatively large current, but operate mostly offpeak, when supply voltage is relatively high. Their maximum will, therefore, be several volts below the top of the voltage spread and their minimum several volts above the bottom of it.

Refrigerator Motors, Oil-Burner Motors, and Similar Motors

These must operate throughout the day and hence throughout the voltage spread, but most of the operation during 24 hours will be at voltages in the top part of the spread, since such voltages exist during the greater number of hours.

It is not intended to infer that the existence of normal voltage spread or of the factors involved in "best voltage" has been unknown to the makers of utilization equipment or has been ignored by them. It is believed, however, that the material which has been presented here will be helpful to both makers and users of such equipment in promoting a better understanding of the nature of the voltage spread and the related numerical values of utilization voltage.

Current Loci for the Capacitor Motor

THOMAS C. McFARLAND
MEMBER AIEE

THE basic theory of the capacitor motor from the cross-field point of view has been recently presented by Puchstein and Lloyd.[1] It is the purpose of this paper to extend the basic relations developed by them so as to demonstrate certain current-loci characteristics of the capacitor motor.

The circuit to be considered is shown in Figure 1. A variable condenser of impedance Z_C is connected in series with the auxiliary winding. The rotor squirrel-cage winding is considered equivalent to a d-c winding with the commutator brushes arranged to short circuit the winding along the main and auxiliary axes of the stator winding. A common voltage is impressed on the two windings.

The flux relations are illustrated in Figure 2. There is a mutual flux linking the stator and rotor windings along each axis of the machine. Considered as a transformer there are leakage fluxes linking with each of the stator windings, and also leakage fluxes which link the rotor winding on the main and auxiliary axes. Each of these fluxes is considered to be stationary in space and variable in time. As a consequence the mutual fluxes and rotor-leakage fluxes are cut by the rotor conductors as they rotate.

Current and voltage relations are indicated by the vector diagrams of Figure 3. The vector diagram for the auxiliary axis is drawn so that the mutual flux ϕ_{mb} is in space quadrature with the main-axis mutual flux ϕ_{ma}, and is lagging. This makes it possible to represent each of the speed voltages in its proper phase relation. In each stator winding there is a local-impedance drop and a component of impressed voltage equal and opposite to the rotor-induced voltage, assuming a ratio of transformation of unity for each axis. In each rotor circuit there is an induced voltage, a local-impedance drop, a generated voltage due to cutting the mutual flux of the other axis, and a generated voltage resulting from cutting the rotor-leakage flux of the other axis. Applying Kirchoff's law of voltages to each circuit on the main and auxiliary axes the following equations can be written:

Main Axis (Figure 3a)

(Stator) $$V = I_aZ_a + (I_a - I_{2a})Z_{ma} \quad (1)$$

(Rotor) $$O = -(I_a - I_{2a})Z_{ma} + I_{2a}Z_2 + jS\left[-\frac{Z_{mb}}{k}(I_b - I_{2b}) + jkX_2I_{2b}\right] \quad (2)$$

Auxiliary Axis (Figure 3b)

(Stator) $$V = I_b(Z_b + Z_c) + (I_b - I_{2b})Z_{mb} \quad (3)$$

(Rotor) $$O = -(I_b - I_{2b})\frac{Z_{mb}}{k} + kZ_2I_{2b} - jS[-Z_{ma}(I_a - I_{2a}) + jX_2I_{2a}] \quad (4)$$

wherein

V = applied or line voltage
I_a = current in main stator winding
I_b = current in auxiliary stator winding
I_{2a} = rotor current in main-axis circuit
I_{2b} = rotor current in auxiliary-axis circuit
$Z_a = r_a + jX_a$ = local impedance of main stator winding
$Z_b = r_b + jX_b$ = local impedance of auxiliary stator winding
$Z_{ma} = jX_{ma}$ = mutual inductive impedance of main-axis stator and rotor windings
$Z_{mb} = jX_{mb}$ = mutual inductive impedance of auxiliary-axis stator and rotor windings
$Z_2 = r_2 + jX_2$ = local impedance of each rotor circuit
$Z_c = r_c - jX_c$ = impedance of capacitance in series with auxiliary winding
k = ratio of auxiliary-winding turns to main-winding turns
S = speed as a decimal fraction of synchronous speed

From equations 1 and 3

$$\left.\begin{aligned} I_{2a} &= \frac{I_a(Z_a + Z_{ma}) - V}{Z_{ma}} \\ I_{2b} &= \frac{I_b(Z_b + Z_c + Z_{mb}) - V}{Z_{mb}} \end{aligned}\right\} \quad (5)$$

Substituting these relations into equations 2 and 4 find

$$\left.\begin{aligned} A_aI_a + B_aI_b &= K_aV \\ A_bI_a + B_bI_b &= K_bV \end{aligned}\right\} \quad (6)$$

wherein,

$$A_a = Z_a + Z_b + \frac{Z_aZ_2}{Z_{ma}} \quad (7)$$

$$A_b = S\left[X_2\left(1 + \frac{Z_a}{Z_{ma}}\right) - jZ_a\right] \quad (8)$$

$$B_a = S\left[(Z_b + Z_c)\left(j\frac{1}{k} - k\frac{X_2}{Z_{mb}}\right) - kX_2\right] \quad (9)$$

$$B_b = kZ_2 + (Z_b + Z_c)\left(\frac{1}{k} + k\frac{Z_2}{Z_{mb}}\right) \quad (10)$$

$$K_a = 1 + \frac{Z_2}{Z_{ma}} + S\left(j\frac{1}{k} - k\frac{X_2}{Z_{mb}}\right) \quad (11)$$

$$K_b = S\left(-j + \frac{X_2}{Z_{ma}}\right) + \left(\frac{1}{k} + k\frac{Z_2}{Z_{mb}}\right) \quad (12)$$

In each of these equations the complex expressions for the impedances must be substituted (see nomenclature). When the substitutions have been made find

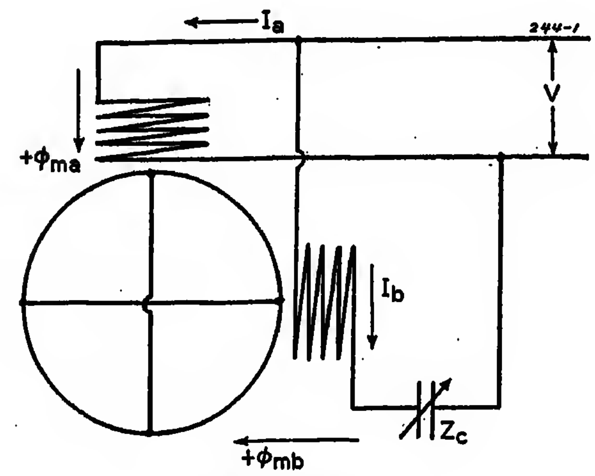

Figure 1. The circuit

$$A_a = \left(r_a + r_2 + \frac{r_aX_2 + r_2X_a}{X_{ma}}\right) + j\left(X_a + X_2 + \frac{X_aX_2 - r_ar_2}{X_{ma}}\right) \quad (13)$$

$$A_b = S\left[X_2 + X_a\left(1 + \frac{X_2}{X_{ma}}\right)\right] - jSr_a\left(1 + \frac{X_2}{X_{ma}}\right) \quad (14)$$

$$B_a = -S\left[kX_2 + (X_b - X_c)\left(\frac{1}{k} + \frac{kX_2}{X_{mb}}\right)\right] + jS(r_b + r_c)\left(\frac{1}{k} + \frac{kX_2}{X_{mb}}\right) \quad (15)$$

$$B_b = \left[kr_2\left(1 + \frac{X_b - X_c}{X_{mb}}\right) + (r_b + r_c)\times\left(\frac{1}{k} + \frac{kX_2}{X_{mb}}\right)\right] + j\left[kX_2 + (X_b - X_c)\times\left(\frac{1}{k} + \frac{kX_2}{X_{mb}}\right) - \frac{kr_2}{X_{mb}}(r_b + r_c)\right] \quad (16)$$

$$K_a = \left(1 + \frac{X_2}{X_{ma}}\right) + j\left(\frac{S}{k} + \frac{kSX_2}{X_{mb}} - \frac{r_2}{X_{ma}}\right) \quad (17)$$

$$K_b = \left(\frac{1}{k} + \frac{kX_2}{X_{mb}}\right) - j\left[\frac{kr_2}{X_{mb}} + S\left(1 + \frac{X_2}{X_{ma}}\right)\right] \quad (18)$$

Solving the equations of (6) simultaneously,

$$\left.\begin{aligned} I_a &= \frac{B_bK_a - B_aK_b}{A_aB_b - A_bB_a}\cdot V \\ I_b &= \frac{A_aK_b - A_bK_a}{A_aB_b - A_bB_a}\cdot V \end{aligned}\right\} \quad (19)$$

Paper 42-44, recommended by the AIEE committee on electrical machinery for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 25, 1941; made available for printing December 12, 1941.

THOMAS C. McFARLAND is associate professor of electrical engineering, University of California, Berkeley, Calif.

Substitution in the equations of 19 from equations 13–18 inclusive yields

$$\left.\begin{aligned} I_a &= \frac{M+jN}{U+jW}\cdot V \\ I_b &= \frac{P+jQ}{U+jW}\cdot V \end{aligned}\right\} \quad (20)$$

wherein,

$$M=\frac{1}{k}\left[(r_b+r_c)\left(1+\frac{X_2}{X_{ma}}\right)(1-S^2)+\frac{r_2(X_b-X_c)}{X_{ma}}\right]+k\left[r_2\left(1+\frac{2X_2}{X_{ma}}\right)+\frac{X_2}{X_{mb}}(r_b+r_c)\left(1+\frac{X_2}{X_{ma}}\right)(1-S^2)+\frac{r_2}{X_{mb}}(X_b-X_c)\left(1+\frac{2X_2}{X_{ma}}\right)-\frac{(r_b+r_c)r_2^2}{X_{ma}X_{mb}}\right] \quad (21)$$

$$N=\frac{1}{k}\left[(X_b-X_c)\left(1+\frac{X_2}{X_{ma}}\right)(1-S^2)-\frac{r_2(r_b+r_c)}{X_{ma}}\right]+Sr_2+k\left[X_2\left(1+\frac{X_2}{X_{ma}}\right)(1-S^2)-\frac{r_2^2}{X_{ma}}-\frac{r_2}{X_{mb}}(r_b+r_c)\left(1+\frac{2X_2}{X_{ma}}\right)+\frac{X_2}{X_{mb}}(X_b-X_c)\left(1+\frac{X_2}{X_{ma}}\right)(1-S^2)-\frac{(X_b-X_c)r_2^2}{X_{ma}X_{mb}}\right] \quad (22)$$

$$P=\frac{1}{k}\left[r_2+r_a(1-S^2)+\frac{r_2X_a+r_aX_2(1-S^2)}{X_{ma}}\right]+k\left[\frac{r_aX_2(1-S^2)+r_2(X_a+2X_2)}{X_{mb}}+\frac{r_aX_2^2(1-S^2)+r_2(2X_aX_2-r_ar_2)}{X_{ma}X_{mb}}\right] \quad (23)$$

$$Q=\frac{1}{k}\left[(X_a+X_2)(1-S^2)+\frac{X_aX_2(1-S^2)-r_ar_2}{X_{ma}}\right]-Sr_2+k\left[\frac{X_2(X_a+X_2)(1-S^2)-r_2(r_a+r_2)}{X_{mb}}+\frac{X_aX_2^2(1-S^2)-r_2(2r_aX_2-r_2X_a)}{X_{ma}\,X_{mb}}\right] \quad (24)$$

$$\begin{aligned} U=\frac{1}{k}\Bigg[&(r_b+r_c)\left\{r_2+r_a(1-S^2)+\frac{r_2X_a+r_a(X_2-S^2)}{X_{ma}}\right\}+(X_b-X_c)\left\{\frac{r_ar_2-X_a(X_2-S^2)}{X_{ma}}-(X_a+X_2)(1-S^2)\right\}\Bigg]+\\ k\Bigg[&r_2(r_a+r_2)-X_2(X_a+X_2)(1-S^2)+\frac{r_2(r_2X_a+2r_aX_2)-X_aX_2(X_2-S^2)}{X_{ma}}+\\ &(r_b+r_c)\left\{\frac{r_aX_2(1-S^2)+r_2(X_a+2X_2)}{X_{mb}}+\frac{r_2(2X_2X_a-r_ar_2)+r_aX_2(X_2-S^2)}{X_{ma}X_{mb}}\right\}+\\ &(X_b-X_c)\left\{\frac{r_2(r_a+r_2)-X_2(X_a+X_2)(1-S^2)}{X_{mb}}+\frac{r_2(r_2X_a+2r_aX_2)-X_aX_2(X_2-S^2)}{X_{ma}X_{mb}}\right\}\Bigg] \end{aligned} \quad (25)$$

$$\begin{aligned} W=\frac{1}{k}\Bigg[&(r_b+r_c)\left\{(X_a+X_2)(1-S^2)+\frac{X_a(X_2-S^2)-r_ar_2}{X_{ma}}\right\}+(X_b-X_c)\left\{r_2+r_a(1-S^2)+\frac{r_2X_a-r_a(X_2-S^2)}{X_{ma}}\right\}\Bigg]+\\ k\Bigg[&r_2(X_a+2X_2)+r_aX_2(1-S^2)-\frac{r_2(r_ar_2-2X_aX_2)-r_aX_2(X_2-S^2)}{X_{ma}}+\\ &(r_b+r_c)\left\{\frac{X_2(X_a+X_2)(1-S^2)-r_2(r_a+r_2)}{X_{mb}}+\frac{X_aX_2(X_2-S^2)-r_2(r_2X_a+2r_aX_2)}{X_{ma}X_{mb}}\right\}+\\ &(X_b-X_c)\left\{\frac{r_2(X_a+2X_2)+r_aX_2(1-S^2)}{X_{mb}}+\frac{r_aX_2(X_2-S^2)+r_2(2X_aX_2-r_ar_2)}{X_{ma}X_{mb}}\right\}\Bigg] \end{aligned} \quad (26)$$

Substitution of the complex expressions for the impedances in the equations of 5 results in

$$\left.\begin{aligned} I_{2a} &= I_a\left[1+\frac{X_a}{X_{ma}}\right]+j\frac{V-I_ar_a}{X_{ma}} \\ I_{2b} &= I_b\left[1+\frac{X_b-X_c}{X_{mb}}\right]+j\frac{V-I_b(r_b+r_c)}{X_{mb}} \end{aligned}\right\} \quad (27)$$

The equations of 20 and 27 are better for purposes of extended computation than are those of 19 and 5 because they require a minimum number of operations involving complex numbers. Although most engineers can handle the complex algebra without difficulty, it is generally admitted that the chances of error are reduced if the equations are such as to minimize the number of manipulations requiring complex algebra.

To illustrate the application of the preceding relations, computations have been made for the four-pole one-fourth-horsepower 110-volt single-phase motor for which constants are given in Morrill's[2] paper of April 1929. In Morrill's paper corresponding values of resistance and reactance for the capacitive impedance are given for only two different values of impedance. Here the interpolation curve of Figure 4, which includes the two values, is assumed to represent the variable capacitance used. Other values of the constants for this machine, as recorded by Puchstein and Lloyd,[1] are

$r_a=2.02$ (ohms) $\quad X_a=2.79$ (ohms)
$r_b=7.13$ " $\quad X_b=3.22$ "
$r_2=4.12$ " $\quad X_2=2.12$ "
$X_{ma}=66.8$ (ohms)
$X_{mb}=92.9$ "
$k=1.18$ "

Substitution of these constants into the equations 21–26 inclusive yields

$$\left.\begin{aligned} M&=12.17+0.912r_c-0.109X_c-S^2(6.589+0.914r_c)\\ N&=4.425-0.109r_c-0.903X_c+4.12S+S^2(0.906X_c-5.448)\\ P&=5.853-1.826S^2\\ Q&=4.167-4.12S-4.38S^2\\ U&=47.0+5.88r_c+3.95X_c+S^2(13.52-1.795r_c-4.333X_c)\\ W&=86.2+3.93r_c-5.73X_c-S^2(41.68+4.34r_c-1.79X_c \end{aligned}\right\} \quad (28)$$

By using these relations in conjunction with the data of Figure 4, computations were made for several values of S. The results of these computations are shown in Figures 5, 6, and 7. It is seen that P and Q are independent of the capacitance, and plot as linear functions of speed over the operating range of speeds. The constants, M, N, U and W are seen to be approximately linear functions of the capacity reactance for all speeds over the operating range of capacitances. The curves may be extrapolated linearly. For the practical range of operation P and U are always positive and M, N, Q and W are always negative.

For several constant values of S computations of I_a and I_b were made as functions of X_c using the equations of 20. A plot of these values is shown in Figures 8 and 9. It will be observed that

(*a*) The locus of each current for constant S is a circle.
(*b*) The locus of each current for constant X_c is a circle.
(*c*) The centers of each circular locus lie on the arc of a circle.
(*d*) For I_a the locus of centers of circles of constant S passes through the blocked rotor value of current (Figure 8).
(*e*) For I_b the locus of centers of circles of constant X_c passes through the origin of co-ordinates (Figure 9).
(*f*) For the loci of I_a with constant S the triangles ABC remain similar. A is the blocked-rotor point, B is the extremity of a diameter which passes through A, and C is a point on the locus corresponding to a fixed value of X_c.
(*g*) For the loci of I_b with constant S, the angle δ between a line joining the point on the locus corresponding to a fixed value of X_c to the origin and the diameter which passes through the origin is constant.
(*h*) Over the whole range of speeds ($S=1.0$ to $S=0.0$) the radius of a circular locus of constant S for I_a is very closely equal to S^2

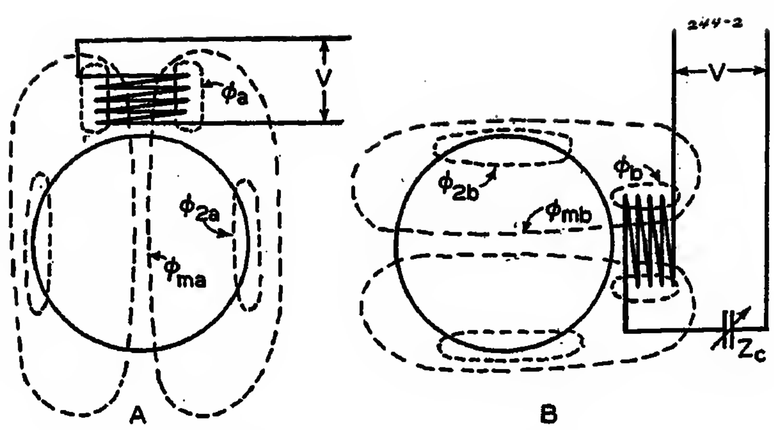

Figure 2. The flux relations

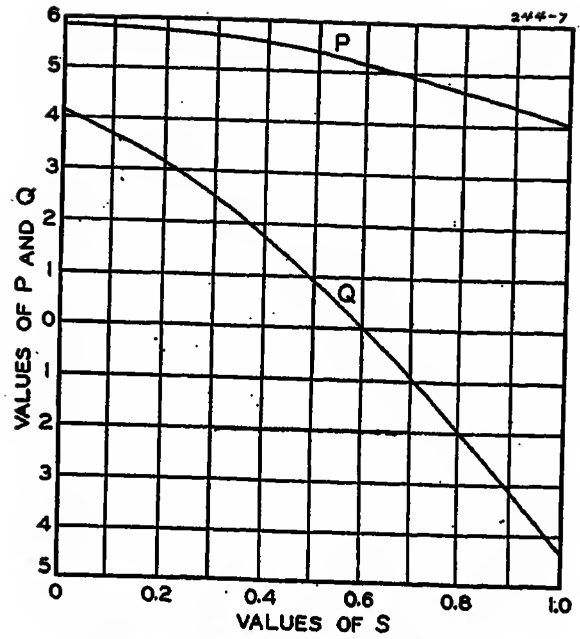

Figure 7. P and Q as functions of S

times the radius of the circle for $S=1$. For I_b the radius is approximately S^2 times the radius of the circle for $S=1$, over the operating range of speeds ($S=1.0$ to $S=0.9$).

As a consequence of these observations the following procedure is suggested for the determination of loci:

(*a*) Compute constants M, N, P, Q, U and W for three widely separated values of X_c, such as $X_c=20$, $X_c=40$, and $X_c=200$, at speeds of $S=1$, $S=0.8$, and $S=0$.

(*b*) Using the constants thus determined find corresponding values of I_a and Ib (any one computation for I_a with $S=0$ will suffice).

(*c*) Plot the computed currents as shown in Figure 8 and Figure 9.

(*d*) Using perpendicular bisectors locate the centers of circles for $S=1$, $S=0.8$ and $S=0$.

(*e*) Using perpendicular bisectors locate the center of the circular arc passing through the centers of circular loci found in (*d*), and draw the arc.

(*f*) On the plot of I_a draw the locus for $S=1$, and then draw the diameter of this circle which, if extended, passes through the current value for $S=0$.

(*g*) Connect the end of the diameter thus drawn, and the blocked-rotor point, to the point on the locus corresponding to the largest value of X_c, and determine the angle β.

(*h*) On the plot of I_b draw the locus for $S=1$, and the diameter which passes through the origin.

(*i*) Measure the angle δ between this diameter and the vector I_b corresponding to the largest value of X_c.

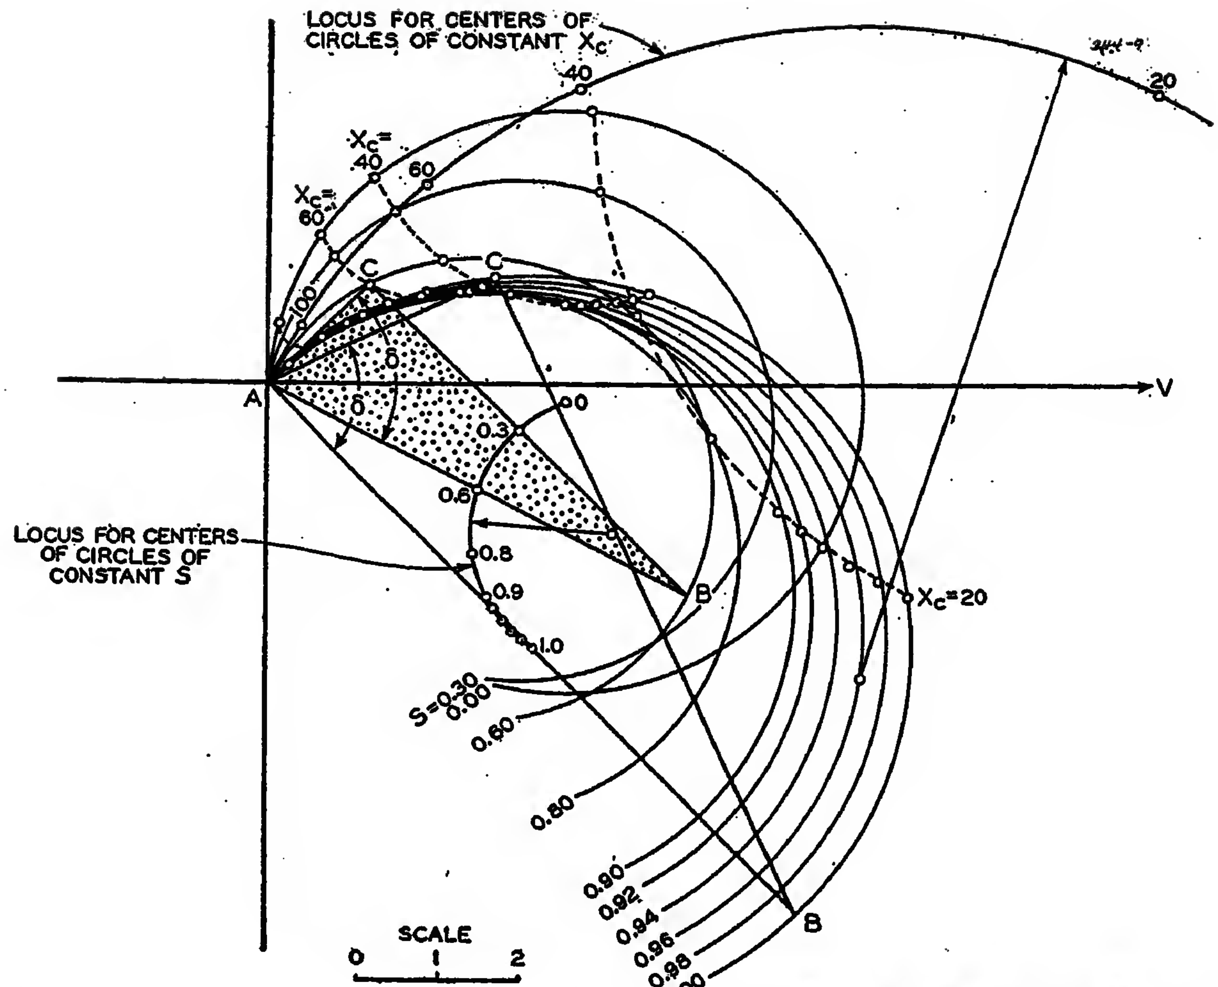

Figure 9. Auxiliary-coil current loci

(*j*) For I_a compute the radii of other circles of constant S between $S=1$ and $S=0.9$ as S^3 times the radius for $S=1$. For I_b use S^2 intead of S^3.

(*k*) By trial find the centers of these circles subject to the conditions that the centers lie on the locus of centers, and triangles ABC remain similar. (The first condition is sufficient for I_b.) Draw the circles.

(*l*) From the loci for $S=1$ determine and plot β and δ as functions of X_c. (Three points are sufficient to determine the curve if it is borne in mind that β changes very slowly with large values of X_c.) From this curve any desired value of X_c on the loci can be found, and any locus of I_a and I_b for constant X_c is readily determined.

(*m*) For each of the values of I_a and I_b found in item (*b*) compute corresponding values of I_{2a} and I_{2b} by the equations of 27.

(*n*) Plot the values of I_{2a} and I_{2b}. The loci are similar to those of I_a and I_b, respectively, but displaced from them by the

Large Adjustable-Speed Wind-Tunnel Drive

C. C. CLYMER
MEMBERSHIP APPLICATION PENDING

PROPELLER-drive equipment for use in wind-tunnel work, where airplane model testing is involved, presented no unusual problems until the advent of the present national emergency. The emergency stressed the importance of research work in airplane design, necessitating the application of the largest motor drive so far considered where a fixed frequency supply provided the energy source. Tunnels are now in operation or in the process of construction, powered by drives rated up to 40,000 horsepower. The primary condition for all such drives is variable or adjustable speed over at least a 6 to 1 range, with a large number of speed-control points and accurate speed regulation.

The accepted method of controlling wind-tunnel motors heretofore was by means of adjustable-voltage control using conventional apparatus, or multispeed wound-rotor induction motors with slip regulators. The conventional adjustable-voltage or generator-field-control system is out of the question, for either single or double units in the above capacities. Two-speed wound-rotor induction motors using slip regulators presented formidable design problems, and offered such questionable operating characteristics as to discourage their consideration. Aside from the questionable practice of starting such large motors directly from existing power systems, the problem of disposing of the slip energy is quite serious. It appears that the problem of the dissipation of energy in large quantities is almost as difficult as the problem of producing it.

Paper 42-65, recommended by the AIEE committees on electrical machinery, industrial power applications, and air transportation for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 12, 1941; made available for printing December 19, 1941.

C. C. Clymer is in the industrial engineering department, General Electric Company, Schenectady, N. Y.

The drive under discussion requires 40,000 horsepower in two counterrevolving propellers at a speed of 300 rpm. Assuming wound-rotor induction-motor drive, the power requirements are as given in Figure 1. The curve marked "fan hp" gives the shaft horsepower required by the fan for any given speed. The curve marked "slip hp" gives the rotor electrical energy to be disposed of in the most satisfactory manner. The motor input, or the load taken from the line is, of course, the sum of these two curves at any particular operating point.

Needless to say, every known method of speed control was analyzed and its advantages and disadvantages tabulated before the described system was selected. None of the existing systems completely met the conditions; hence, this combination of machines. This arrangement is shown schematically in Figure 2. The two d-c machines were used on each set simply because of design consideration. A smaller drive would use but one such d-c machine.

Obviously the main drive motor can not operate with zero slip except with an unwarranted complication. Accordingly, the main drive motors were selected with a synchronous speed of 327 rpm, but intended to operate only to a speed of 300 rpm, as the maximum operating point. The determination of the proper amount of slip is a matter of economics. If the slip is too low, means must be provided to compensate for the IR drop in the windings.

It will be observed that the rotors of the two main drive motors are, in effect, connected in series. This connection introduces a synchronous machine damping into the circuit. Were the rotors of the two main motors connected directly in parallel with the stators connected in parallel, the machines could oscillate independently of the restraining force provided by the synchronous machine.

The characteristics deemed essential for the successful operation of the tunnel follow:

1. Two propellers will be used, each absorbing approximately 20,000 horsepower at 300 rpm. These propellers are to operate in opposite directions but in absolute synchronism.
2. Variable speed with vernier control from 50 to 300 rpm.
3. Accurate speed control for any given speed setting to within one fourth of one per cent.
4. Power-factor correction.
5. Low-starting kilovolt-amperes.
6. Control of the rate of change of power.

Desirable but not necessarily cardinal characteristics may be listed as follows:

1. High efficiency.
2. Low maintenance cost.
3. Ease of speed control.
4. Negligible line disturbance.

The motors under discussion could be located in the tunnel proper, mounted in a streamlined nacelle or mounted outside the tunnel and the fans operated through shafting. The total input to the stator minus the output from the rotor is dissipated in the tunnel air stream. The motor losses are, of course, dissipated in the nacelle if the motors are tunnel-mounted. Since the tunnel air reaches a rather high temperature, it is not satis-

factory as a cooling medium. It is, therefore, necessary to remove the heat from the nacelle by other means. Air-to-water heat exchangers could be used for this purpose, the coolers being so arranged that blowers located in the nacelle draw the hot air through the cooler, where it gives up its heat, delivering the cool air back to the motor. Water for the coolers is obtained from the sump of a cooling tower. The use of the coolers will reduce the ambient appreciably over the tunnel ambient, thus permitting higher temperature rise with consequently smaller and less expensive equipment.

Referring again to Figure 2, induction motors operated in this manner are doubly fed. The speed at any instance is proportional to the difference between the stator and rotor frequency. The machines, therefore, operate without slip in the sense that that term is usually applied, and, in effect, operate substantially as a synchronous machine. In fact, if we arrange to compensate for the *IR* drop in the machine windings, they can be made to operate exactly in synchronism.

Speed variation is accomplished by varying the fields of the d-c machines used in the circuit. This provides the equivalent of full adjustable-voltage or generator field control, and this control is accomplished through the use of d-c machines having approximately one-sixth the capacity of the total power absorbed by the propellers.

Accuracy of speed control is obtained through the use of high-speed excitation on the d-c machines. The excitation is controlled by matching a tachometer voltage against a standard, amplifying the difference that exists and applying this difference to the field of a high-speed exciter (Amplidyne generator).

The voltage standard is a 250-volt excitation bus whose voltage is maintained within $^1/_{10}$ of a volt. Speed variation is obtained by positioning a potentiometer rheostat having approximately 800 positions for the speed range of 50 to 300 rpm. This rheostat need be no more formidable than the rheostat used to control the tuning of a radio. However, since the problem of controlling this much power extends back to the central station serving the project, it is necessary to impose restrictions on the operators in order not to build up the load too rapidly, on the one hand, lest the power system be unnecessarily disturbed, and on the other, to prevent operators whose attention might be engrossed at the moment from blowing low-speed models to pieces in a high-speed tunnel.

Power-factor correction is obtained by varying the excitation on the variable-speed synchronous machine connected across the slip rings. In order to relieve the operator of the responsibility of holding the proper power factor, amplidyne control was applied to the field of the synchronous machines and adjusted to provide a power factor of 90 per cent at all loads and speeds. This is quite an important feature, since induction motors ordinarily applied to an operation of this kind would draw approximately 10,000 kva lagging at the lower speed range where a large percentage of the operation will take place.

Low-starting kilovolt-amperes is obtained by starting the constant-speed motor-generator set. After this set is started, the variable-speed set is brought up to provide 60 cycles, and with proper excitation applied at the rotor, it is possible to match the line voltage and frequency very accurately on the stator of the induction machine. When the voltage and frequency are matched, the running breakers may, of course, be closed. The voltage and frequency of the variable-speed synchronous machine are controlled through automatic synchronizing devices. Through this system, a 40,000 horsepower drive may be started with an inrush under 6,000 kva.

The rate of power change is controlled by using a motor-driven potentiometer rheostat. This rheostat may, of course, be driven at any desired speed. The rheostat may, if desired, be tapered so as to provide a high rate of change over the lower speed range of the drive with corresponding low rate of change at the higher speed range and, consequently, higher power demand point. On the other hand, it may not be desirable to change the speed of the machine too quickly at any part of the range, as this might make it difficult to obtain accurate data. It is conceivable that it might be desirable to change the speed very slowly in order to observe the effect of this speed change on the model. Suffice it is to say that practically any type of speed-versus-time characteristic could be obtained very easily within the design limitations of the associated apparatus.

Concerning the desirable though not necessarily mandatory characteristics, it is well to mention that the load factor on an operation of this kind is low, perhaps not more than 10 per cent. Power consumption will, therefore, be the least expense associated with the operation of the tunnel, and the economics of the problem do not justify any appreciable lay-

out for increased efficiency. It is well to point out in this connection, however, that while it is necessary to pay for this energy on the one hand, the expense of disposing of it may more than equal its cost in the first place. The maximum demand on such an installation is often of greater importance than the power consumed. Therefore, the higher the efficiency, the lower will be the demand, and at the maximum loss point which occurs around 70 per cent speed, the maximum demand may be reduced 27 per cent over another system which would waste this slip energy.

The efficiency of the system described here is necessarily high since all slip energy is returned to the line minus machine losses. In the case of slip-regulator operation, it is necessary to operate with a higher slip than is provided by an induction motor operating with a shorted secondary. The electrodes of slip regulators can not be brought in too close proximity, otherwise erratic operation is obtained. Therefore, the full load efficiency of the two systems is comparable. At any reduced operating-speed point, however, the efficiency of the doubly fed motor will be much higher than the efficiency of any system where the slip energy is dissipated.

Ease of speed control is, of course, a by-product of the system used. Speed with this system is a function of frequency rather than voltage, and frequencies of present day distribution systems are maintained with a high degree of accuracy. Temperature changes are ineffectual except in the loop circuit of the d-c machine. Changes here are very gradual and are easily taken care of by the regulating equipment. Any type of induction-motor drive which is not doubly fed provides a speed which is both a function of voltage and frequency, and, therefore, voltage fluctuations will produce speed variations in the tunnel.

Line disturbances with this system are, of course, reduced to an absolute minimum, since there is no high-voltage switching under power, and after the machines are once started, the only change is a gradual build-up or decay of the load. Since the rate of change of this load may be very accurately and completely controlled, the generating system will be enabled to pick up and drop the load at a uniform rate, permitting the distribution system regulating devices to function and maintain normal service.

Low maintenance should result where only the rotating apparatus is employed and where there is no switching of dynamic current. In fact, the entire control operation is performed by handling current in the order of a fraction of an ampere. Maintenance is always appreciable where dynamic currents are switched regardless of the means provided to accomplish a change in operating conditions.

The system is, of course, new, and it is particularly adapted to the operation of fan loads, centrifugal pumps, frequency-converter systems, where the two frequencies do not necessarily match exactly, and where it is desired to accurately control the flow of power.

The Influence of Towers and Conductor Sag on Transmission-Line Shielding

ROYAL W. SORENSEN
FELLOW AIEE

ROBERT C. McMASTER
ASSOCIATE AIEE

THIS paper is the third of a sequence of papers intended to present data which may be used in determining the degree of protection from lightning obtainable by shielding transmission lines and structures with grounded overhead wires and masts. The first two papers of the sequence are: "Shielding of Transmission Lines,"[1] and "Shielding of Substations."[2]

Results Based on Earlier Model Tests

One sentence in the synopsis of a paper, "Lightning Protection for Oil Storage Tanks and Reservoirs,"[3] presented at the 1927 Pacific Coast convention of the AIEE, reads as follows:

> "Tests show that excellent protection can be obtained by towers properly installed, but they do not indicate absolute immunity against hits."

The tests described in that sentence were laboratory tests on small-scale models. Using data obtained from those and other tests, a plan for protecting reservoirs by means of masts was developed. The integrity of those tests in indicating the protective value of shielding by grounded masts is well demonstrated. All oil reservoirs equipped with masts designed according to the data obtained from the tests described in that paper have been free from damage by lightning since the masts were erected during 1926 and 1927. In some installations, well-grounded masts only were used, and in others, where conditions indicated it advisable, the masts were supplemented by interconnecting overhead conductors.

In the 14 years which have elapsed since that method of protection was adopted for the oil reservoirs in question, many field data and many model tests have added to our knowledge of lightning and ways to guard against lightning damage. A bibliography of the reported work relating to this particular discussion was presented in the paper, "Shielding of Transmission Lines." One dictate of the knowledge obtained is that lightning protection for electrical transmission lines and other structures can be obtained most economically in any scheme of protection by taking advantage of the shielding effect of overhead ground wires and grounded masts located in proper juxtaposition to the objects to be protected. Since absolute protection for such structures is not usually economically practical, engineers desire statistical data which will enable them to determine the degree of protection provided by particular arrangements of overhead ground wires and masts. Such data must be obtained by many observations of actual lightning strokes and by careful model tests in the laboratory. The model tests must show valid correlation with field observations, and duplicate those characteristics of natural lightning which determine the paths taken by strokes. A full discussion of this topic appears in the first paper of the sequence.

Recent Model Tests

The first paper presented data showing the value of ground wire protection for a laboratory model representing a section of transmission line with a tightly-stretched conductor protected by a parallel tightly-stretched overhead ground wire. There was no appreciable sag in the section of model line tested, and no supporting towers were included within the test area.

The present paper gives the results of two check tests made in the California Institute of Technology high-voltage laboratory upon models identical with those used for two of the tests made at Trafford, and of further tests which determine the shielding effect, additional to that of overhead ground wires, provided by the transmission towers and conductor sag. Correction factors are given by means of which shielding data for parallel wires can be modified to account for the additional protection resulting from the presence of transmission towers.

The large amount of published data relating to lightning, surge testing with models, and the correlation between field observations and model tests under various conditions, permits the writing of this paper without including any matter relating to the "mechanism of natural lightning," and with little reference to the "fundamentals of model tests."

In keeping with conclusions of other experimenters, and the experience of the authors, it was considered justifiable for these tests to duplicate as closely as possible the test conditions used in obtaining the data for the first paper.

Laboratory Model and Test Conditions

The 2,000,000-volt 0.065-microfarad surge generator, built by graduate students at Pasadena, was used as the voltage source for the work of this report.

The conventional surge-generator circuit, with a resistance in parallel with the

test gap, was used. The wave form was approximately a $1^1/_2$- by 40-wave; and all strokes were fired at the minimum arc-over voltage of the test gap, with cloud electrode polarity positive. The discharge electrode was a $^3/_8$-inch diameter rod with a rounded end, mounted vertically with its lower end 50 inches above the ground plane of the model. The ground plane was a large salt water basin in which was submerged a grid of ground wires, covering the entire area of the basin and providing a 12-inch mesh over the test area. Conductors and tower used in the model were solidly grounded.

The model represented 100-foot transmission towers supporting 1,000-foot

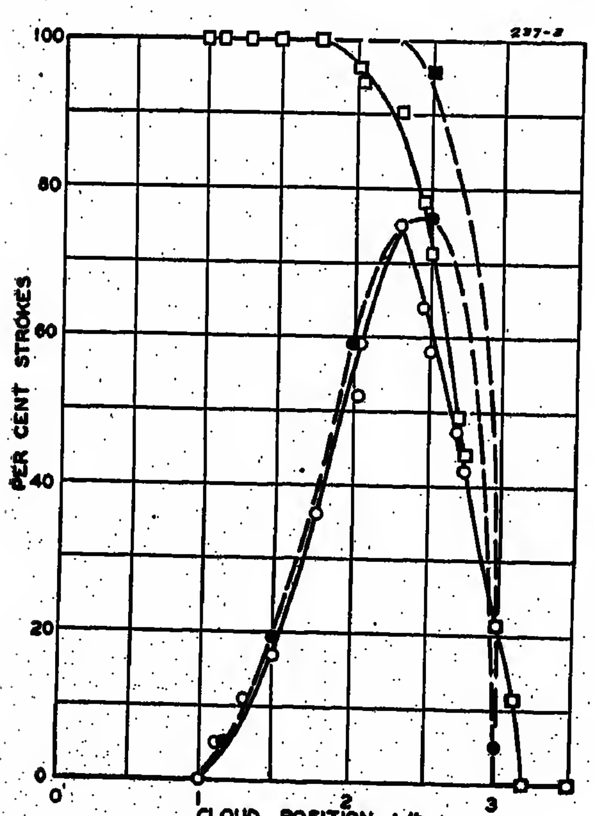

Figure 3. Check tests

spans, built to a scale of 10 inches = 100 feet (see Figure 1). Only one mode lscale was used, because experience has demonstrated that change in model scale does not change the relations of test results.[1] For test purposes, number 14 bare copper wire was used for overhead ground wire and conductor. For tests with sagged wires, the proper catenary was maintained by use of nonconducting anchor cords kept dry by having their lower ends attached to metal hooks just above the water.

To the scale of 10 inches = 100 feet, the equivalent height of the cloud electrode was 500 feet. This is the generally recognized minimum height of cloud from

Scale 10 inches = 100 feet

which lightning develops. This arrangement gives conservative results for shielding conditions. The first paper included a study of the effect of protective angle between ground wire and conductor. One set of data was for an angle of 64 degrees. In that test, a measurable percentage of strokes terminated on the "protected line conductor." This 64-degree angle was chosen as a fixed reference angle and used throughout the tests reported in this paper.

Methods of Observation

In reporting the tests, the total number of strokes for any condition was divided into groups and classified according to the points of stroke termination. The strokes were designated as strokes to conductor, strokes to overhead ground wire, strokes to tower, and strokes to ground plane. At least 100 strokes were "fired" for each position of the cloud electrode. The points of stroke termination were recorded by two observers viewing the model from positions such as to have their lines of vision intersect perpendicularly at the point subject to test. This made it possible to determine accurately and without any difficulty the point of stroke termination. The observers exchanged positions after each 25 strokes. If results of the first 50 strokes were not consistent with those of the following 50 strokes, additional strokes were fired. The lack of dependence of results upon any unique skill or opinion of an observer is well established by the agreement in the reports of the 16 observers used during the series of tests.

Model Arrangements

Tests were made under three conditions:

1. As shown in Figure 2, using taut ground wire and conductor parallel to each other, without tower in place or conductor sagged. These were check tests to correlate this work with that reported in the first paper.

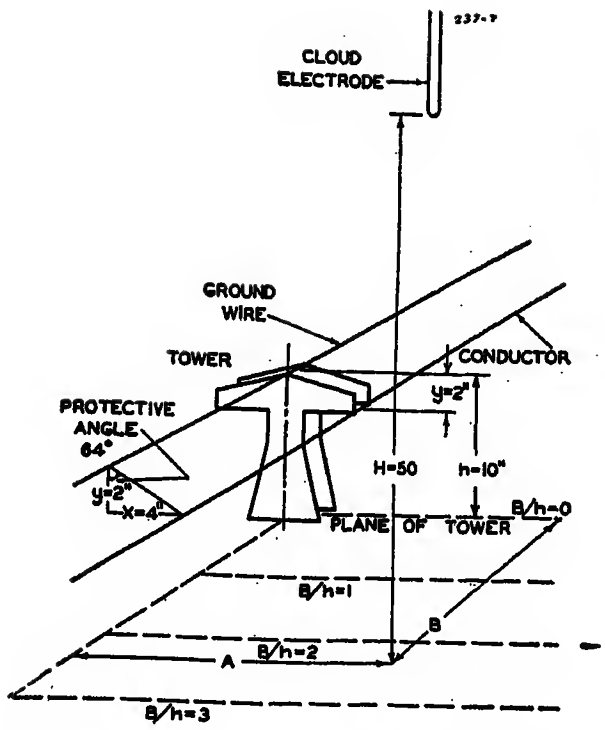

Figure 7. Taut ground wire and conductor parallel

Tower in place. For Figures 8–12, 22, and 24

2. As shown in Figure 7, using taut ground wire and conductor with model tower installed to determine added shielding effect of tower.

3. As shown in Figure 13, using ground wire and conductor under less tension and suspended from model tower to simulate the sag that is always present for actual transmission-line conditions. Tests were made with this arrangement to evaluate the effect of line sag on shielding.

Results of Check Tests

In the check tests, the wires representing the line conductor and the overhead ground wire were tightly-stretched copper wires supported outside the test area and without towers or line sag within the test area. The first check test was made with $h=10.0$ inches; $y/h=0.10$; $H/h=5$; protective angle 64 degrees (see Figure 2); and the second check test was made with the same arrangement except for a change in the ratio y/h from 0.10 to 0.20. Figures 3 and 4 show the comparative results of the tests made in the two laboratories. The Pasadena test results are plotted as solid-line test curves, and the Trafford test results as dotted-line test curves.

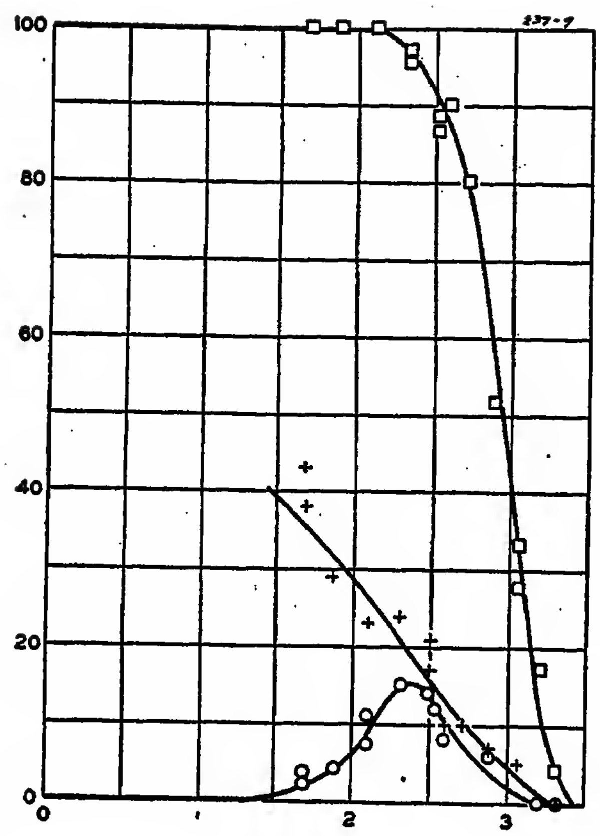

Figure 9

$B/h=0.5$

The results of the two check tests, while not in exact agreement with the Trafford tests, are as much in accord as one could expect for tests of this character made in different laboratories by different experimenters who have no agreement as to number of "shots" for each condition, and other plans of procedure.

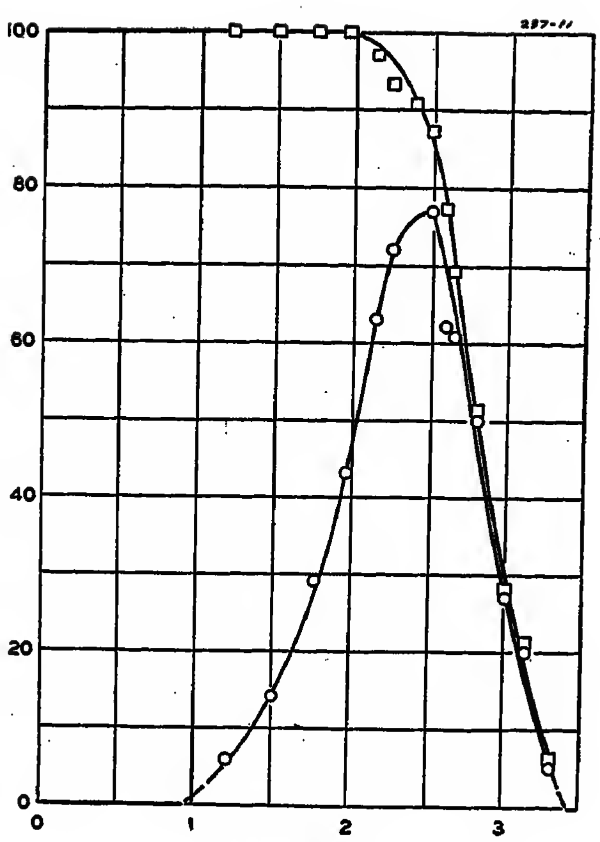

Figure 11

$B/h=2.0$

The differences which are to be noted in the curves may be due to the difference in the number of strokes made to each point. The solid curves represent more than 1,500 strokes for each curve and a minimum of 100 strokes for each A/h value used in plotting the curve. However, in considering actual lines, the effect of line sag and towers is such as to more than make up for the difference in the two

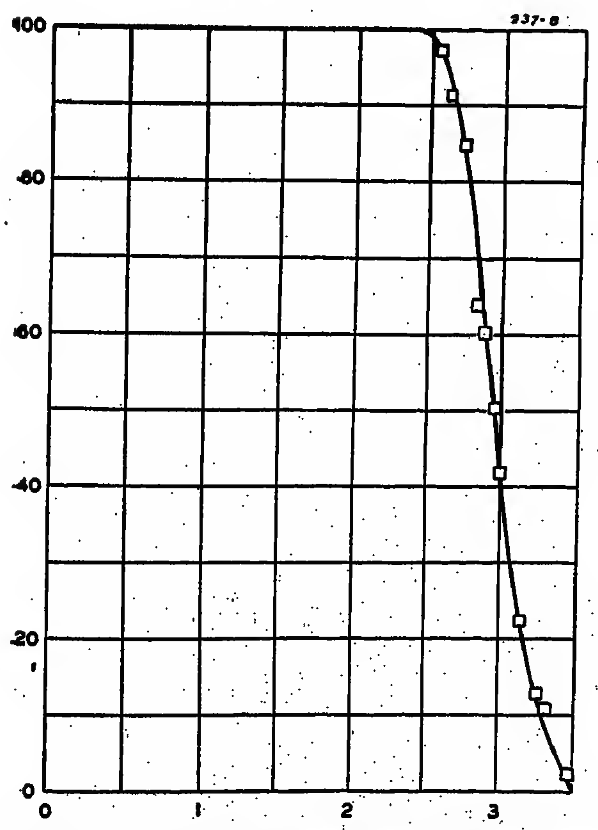

Figure 8. For cloud electrode in plane of tower

curves. One result of the comparison just made is the indication that it is well in making surge tests of the character under discussion to base findings on results obtained by making at least 100 "strokes" for each plotted point. See Table II.

Shielding Effect of Towers

The data obtained with towers in the model line added to our general realization of their value as aids in line shielding by providing data which show that, for a cloud electrode at five times tower height above ground, a line conductor suspended below a metallic cross arm is completely protected from strokes originating from a cloud point in a plane through the tower

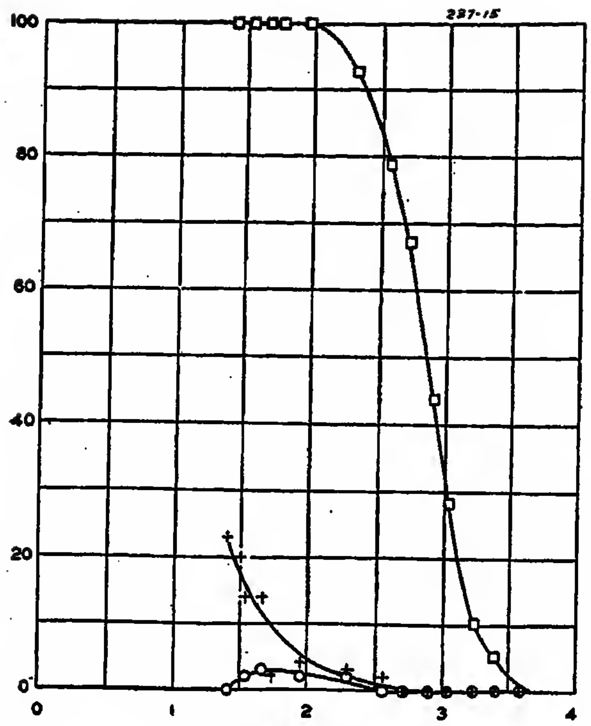

Figure 15

$B/h = 0.5$

and perpendicular to the line. The data also show that the protection furnished by the tower decreases with distance from the tower measured along the line, as follows:

With 100 per cent protection at the tower, there is only 85 per cent protection with the cloud point moved parallel to the line a distance of one-half tower height from the tower. If the distance from the plane of the tower to the point of cloud discharge is equal to a full tower height, the protection is only 50 per cent. The towers offered no protection to the line conductor against strokes originating from a cloud point more than two times tower height along the line from the plane of the tower (see Figure 22). Towers 100 feet high and spaced 1,000 feet apart in a transmission line reduce the number of probable strokes to the conductor for the over-all line to 80 per cent of the number that would be expected for a section

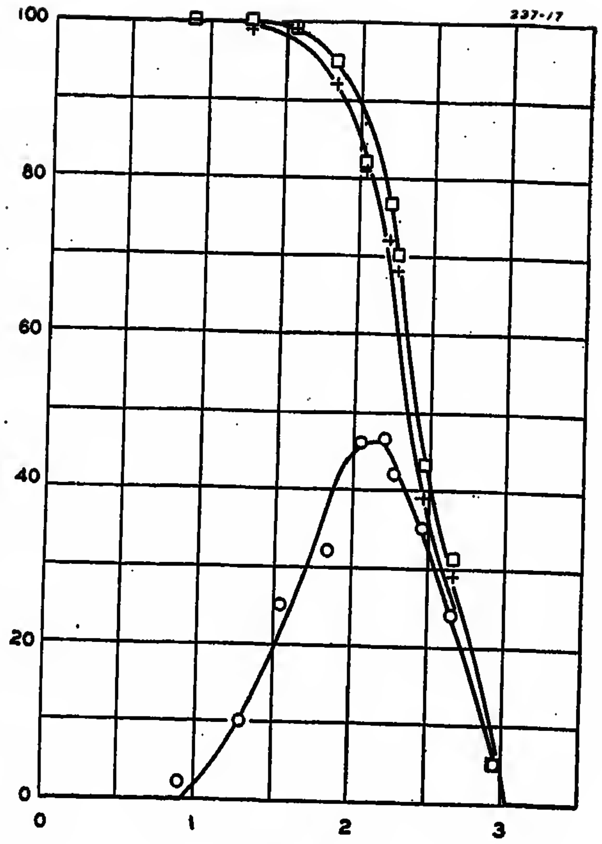

Figure 17

$B/h = 2.0$

of line without towers. The line conductor and overhead ground wire were kept taut without appreciable sag in these tests (see Figure 7).

Shielding Effect of Line Sag

The third set of tests on the model line was made with the tower in place and with line conductor and overhead ground wire kept parallel to each other, both being sagged 40 per cent of the tower height at the center of the span (see Figure 13). These tests show that with 100-foot towers 1,000 feet apart, the number of strokes that hit the conductor for the cloud

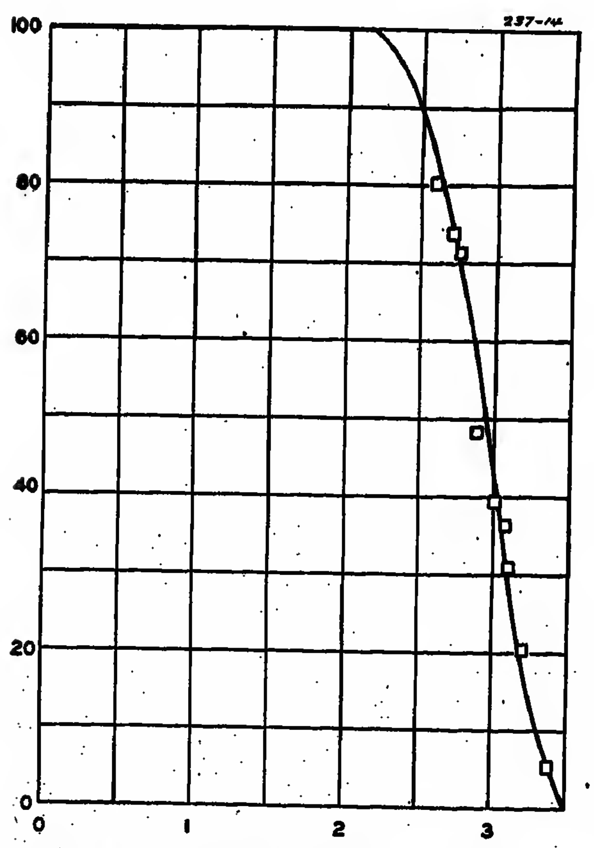

Figure 14. Cloud electrode in plane of tower

$B/h = 0$

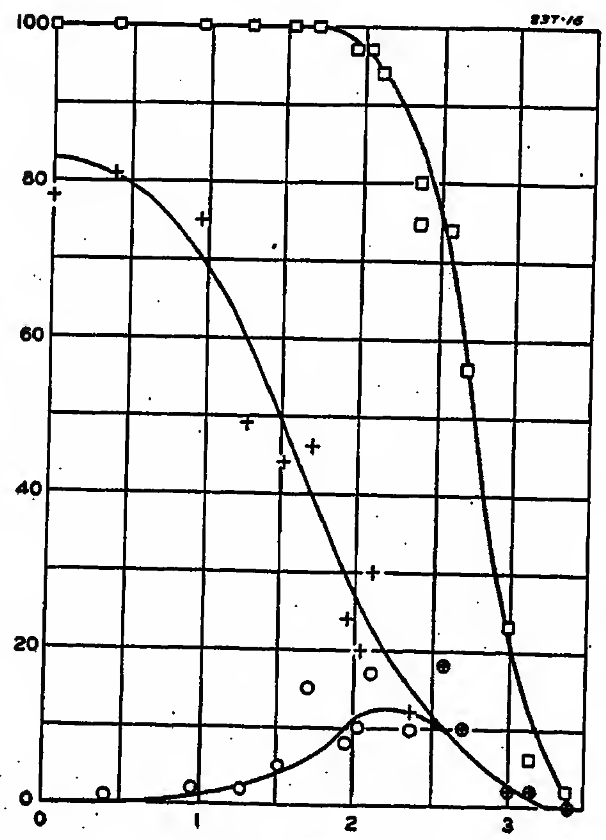

Figure 16

$B/h = 1.0$

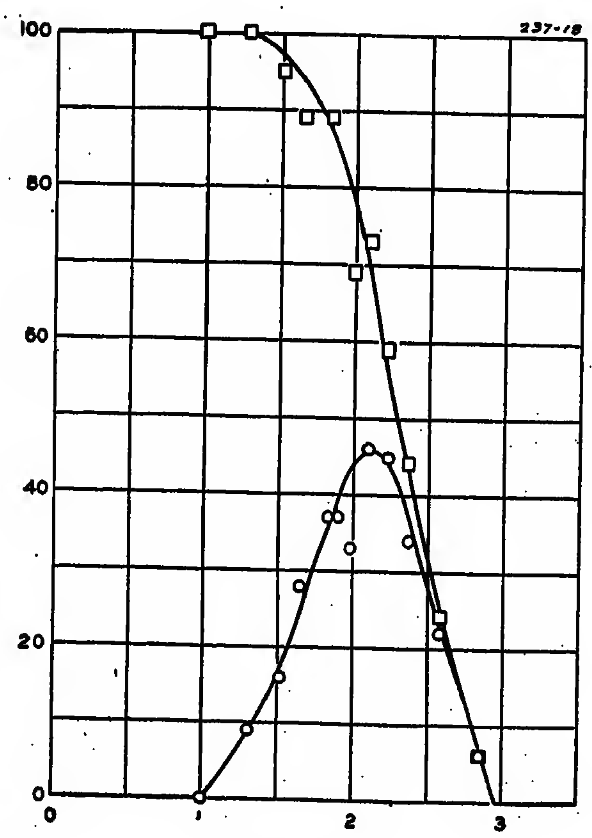

Figure 18

$B/h = 3.0$

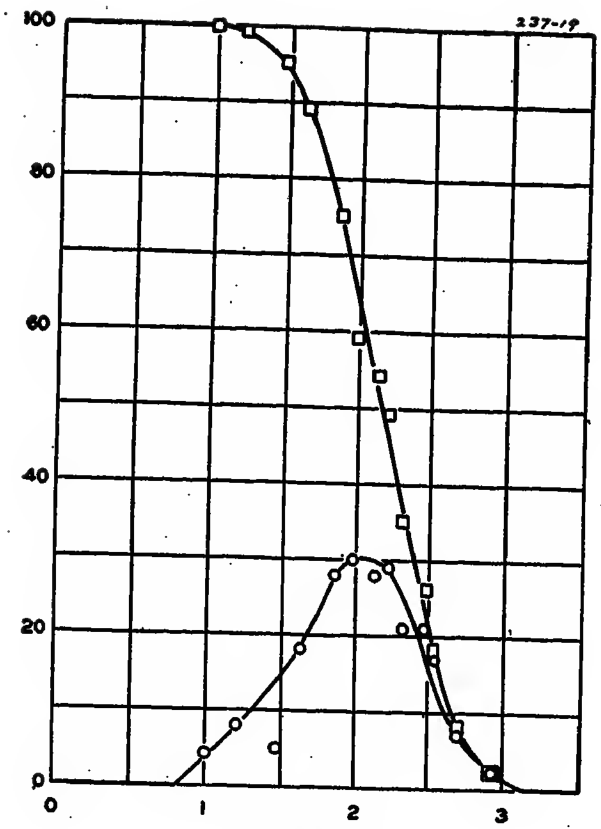

Figure 19

$B/h = 4.0$

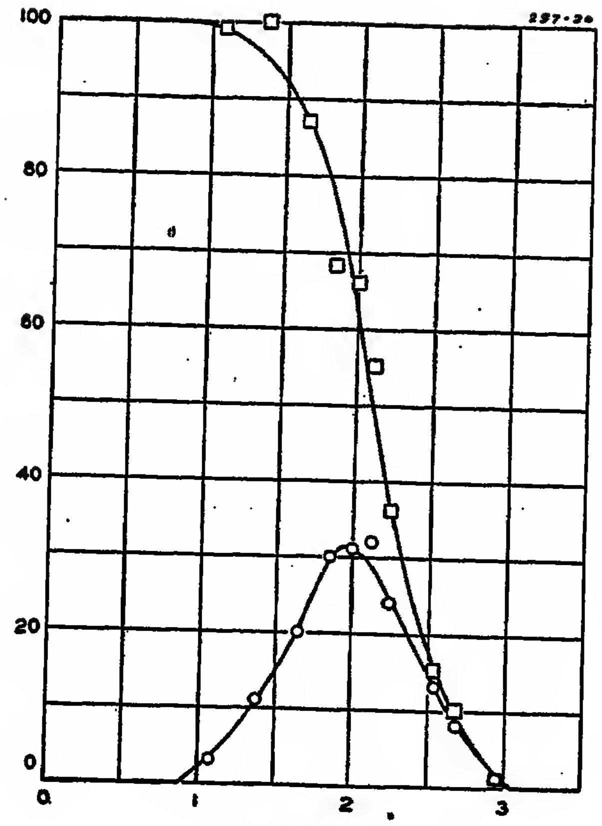

Figure 20

$B/h = 5.0$

electrode opposite the center of the span was only 38 per cent of the number observed when the lines were not sagged. For a uniform distribution of strokes originating from clouds along the line, the line sag reduced the number of strokes to conductor to 52 per cent of the number obtained when towers were in place but there was no line sag (see Figure 23).

Distribution of Strokes

Tests involving thousands of strokes to the model-line area from a minimum cloud height of five times the tower height showed that the line is immune to strokes that originate along the line, outside a band, the width of which is about seven times the tower height. Table I presents the distribution for strokes originating from the cloud electrode located above the line at points uniformly distributed within a band having a width of seven tower heights and with its axis parallel to the axis of the transmission line.

Explanation of Figures

Figures 2 to 24, showing model arrangement and results of tests, enable ready comparison of results. In these diagrams:

h = Height of tower and ground wire at point of tower support. In tests this model was always 10 inches high.
y = Vertical component of displacement of conductor below ground wire.
x = Horizontal component of displacement of conductor from ground wire.
$/P$ = Protective angle = $\tan^{-1} x/y$.
H = Height of lower end of cloud electrode above ground plane = 50 inches.
A = Horizontal component of displacement of cloud electrode *normal* to the line, measured from ground wire.
B = Horizontal component of displacement of cloud electrode *parallel* to the line, measured from center line of tower.
s = Sag of ground wire and of conductor at center of span, from heights at tower support points.

For each of the three tests, all model dimensions were fixed, except the horizontal displacement of the cloud electrode, given by A and B, which was varied throughout the region from which strokes might terminate on the model line.

Figure 5 explains the curves of test results. For each value of A/h, the percentage strokes to conductor are shown by the ordinate to the lowest curve, test points shown by ⊙; the percentage to ground wire by the difference between the ordinate of the curves whose points are (+) and the curve whose points are ⊙; the percentage strokes to tower by the differences between the curves whose points are (□) and the curve whose points are (+). Strokes to ground plane are represented by the difference between the 100 per cent ordinate and the curve whose ordinates are marked by (□).

Figure 2, shows arrangement of model line with taut wires only.

Figure 3 shows results for $y/h = 0.1$, and Figure 4 results for $y/h = 0.2$ for tests at both laboratories, with wires only as shown in Figure 2. Figures 5 and 6 are the explanatory curve and detail of model tower, respectively.

Figure 7, shows arrangement of model line with tower in place and taut wires.

Figure 8 shows stroke distribution for electrode at various positions (A/h) in the plane of tower ($B/h = 0$).

Figure 9 shows stroke distribution for electrode at various positions (A/h) in the

Figure 13, shows arrangement of model line with tower in place and 40 per cent sag in wires. Figures 14 through 20 show stroke distribution for electrode at various positions A/h in planes for values $B/h=0.0$; 0.5; 1.0; 2.0; 3.0; 4.0; and 5.0.

Interpretation of Test Data

The areas *C*, *G*, and *T*, bounded by the curves, as illustrated in Figure 5, show values of stroke distribution to conductor, to ground wire, and to tower, integrated for all values of A/h. The remaining area shows strokes to ground plane for integrated values of A/h up to about 3.5 times tower height.

Figures 21, 22, and 23, in columns 1, 2, and 3, respectively, show the distribution of strokes along the line, where B/h measures distance from tower in terms of tower height (h). The ordinates of these curves for each (B/h) value were obtained from the areas of the preceding curves. The areas of Figures 21, 22, and 23 show the distribution for stroke terminations for an entire span. The data for Table I were obtained by measuring these areas.

Figure 24, derived from data for Figure 22, shows as a function of span length the percentage of added shielding provided by towers. For a 40 per cent sag in a 1,000-foot span, a similar curve could be drawn showing the added shielding effect of towers and sag. This has not been done because in actual practice sag changes with tower spacing and conductor tension.

Conclusions

The tests on which this report is based show that the Wagner, McCann, and MacLane protection values are conservative, because they do not include the protection provided by towers and line sag. The preceding curves can be used to determine the additional protection due to towers and conductor sag for a protective angle of 64 degrees. For other protective angles estimates of the added protection can be based on reasonable interpretation of these results. The magnitude of this added protection is important, since for typical spans it shows an increased protection of 20 to 80 per cent.

Appendix

Figure 25 is included in this paper to call attention to the pattern formed in the grounding pool, apparently on the surface of the water. At the time this picture was made, the water had a somewhat higher resistance than was used during the regular testing program. Figure 1 was made after the addition of more salt to the water. The "crowfoot" figures were then less noticeable. Figure 8 in the paper, "Lightning Protection for Oil Storage Tanks and Reservoirs"[3] showed the spread of discharge current over a concrete floor. The "crowfoot" travel of current over that floor made a photograph much like the ones shown in this paper. These pictures are of interest in showing what may happen when large currents arrive at a point of sudden change in resistance. The resistance of the concrete floor was very high.

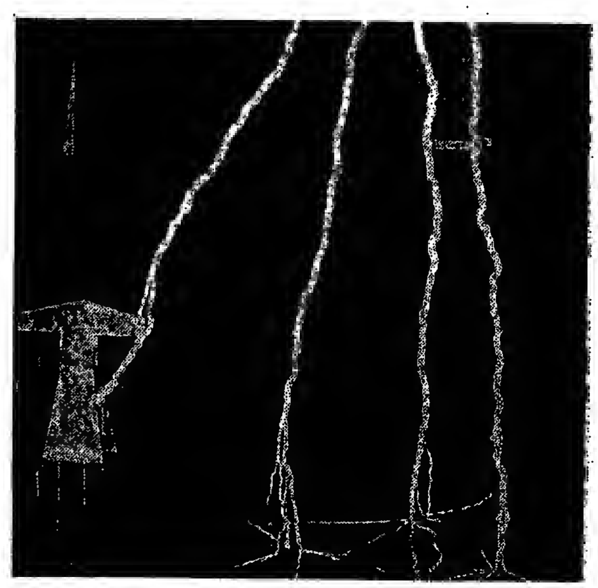

Figure 25. "Crowfooting" or spreading of streamers on surface of abnormally high-resistance water plane

A Fast Circuit Breaker

D. I. BOHN
MEMBER AIEE

OTTO JENSEN
ASSOCIATE AIEE

DURING the past few years the rapid expansion of mercury-arc rectifier installations at 600 volts d-c, both as to the total kilowatts installed and the relatively large number of units operated in parallel, has emphasized the importance of switchgear in providing suitable rectifier operation. In the event of a backfire, the rates of current rise through a rectifier and its transformer windings lie, in general, between three million and six million amperes per second. With large installations, such as shown in Figure 1 where 60 units of 5,000 amperes each are operated in parallel, the ceiling value of these currents is far above a figure which could be tolerated both from the standpoint of continuity of operation and safety to equipment.

High-speed breakers having a time of approximately 0.5 cycle from backfire initiation to current limitation may permit, in some installations, peak currents in the neighborhood of 60,000 amperes. While such a value is appreciably below that which would cause equipment damage, it is nevertheless undesirably high, in that surges and "sympathetic" backfires on other units often result. Breaker duty and maintenance are higher than would be the case with lower values of backfire current, and the factor of safety is not so great as is desirable.

Figure 2 shows the current path during a backfire in a six-phase rectifier. It will be noted that the current flowing through the cathode breaker is supplied by other rectifiers on the bus, and that the current flowing through the anode breaker is the same current plus the additional current from the other anodes of the faulted rectifier.

Figures 3 and 4 show two accepted connection schemes for rectifier stations. In Figure 3 a high-speed cathode breaker opens the backfire current fed from other units on the bus of the backfiring unit. At some later period, such as six or eight cycles, the rectifier-transformer primary oil switch opens and clears the backfire current supplied by anodes in the backfiring unit. Since an oil circuit breaker ahead of the transformer may be called upon to interrupt the full capacity of the system, its economical disadvantage is obvious. Furthermore, its slow clearance of a transformer secondary short circuit, caused by a backfire, is undesirable.

Figure 4 shows an alternative connection scheme in which the individual trip-free poles of a six-pole anode breaker clear backfire currents fed from the other rectifier operating in parallel with the backfiring unit, and also interrupt the backfire current supplied by the anodes in the unit. The semihigh-speed cathode breaker is used for backup protection and to provide, through gang tripping, means of dropping a large unit of load fed from a group of rectifiers.

This paper discusses a six-pole anode breaker primarily designed to provide reduced operating time on reverse current and thus to cut to a minimum the undesirable effects of backfires. The same principles of design incorporated in this circuit breaker could apply equally well to a high-speed cathode breaker.

High-speed breakers may be of either the latched-in or nonlatched-in type. If of the former design, the latch-releasing mechanism may be in the form of a simple trip, presumably designed with a maximum force-to-weight plunger ratio when energized with reverse current, or it may have some form of bucking-bar latch-releasing mechanism, or the latch may consist of a friction clutch. With all of these types of breaker, a relatively large

Paper 42-38, recommended by the AIEE committee on protective devices for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 3, 1941; made available for printing December 12, 1941.

D. I. BOHN is with the engineering department of the Aluminum Company of America, Pittsburgh, Pa., and OTTO JENSEN is with the I-T-E Circuit Breaker Company, Philadelphia, Pa.

The discharge currents from the arc path into the water forming the ground plane for Figures 1 and 25 were estimated to be of the order of 10,000 amperes. No effort was made at the time of the experiments to measure the resistance of the ground circuit including the arc during the stroke. To get some idea of the probable resistance of the arc path to ground, a brass rod was substituted for the arc path. With the end of the rod dipped one inch into the water, the ground circuit resistance was found with an ohmmeter to vary from 390 ohms to 250 ohms, depending upon the amount of salt added to the water. With one-half inch of electrode immersed in the water, the resistance was 800 ohms. In the tests made with the tower in place, the resistance of tower to ground was three ohms.

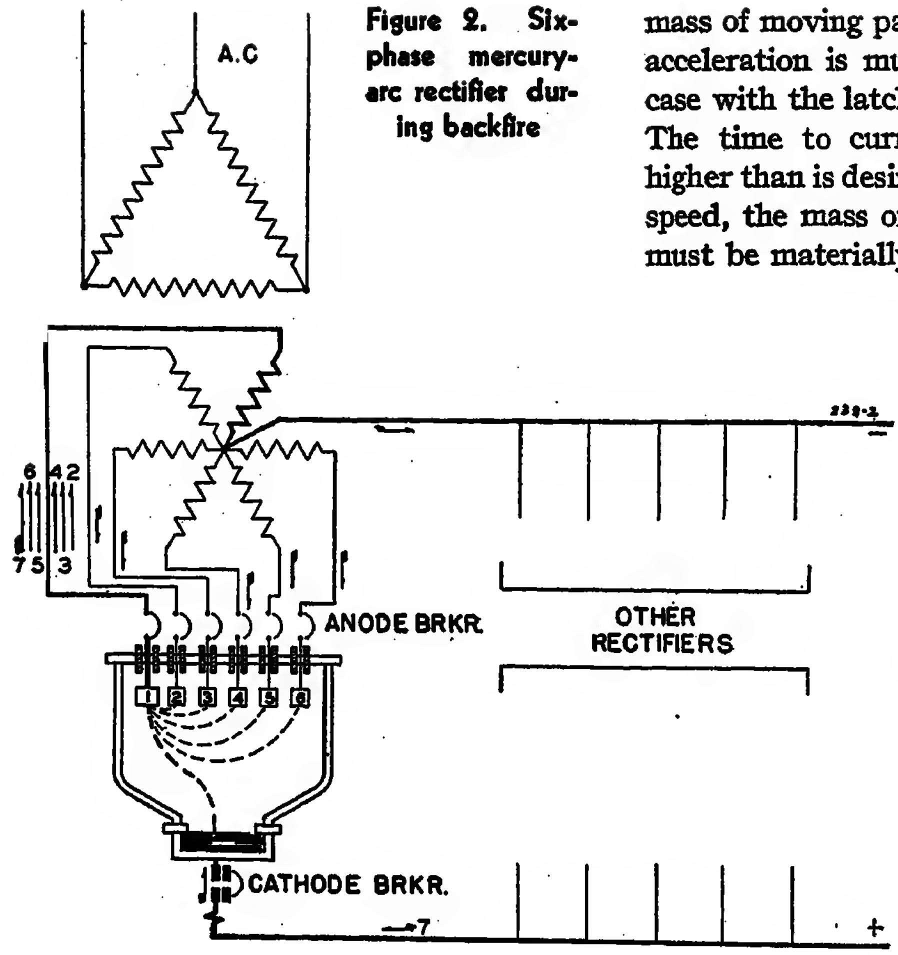

Figure 2. Six-phase mercury-arc rectifier during backfire

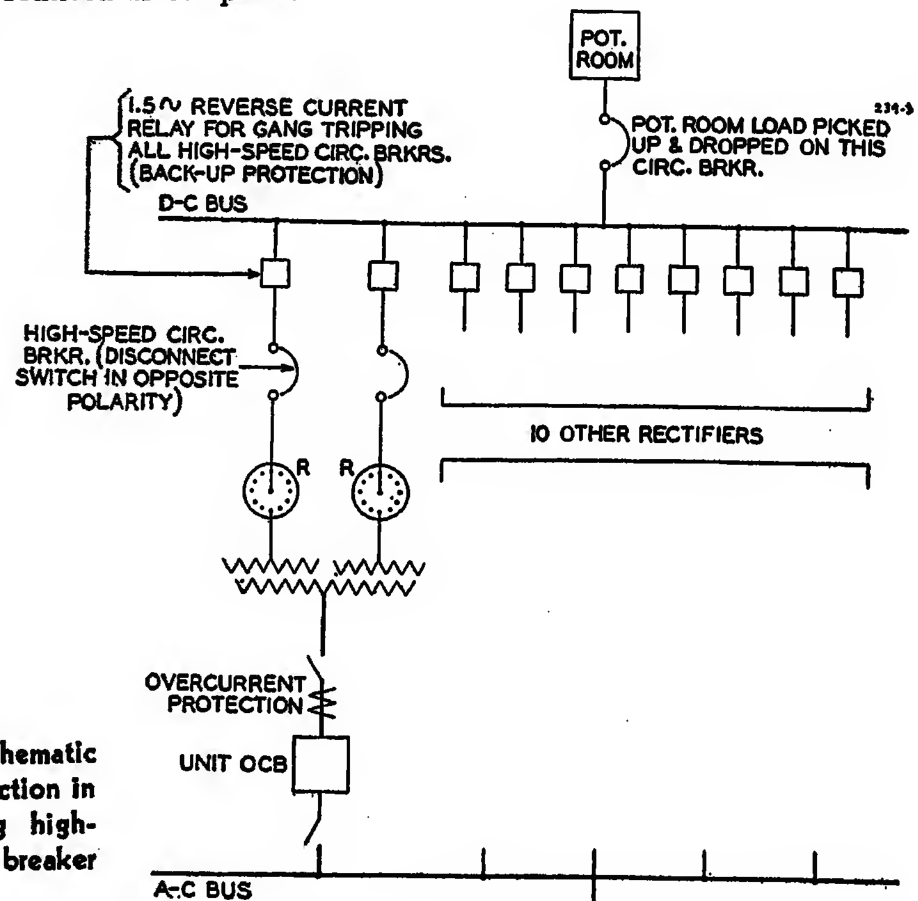
mass of moving parts is so great that the acceleration is much slower than is the case with the latched-in type of breaker. The time to current limitation is still higher than is desirable. In order to gain speed, the mass of the holding armature must be materially reduced as compared

greatly altered, although the armature area and hence its pull are the same as shown in Figure 5.

It will be observed that the design in Figure 6 shows a weight reduction of



proportion of the total operating time is absorbed in operating the releasing mechanism.

Figure 3 (right). Schematic diagram of main connection in rectifier station, using high-speed cathode circuit breaker

For example, a predecessor of the breaker herein discussed has a polarized solenoid-trip mechanism whose plunger releases a latch engaging a ball-bearing-mounted latch pin on the main arm. This breaker trips on about 1,500 amperes reverse current and about 6,000 amperes forward current, the polarizing providing a bias. A typical time study of this circuit breaker, based on oscillograms simulating backfires, shows the following:

Completion of trip plunger stroke and release of latch	0.17 cycle
Total time to parting of arcing contacts	0.38 cycle
Total time to current peak	0.50 cycle
Total time to end of arcing	0.7 cycle

It will be observed that of these various times the first value, 0.17 cycle, is completely wasted in that the breaker mechanism proper is not released until the expiration of this time. This indicates that, even if the succeeding times were appreciably reduced, no great reduction in the total time to current peak would be obtained.

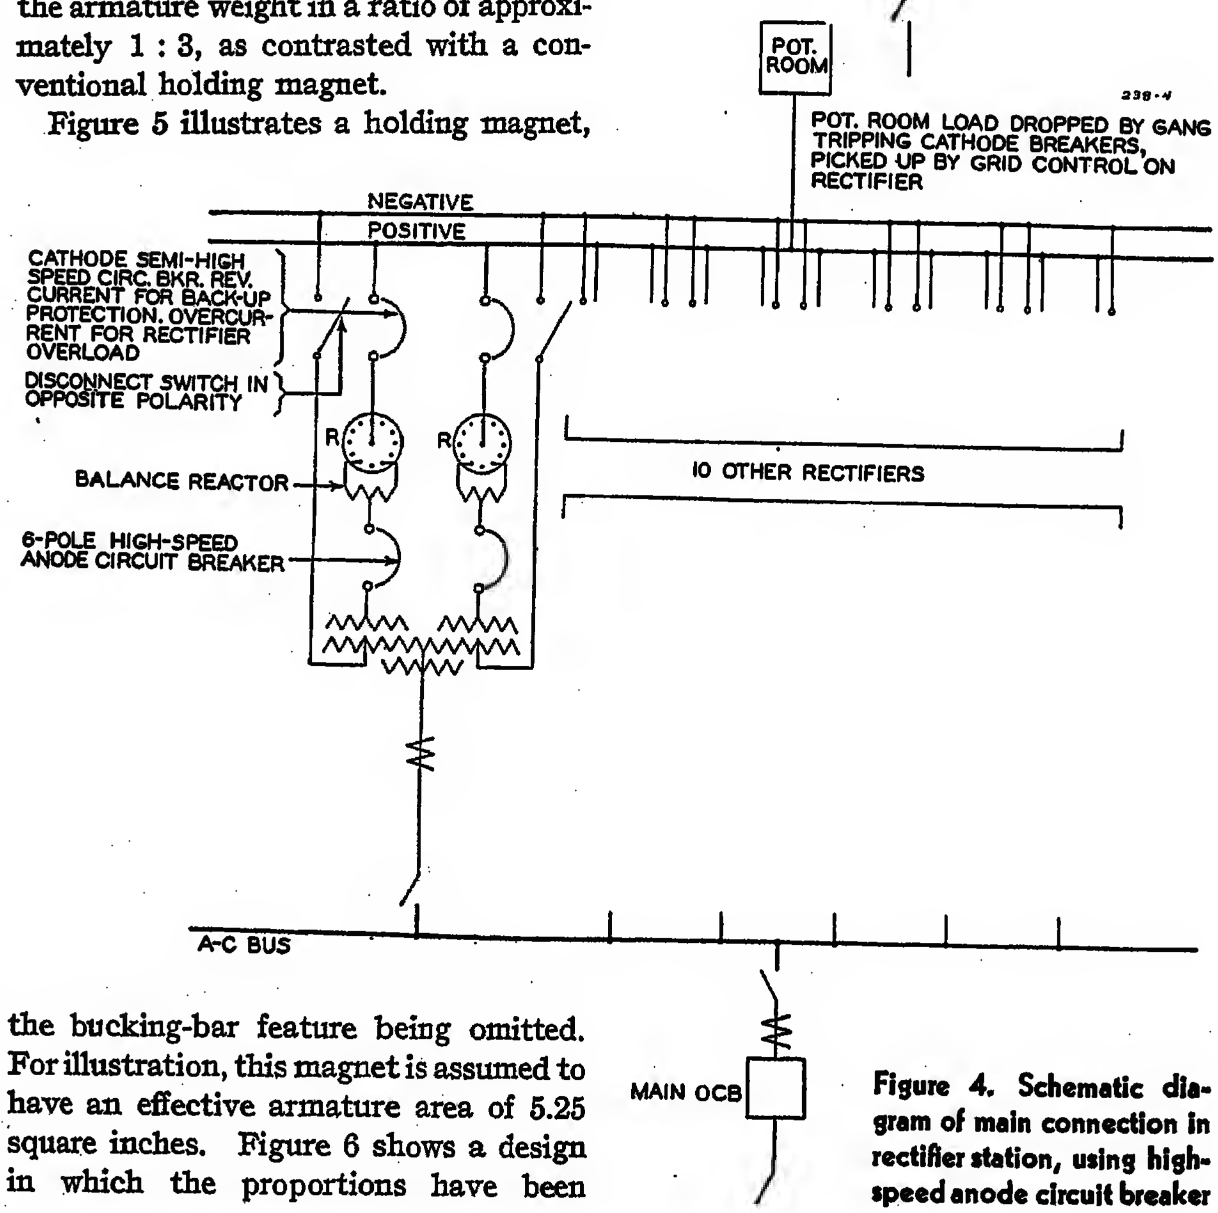
This initial time can be reduced to nearly zero by using a bucking-bar holding magnet with the armature fastened directly to the main operating arm. With this design, the main contact arm starts to move in 0.03 or 0.04 cycle (60-cycle basis) after the backfire is initiated.

Unfortunately, the difference between these latter figures and the previous figure of 0.17 cycle is not a net gain, as the total

with the conventional type of holding magnet armature.

The breaker under discussion employs a magnet and armature design reducing the armature weight in a ratio of approximately 1 : 3, as contrasted with a conventional holding magnet.

Figure 5 illustrates a holding magnet,



the bucking-bar feature being omitted. For illustration, this magnet is assumed to have an effective armature area of 5.25 square inches. Figure 6 shows a design in which the proportions have been

Figure 4. Schematic diagram of main connection in rectifier station, using high-speed anode circuit breaker

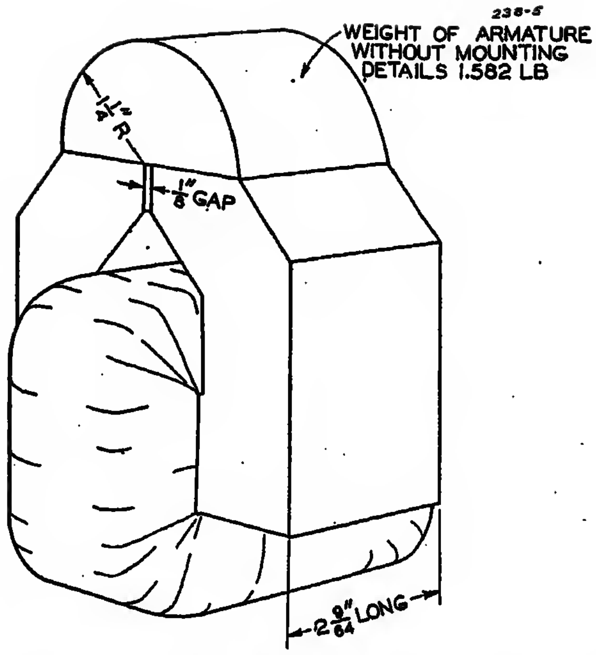


Figure 5. Conventional design of holding magnet

about 3:1, as compared with that in Figure 5, but quite obviously such a design is entirely impractical from a mechanical and stiffness standpoint, so its theoretical advantages cannot be realized.

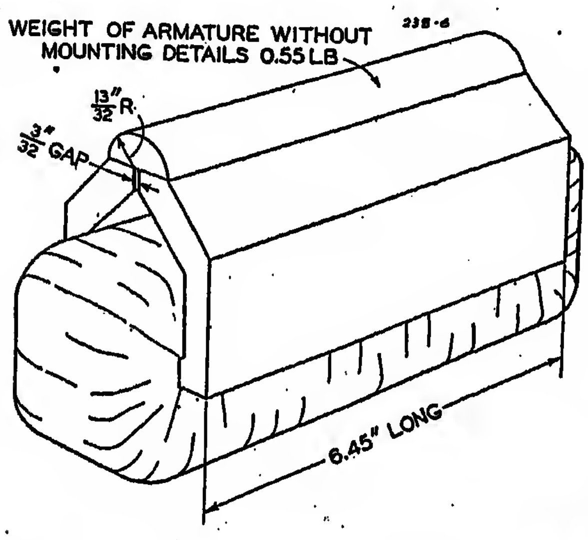

Figure 6. Elongated design of holding magnet

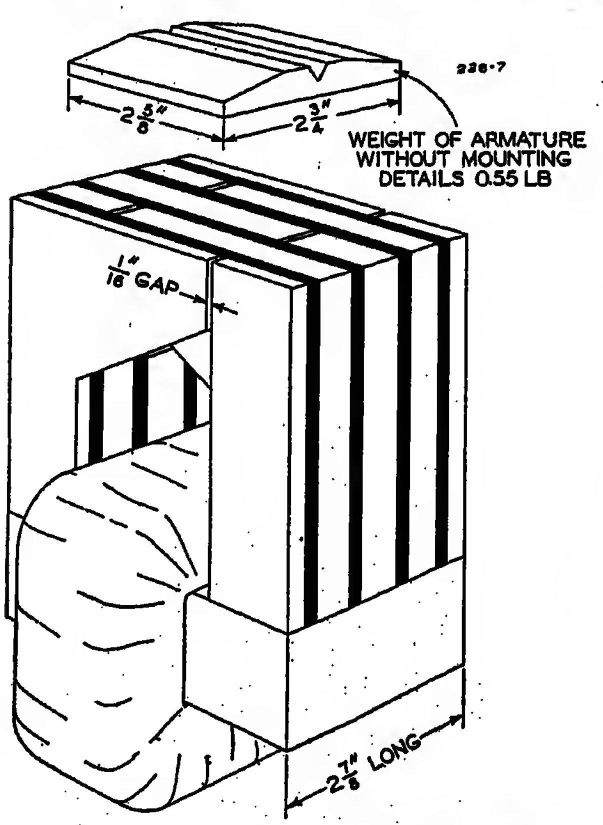

Figure 7. Design of holding magnet used in one-quarter-cycle breaker

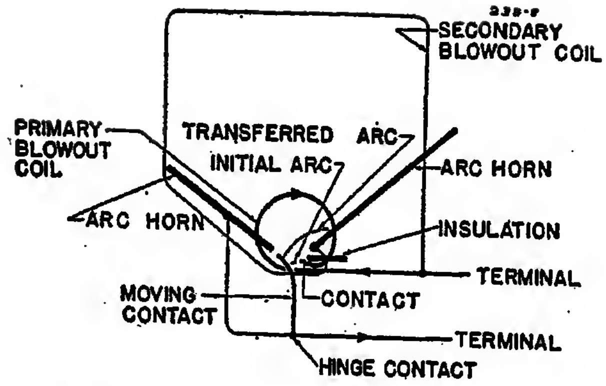

Figure 8. Schematic diagram of circuit-breaker magnetic-blowout structure

Figure 7 shows the design employed in the breaker under discussion. It carries out the same general principle of weight reduction as does the design in Figure 6, but provides a suitable armature and magnet design from a practical and mechanical standpoint. The armature weight is 0.55 pound, the armature pull being 400 pounds.

Actually, the weight ratios between the magnets shown in Figures 5 and 7 are even more favorable to the new design,

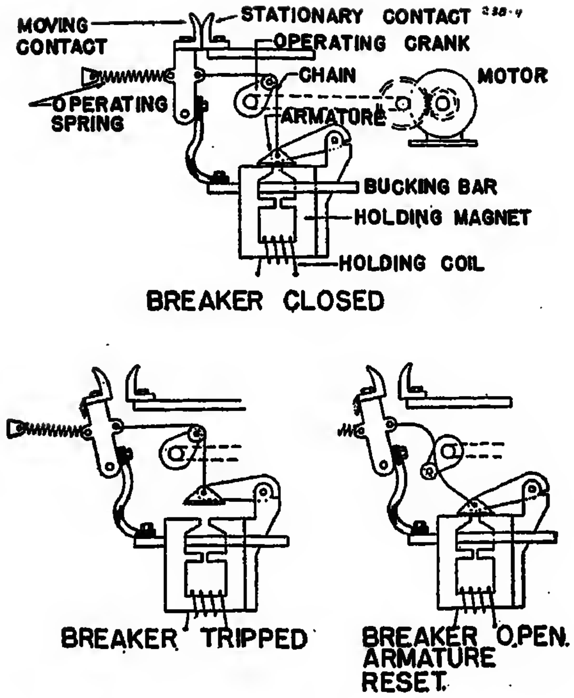

Figure 9 (above). Mechanical operation of one-quarter-cycle breaker

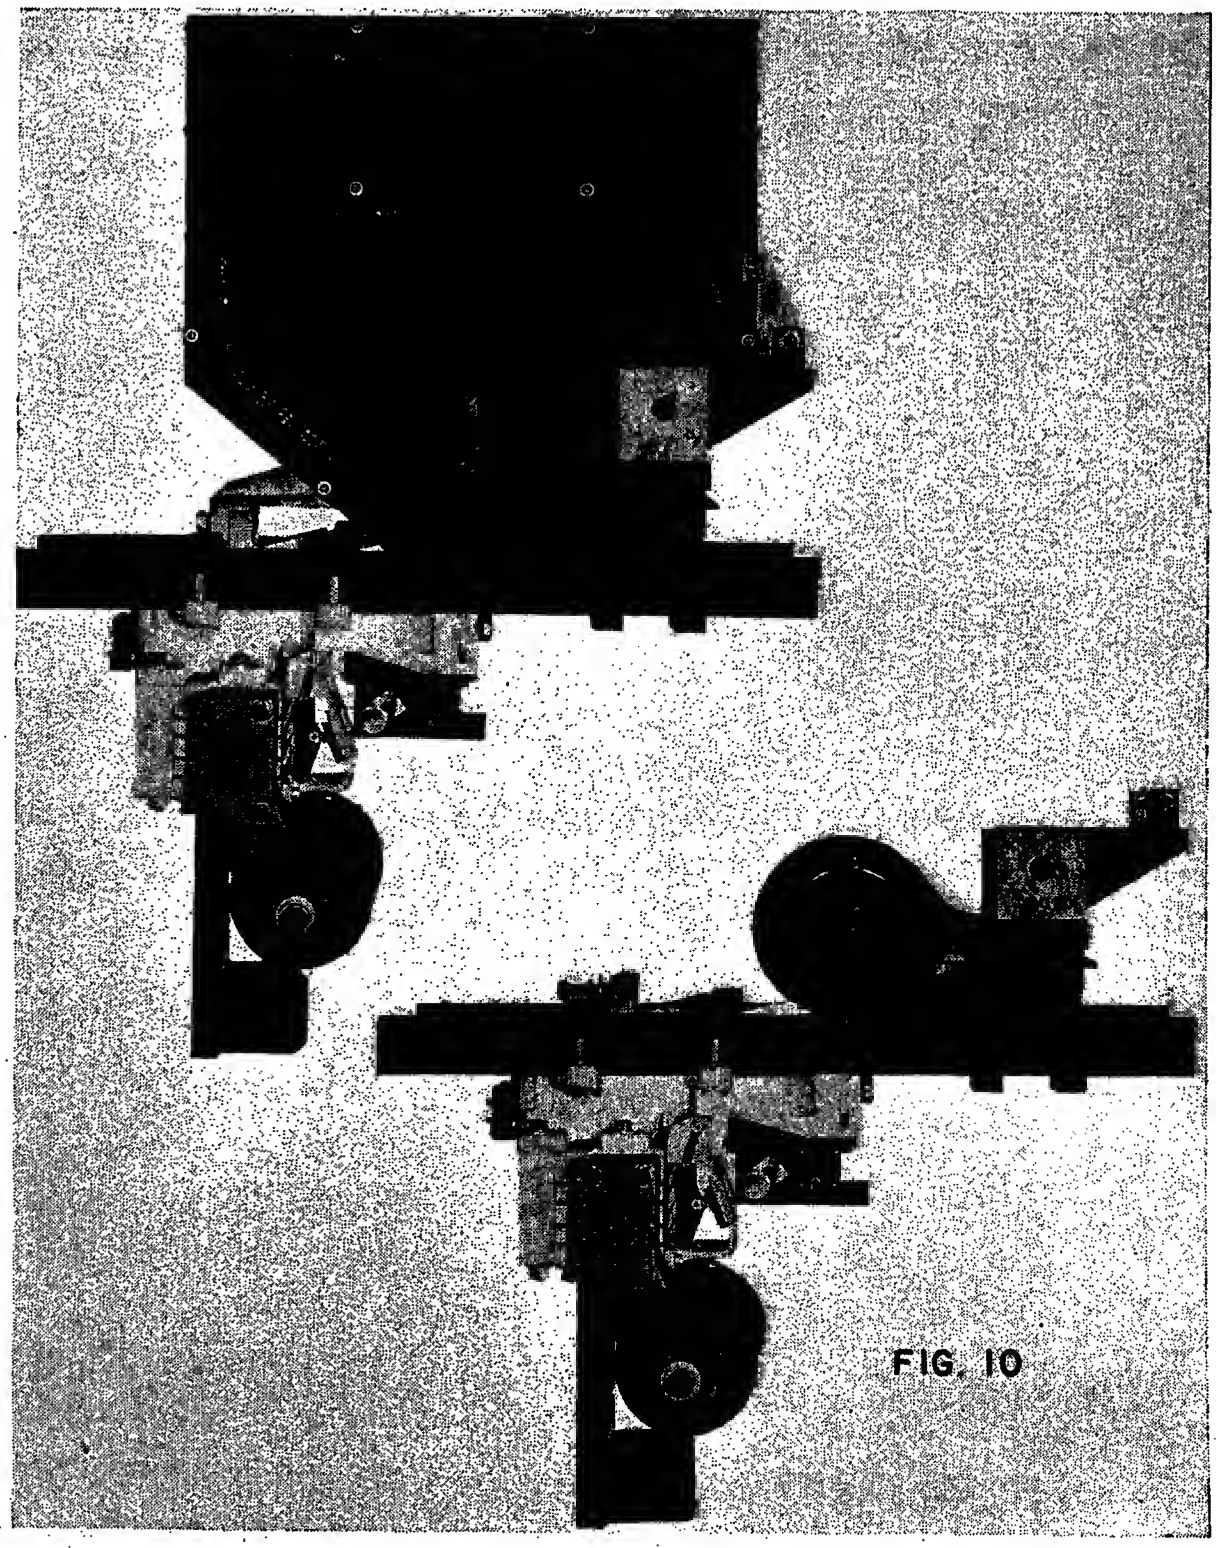
Figure 10 (below). Typical one-quarter-cycle breaker



as the magnet in Figure 5 must have a laminated armature which with suitable mounting details would increase the total armature weight. Combined with the reduction in armature weight, every effort was made to similarly reduce the weights of other moving members. The operating arm consists of furnace-brazed high strength aluminum alloy tubes carrying the 1,600-ampere contact finger assembly. The latter consists of four one-half-inch-wide fingers with nickel silver movable and stationary contacts and one Elkonite-faced arcing tip, which opens slightly later, after the main fingers part.

Initial experiments were conducted with this mechanism, using the blowout structure employed with the previously mentioned latched-in anode breaker. This blowout structure, employed very satisfactorily with the latched-in anode breaker, proved unsatisfactory on the faster breaker. The reason is that with the previous breaker the current reached a value under a certain set of test conditions of 30,000 or 35,000 amperes when arcing was initiated, whereas, with this higher-speed breaker, arcing was initiated at appreciably less than half this value. As a consequence, satisfactory speed of arc travel during the early formation of the arc was unsatisfactory, resulting in distress and delayed current limitation.

The final blowout design, which gave satisfactory performance, is shown in Figure 8. The same general principles,

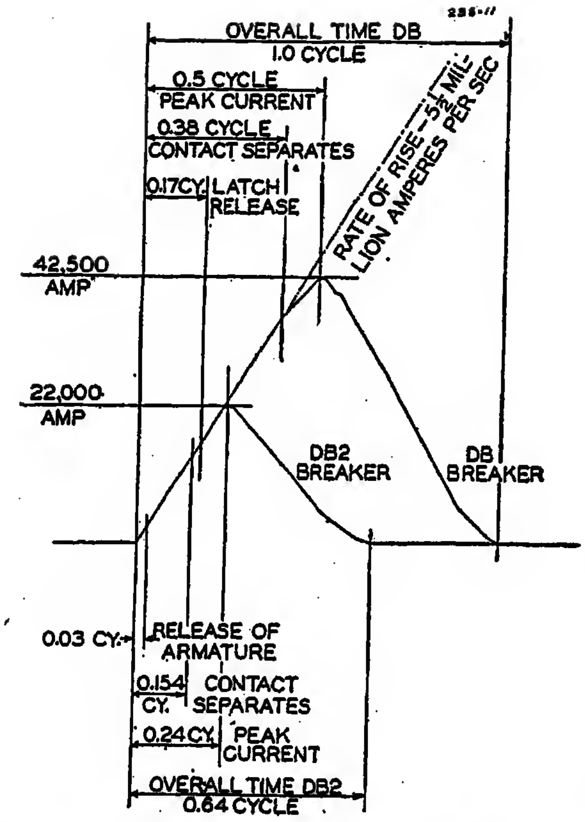


Figure 11. Composite current oscillogram comparing one-half-cycle and one-quarter-cycle anode circuit breakers

previously used, were maintained, but the primary blowout responsible for initial arc motion was strengthened, and the transfer to the secondary blowout was made much earlier.

The method of obtaining trip-free operation is shown in Figure 9. One compound wound motor is used to operate a six-pole unit, driving, through insulated shafts, the high-speed shafts of small speed reducers, one being mounted on each pole.

The low-speed shaft of each reducer carries a crank and roller over which a small steel chain rides. If the motor is run continuously and the armature is sealed against its magnet, the effect of the chain riding on this crank roller is to cause the breaker to go through an open-close cycle. A limit switch, controlling the motor with dynamic braking, insures this crank roller's stopping at the proper point.

Figure 10 shows a photograph of one complete single-breaker pole. For anode use, the holding-magnet shunt coils are energized at all times from the a-c auxiliary power for its rectifier through a small dry-type rectifier. The six holding coils of the six poles are connected in series, the breaker being tripped from the switchboard by means of the motor mechanism.

Figure 11 is a composite current oscillogram comparing the new breaker with its predecessor. The various time intervals are indicated for the two breakers. The information shown was taken from oscillograms made when testing the breakers by connecting them directly across the terminals of two 3,000-kw 600-volt 300-rpm compensated d-c generators in parallel, no reactance or resistance being in series with the breaker. The rate of rise is approximately the same as experienced in the rectifier station where the breakers are employed.

Recent Developments in Burying Telephone Cables

DONALD FISHER
ASSOCIATE AIEE

TEMPLE C. SMITH
NONMEMBER AIEE

THE term "buried cables" has come to mean those underground cables which have no conduit protection. Due to the accelerated demand for such construction in recent years, much effort has been expended in devising methods and developing machinery for burying cables. One of the earlier methods used in this and some foreign countries was to dig a trench by hand alongside the road; unreel the cable from a moving truck, thus laying it beside the trench; work the cable over into the trench by having 30 to 50 men handle it in relays; splice the cable in the trench, and finally backfill the spoil and tamp it by hand. Later variations of this method introduced one or more of the following units of machine equipment:

Power trenching machines.

Caterpillar tractors with trailers to straddle the trench, laying the cable directly from the reel into the trench.

Drag-line or other types of power backfillers.

Power tampers or rollers.

In order to further reduce the number of operations involved, speed up the installation, and reduce the cost, large plow trains have recently been developed which, except for splicing, in ordinary soil complete the job of burying a cable in one pass over the route. The idea of plowing cable into the ground is not new. In fact the great grandfather of all the cable plows was designed by Ezra Cornell long before he established the university. His "ponderous machine" drawn by a "long line of horses" was designed for laying telegraph cable in the early 1840's, but the development was dropped when the simple expedient of carrying wires on poles and insulators was conceived.

The large plow trains recently developed for installing telephone cable are capable of burying either a single cable or a pair of cables together with as many as three properly spaced lightning-protection wires, and of cutting a slot for them as much as 50 inches deep where such a depth is required. To provide the complete plow train has required the design of many pieces of equipment which the word "plow" does not suggest to one's mind. The plows and some of this equipment are discussed in the following paragraphs.

The Plow Train

Arrangement of the equipment in the train varies with the conditions. In Figure 1 two identical plows are included; the front one roots a trench $3^3/_4$ inches wide by 30 to 50 inches deep, thus insuring uninterrupted passage of the following plow which deposits two cables and the lightning shield wires, all properly spaced in the ground. This 100-ton train moves forward at the rate of a brisk walk, laying the cables and wires as it goes, with pauses for reel changes.

Where the ground is not hard and is free of rocks, and thus there is no danger of interruption to the plow from buried obstructions, the train make-up may omit the rooter plow, leaving three tractors, the cable plow, and the two trailers carrying reels of cable. On the other hand, it frequently happens that more difficult plowing conditions exist, or underground obstructions are known to be present, as, for example, with nests of heavy boulders (Figure 2). Here, two or three tractors and one plow will first go over the line one or more times to root the trench. As a separate operation, there will follow one or two tractors pulling a plow followed by a number of cable-reel trailers corresponding to the number of cables to be placed in the trench.

In rooting or plowing, occasionally the train may become stalled. The front tractor will then run ahead with its 76,000-pound single-line capacity winch and "winch out" the train with a two-to-one pull (Figure 3). One of the caterpillar tractors, weighing with full equipment more than 20 tons, has a maximum drawbar pull of 30,000 pounds on the level.

Burying Cable on Steep Grades

Unfortunately, when pulling up hills the available tractor drawbar pull decreases in proportion to the steepness of the grade, since a part of the power is consumed in raising the tractor weight. However, by careful handling of the equipment and generous use of the winch, cable can be plowed up or down hillsides even where the grades are as great as 60 per cent.

The preferred method of operation on mountainsides is to root down the grades, leaving a tractor on top to steady the heavy train with its winch line. In order to obviate any possibility of buried stones wedging at the side of the plowshare when placing the cable, the last pass of the plow doing the rooting work is in the same direction as the cable-laying plow will take. The trusty winch is also located on the hilltop when it is necessary to plow uphill. In contrast with the rooting operation, the cable must be laid uphill as well as downhill. This is because the reel lengths of cable normally used (1,500 to 3,000 feet) will span more than one hill, and it is undesirable to introduce any more splices than necessary in the cable.

Paper 42-58, recommended by the AIEE committee on communication for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 25, 1941; made available for printing December 26, 1941.

A roadway for plow train was cut by bulldozer to permit passage through creek banks

Selecting and Preparing the Right of Way

Now that we have seen something of what the plow train is like and how it can winch itself out of difficult situations, let us go back in the sequence of the operations and see how the route for the buried cable is selected, surveyed and explored so that the work of preparing the right of way can be started.

When it has been determined that a buried cable will be required between two points, possible routes are explored to establish the best location, such factors being kept in mind as accessibility, estimated cost of the construction, nature of the terrain, plant of other utilities, cost of right of way, future developments, and so on. In rugged country, this initial survey of the route may be made with the assistance of aerial photography. The airplane survey pictures are carefully studied through special lenses which give a three-dimensional effect in viewing them, and remarkable detail is afforded by the present-day photographic and viewing equipment (Figure 4). The relative heights of trees and buildings stand out with all the clarity of the old-time stereoscope. Since private right of way is generally followed, the use of this ideal method of route selection is often found to be worthwhile.

The tentative route laid out on maps or on the aerial-survey picture is now explored on the ground by engineers. As has been mentioned, the route ordinarily goes across fields, woodlands, mountains, and streams, but always consideration is given to accessibility from the highways and to the other factors which have been discussed. This is important both from the viewpoint of the ease of installing the

Figure 13. Relay winch

This winch pulls tongue end of rear trailer into special keeper which acts as a coupling. Paying out this rope permits rear trailer to lay behind the train

cable and that of maintaining it in the future.

Information regarding soil conditions and underground obstructions is very valuable in planning the route. Sometimes oil- and gas-pipe lines are encountered. The plow is sufficiently rugged, and the tractors have ample power to snap a good sized underground pipe in two. This method of striking oil is not to be recommended.

By the use of suitable apparatus, underground pipes can be readily located without excavating. There is commercially available a radio-tube type of underground-pipe locator which indicates the route but not the depth of the buried pipe. To determine its exact location, another electrical detector, developed by the Bell Telephone Laboratories, can be used. This device is so accurate that an underground pipe or cable can be located within less than an inch both laterally and in depth below the surface.

Through use of the information accumulated by the methods mentioned, the line of the proposed buried cable can now be staked out ready for the work crews. Buried boulders, ditches, and other obstacles interfere with the cable-plowing operation. Whatever preparatory work can be done to anticipate delays to the rooting and cable-plowing crews helps to "keep the train moving." At sharp ravines, road ditches, or creeks, the crossings become quite simple if a bulldozer on the front of a tractor (Figure 5) has first cut a roadway through the banks. Creek and river banks particularly require this treatment (Figure 6). It might be noted in passing that at such locations, if there is any danger of the cable being disturbed later by road-construction work or earth washing, the cable is plowed in at full 50-inch depth to afford maximum protection. The sides of steep road ditches are sloped off, not only to facilitate pulling the train across, but also to minimize the tilting of the plow, with the resulting tendency to raise the bottom of the share, thus laying the cable too shallow (Figure 7).

The plow operates satisfactorily across gravel and macadam roads as well as those which are not surfaced. Of course, the roads and ditch banks are restored to their former condition.

Experience indicates that it is not safe to operate along hillsides where the grades are more than about 10 per cent. In attempting to pull around the side of the hill, there is always a tendency for the train to work down grade. For such conditions, the bulldozer is used to good effect cutting out a level roadway.

Of course, in wooded country, a roadway must be prepared for moving the cable reels and equipment along the right of way as well as for clearing a place to plow.

On private right of way an easement on a strip of ground about one rod wide is ordinarily secured, anticipating the possible future need of a second buried cable. A passageway at least 10 feet wide is cleared, and at reel-change points additional width is required to maneuver the equipment. The 10-foot width will permit passage of the train in rooting and plowing. However, unless the cost of clearing an extra 3 feet of right of way is excessive, it is very desirable to have a 13-foot passageway so that the $8^1/_2$-foot-wide tractor can be used for tamping, as will be discussed later. Where practicable, the trees within the proposed passageway are pulled out by the roots in order to eliminate the interference with plowing which the roots would cause.

Crossing Swamps and Streams

Swamps and very soft ground present a difficult problem. For such work the tractor-caterpillar tracks are supplemented with "swamp grousers" (Figure 8), constructed of overhanging, bolted-on oak cleats. The plow tongue is supported by a special steel skid (Figure 9) $3^1/_2$ feet wide and 11 feet long. To provide increased bearing surface for carrying the load of the plow, skids may be added under the 12.75- by 24-inch pneumatic tires. These are in addition to the mud-bearing plates under the plow frame. The cable-reel trailers carry large mud-bearing plates under their frames.

By such expedients as these, the unit bearing pressure on the mud is so reduced for each member of the train that it can be slid over the soft surface placing at the same time the buried cables and wires at the proper distances beneath the surface (Figure 10).

The technique followed in crossing streams is similar in some respects to that used in negotiating marshy ground (Figure 11). If the water is deep, the tractor may find it necessary to detour to shallower water or by the nearest bridge, and it may be found desirable to root across before laying the cable under the stream, whereas, in the soft marsh the rooting may not be necessary.

Important Features in Operation of Plow Train

The caterpillar tractor placed next to the plow in the train is equipped with a four-drum winch (Figure 12) with independent lever controls conveniently located for the tractor driver so that he can exert a pull up to about 6,000 pounds in

Figure 14 (left). Yoke of winch loading trailer lifting a reel of cable

Yoke is pulled up by winch rope from one drum of multi-drum tractor winch. Spindle has one foot to go before latches will catch it

Figure 15 (above). Cables emerging from plowshare

In starting a job cable ends are pulled through share and staked before plow moves ahead

any one or more of the four winch ropes.

Two of the ropes are used to raise and lower the plowshare, thus adjusting the cable depth. The third rope feeds to a new-type "relay winch" (Figure 13) mounted in the front trailer. On dual-cable jobs this winch pulls the rear trailer up to its coupling under the axle of the front trailer in the operation of changing reels.

The fourth rope from the multidrum winch leads to the arm of the reel-lifting yoke on either trailer as shown in Figure 14. Pulling the yoke forward raises the (possibly 10,000-pound) loaded cable reel into position where the reel spindle is locked in the traveling position. Reversing the operations and slowly paying out the winch line lowers the empty reel from the trailer.

Feeding Cables and Wires Into Plow

In starting a dual-cable job the plowshare is raised to the top position and the cable ends fed in until they emerge from the exit opening (Figure 15). The cable ends are secured against movement along the ground, the share is gradually lowered to depth in the first few feet of travel, and the plow train is moved forward, thus laying the two cables at the desired depth until the reels are empty. After the empty reels are exchanged for full ones, the new cable ends must be fed through the plowshare. This is done by connecting each new length of cable to the one which has just been placed by overlapping the ends and binding them together (Figure 16). As the plow train now starts on the next installation, the spliced ends are guided into the share by two men riding on a platform carried on the front trailer tongue, and a cycle of operations has been completed.

Where lightning-shield wires are required, the reels of wire are carried on the front trailer or on the plow tower as in

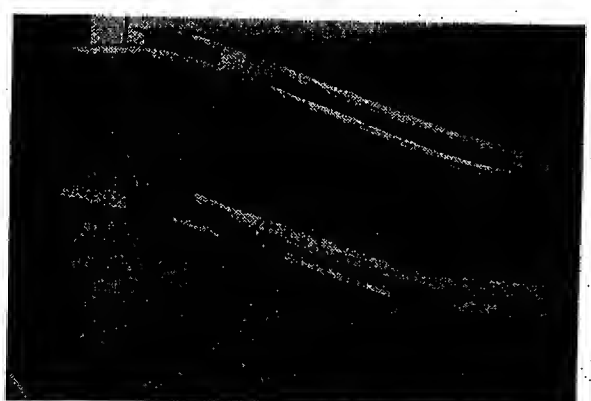

Figure 16. Cable ends clamped ready to enter plow

Each succeeding cable end is clamped to end of cable ahead, in order to pull it into plowshare

Figure 17. Changing reels on front trailer

Train must be broken in order to get new full reel to the front trailer

Figure 7, and they are fed through special ducts in the share from which they are emitted at the desired locations in the ground.

Changing Reels

Changing the reels as mentioned above is necessary for every cable length. Where one cable is being laid, this is a simple matter, but, where two reels are involved, the changing of the front one presents some difficulties, as can be visualized by referring to Figure 3. The rear trailer completely blocks the operation. In order to leave space between the two trailers, thus permitting the front one to be loaded, the rear trailer is dropped from the train as it moves along, about 50 feet before the cable end leaves the rear reel. This is accomplished by releasing the relay winch, thus disconnecting the rear trailer from the train, just as the engineer of a switching locomotive might drop a car from his train. The front trailer is now accessible from the rear so that the reel can be lowered from it (Figure 17). A tractor with a third trailer now moves a full reel to the front trailer and it is loaded. The relay winch comes into action at this point to pull the rear trailer up to its working position where it is automatically coupled in the train, after which it receives a new full reel of cable.

Lubricating the Cable

The buried cables ordinarily used, range in size from 1 to $2^{1}/_{2}$ inches outside diameter. However, cables as large as 3.2 inches in diameter may be used by employing a wider share which the plow is designed to accommodate. Usually they are covered with an asphalt-impregnated jute wrapping under which, in gopher-infested territories, there will be steel gopher tape surrounding the conventional lead sheath. In some cases a thermoplastic rubber and burlap covering is used instead of jute.

The asphalt-impregnated coverings develop high coefficients of friction against the steel walls of the rectangular tube through which they pass while in the plowshare. This results in tensions as high as 5,000 pounds in the cable, which is objectionable for electrical as well as mechanical reasons. The tension is reduced to a safe maximum of less than 1,000 pounds by directing a steady oil spray on the cable as it enters the share. This is accomplished by an adaptation of a paint spray gun using compressed air or nitrogen supplied from a cylinder carried on the plow.

Safety Shear Pin

With the powerful tractors pulling in series formation, what happens if the extremely rugged plow hits, let us say, a buried ledge of solid rock? The plow is an integral part of the very heavy briskly moving rooter train with its combined tractor drawbar pull of 200 or 300 horsepower. Under such a condition a safety shear pin of 72,000-pound strength, in the plow tongue, releases the load.

Backfilling and Tamping

In plowing, some soils may be considerably disturbed by the passage of the $3^{3}/_{4}$-inch-wide share with the extra ducts, familiarly known as "blisters," on the sides to carry the lightning shield wires. As the rear trailer passes over the trench, it drags a V-shaped device which mounds the loose earth over the trench (Figure

Figure 18. Backfiller

A V-shaped device under rear trailer mounds up disturbed earth over trench in which cable has been deposited

Figure 19. Where buried-cable right of way crosses the high Sierras

In this solid granite, a shallow narrow trench will be prepared by chain blasting

18). Then a good job of tamping is done by running a caterpillar-tractor track along the mound. This is done by the tractor which is used for handling reels.

Signals

The clatter of the Diesel engines makes vocal signals on the job unreliable. A tractor exhaust whistle or an electric horn is connected to a long control rope extending back along the train and so located that it can be reached from convenient points at either side of the train to give signals.

Performance of Cable-Burying Gangs

Under ordinary conditions it is possible to place about 17 trench miles of cable per five-day week with this equipment. This would mean that a foreman with his crew of about eight men, on a dual-cable job, might, in a week, bury 34 miles of cable together with whatever lightning-shield wires are required.

Conditions vary widely from the prairies with their black loam and clay to the steep mountains, or the soft marshes, or to soil sown thick with boulder. The mileage of cable buried daily naturally will correspond to the conditions encountered.

Burying Cable by Other Than Plow Methods

Because of its speed and economy the plow train is used wherever practicable for burying cables. In extremely rough mountainous territory some right of way may be too steep or rocky or too inaccessible, but it is surprising how small relatively is the footage even here which cannot be economically plowed.

For instance, a location on the proposed transcontinental cable line, where there has been some question whether the plow could be used, is in the ten miles of hard salt right of way along the highway adjoining and parallel to the Bonneville automobile-racing flats in Utah. However, in exploratory trials at this location, the plow rooted through the hard salt beds very satisfactorily.

There are some locations in the high Sierras where a relatively small portion of the proposed Sacramento-Reno section of the transcontinental cable run must cross areas of practically solid granite (Figure 19). Here the engineers plan to prepare by chain-blasting a narrow shallow trench in which the cables will be laid and the trench filled with an asphaltic material which will hold its position, keep water out of the trench, and protect the cable.

In a paper such as this, only the major operations and the principal items of equipment can be mentioned. Many others have had to be developed in order to make the use of buried cable broadly applicable. There are the jobs of passing under concrete arterial highways where the pavement cannot be disturbed and the soil may be either earth or rock. There is the matter of finding a way to cross under rivers too swift and full of boulders for submarine cable, having solid granite beds which, of course, cannot be plowed. There is the matter of avoiding buried pipes and other obstructions. These are no small matters. On one 83-mile run there were 91 crossings of oil-pipe lines at the time of the survey. Before the work was done, in a few months, four new pipe lines had been gained and three old ones lost.

All these and many other operations must be planned and executed in an extensive program of burying telephone cables, such as is now being carried on by the Bell system.

A New Instrument for Recording Transient Phenomena

S. J. BEGUN
NONMEMBER AIEE

Synopsis: In many cases it is of great importance to study phenomena which do not occur periodically. Such phenomena, called transients, arise, for example, at the time a short circuit appears in a power line, during the discharge of the condenser of a spot-welding machine, during the starting of electric machinery, and on very many other occasions.

Most of the instruments available thus far for investigation of transients employ the method of film recording, which has the disadvantage of requiring a developing process.

A new transient recorder has been developed, employing magnetic-tape recording as a means of preserving the record of a transient and steadily repeating this record on the screen of an oscilloscope. This method has the advantage that it requires no processing and that the same magnetic carrier can be used continuously without loss of material.

THE investigation of transient phenomena has always been of great interest to physicists and engineers. The observing of transient phenomena presents a major problem, mainly when the time the transient occurs cannot be anticipated, and where the duration of the transient is so short that visual inspection of it is impossible.

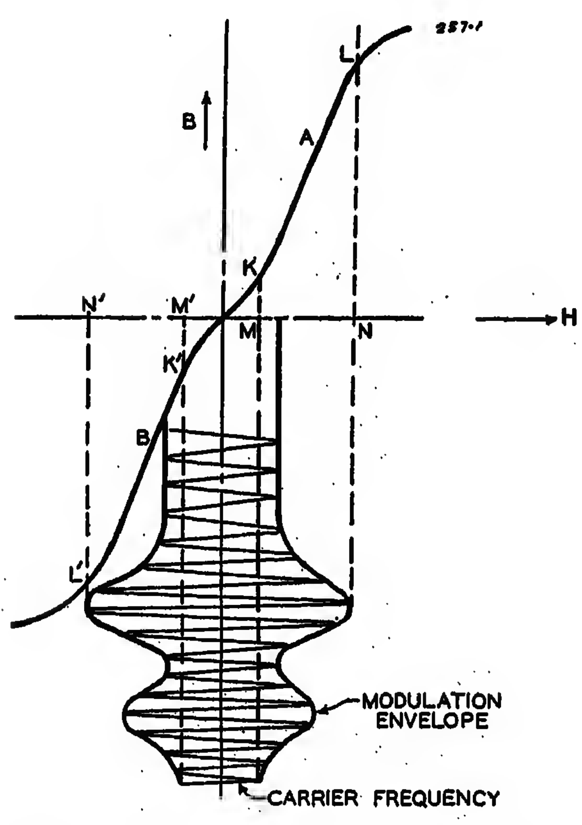

Figure 1. The modulated carrier acting on the magnetization curves of magnetic-recording medium

In most methods known heretofore, recording of the transient phenomena is employed. Usually a permanent record of all occurrences, including the transient under investigation, is made, and the interesting part of the recording is analyzed. Where transient phenomena occur rarely, it seems obviously a waste of material to record continuously the steady-state conditions, only for the benefit of an occasional transient. To meet this difficulty instruments have been developed which will start recording only when the transient occurs. Such instruments require very specialized equipment, particularly since it is usually of great importance to obtain a picture of the complete transient instead of merely one part of it.

Film recording is used in most cases. Mechanical recording, as employed in high speed level—or pen recorders, has not found any wide application, mainly because of the limited frequency range due to the mechanical parts involved.

Different film-recording instruments have been successfully marketed and are now being used in field and laboratory work. The use of film has the great disadvantage that it requires a developing process, and in many cases this requirement makes such an instrument impractical.

These and other difficulties have been overcome by a new transient recording apparatus to be described. This new instrument uses magnetic recording. The principle of magnetic recording and reproduction has been widely discussed in technical literature.[1] The method as used in this instrument, however, involves some novel features which are of interest.

In the magnetic-recording process, small electromagnets known as magnetic heads are subjected to the signal current and produce a magnetic pattern on the recording medium moving between their pole pieces. This magnetic pattern varies in intensity from point to point on the medium, and this variation of the magnetic intensity corresponds to the signal being recorded.

In the reproduction process, this varying magnetic pattern moves past the pole pieces and induces in the pole-piece coils a voltage correlated to the originally recorded signal.

To obliterate the recorded signal it is only necessary to remove the varying magnetic pattern and establish a uniform magnetic state. This is usually accomplished by saturating the magnetic carrier. An alternative way of obliterating is to demagnetize and return the magnetic carrier to its virgin unmagnetized state.

There is, however, one difficulty inherent in the magnetic recording system: it is not possible to reproduce very low frequencies, since the voltage generated in the reproducing head is a function of frequency and becomes small indeed for very low frequencies. On the other hand, transient phenomena often require the recording of not only very low frequencies, but even direct current. Therefore, transient signals in many cases cannot be used directly to actuate the recording head, since it is difficult, if not impossible, in reproducing such recordings to compensate sufficiently for the fall-off at these low frequencies. This difficulty has been overcome by utilizing a carrier frequency which is modulated by the signal to be recorded.

In conjunction with this carrier-recording system, it has been found preferable to obliterate the record by returning the tape to an unmagnetized state. This gives two advantages:

1. It makes unnecessary the use of a d-c polarizing current which normally must be superimposed on the signal to be recorded when obliteration has been obtained by magnetic saturation. This polarizing current, on breaking, would set up its own transient which is unrelated to the investigated transient.

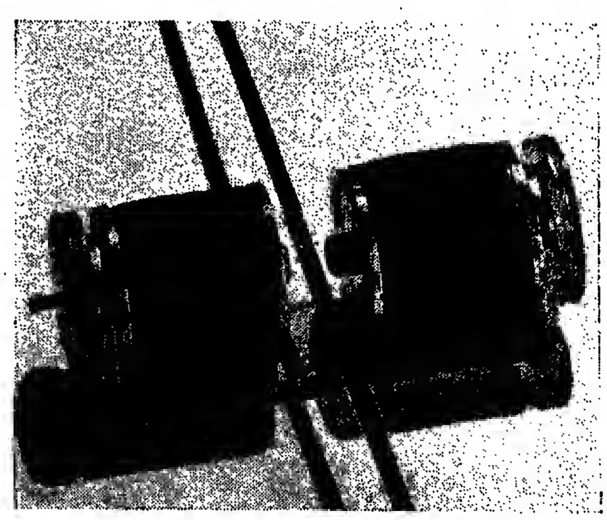

Figure 2. View of obliterating head

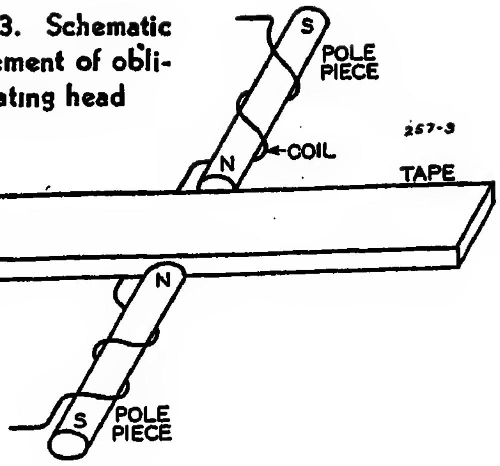
Paper 42-57, recommended by the AIEE committees on instruments and measurements and communication for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted November 12, 1941; made available for printing December 22, 1941.

S. J. Begun is with the engineering department of the Brush Development Company, Cleveland, Ohio.

Figure 3. Schematic arrangement of obliterating head



2. When used in conjunction with the carrier system, this obliteration method produces a higher signal-to-noise ratio.

The carrier-recording process may now be analyzed by reference to the two branches A and B of the magnetization curve as shown in Figure 1. These magnetization curves are relatively linear between points K and L and points K^1 and L^1. The unmodulated carrier current is so adjusted that the extreme values of the envelope produced by the modulating signal lie within this linear portion. One half of the modulated carrier acts on magnetization curve A and the other on curve B. The nonlinearity of the magnetization curve near the origin is of little effect since not more than 70 per cent modulation is used. Therefore, the peak values of magnetic induction recorded on the passing medium will be linearly proportional to the peak values of the carrier frequency, thus producing a magnetic facsimile of the envelope.

To obtain a proper reproduction, the reproducing head must be able to take care of the frequency range which is determined by the carrier frequency and the side bands. This, however, can be done without any great difficulty.

The present instrument uses a thin magnetic steel tape as recording medium.

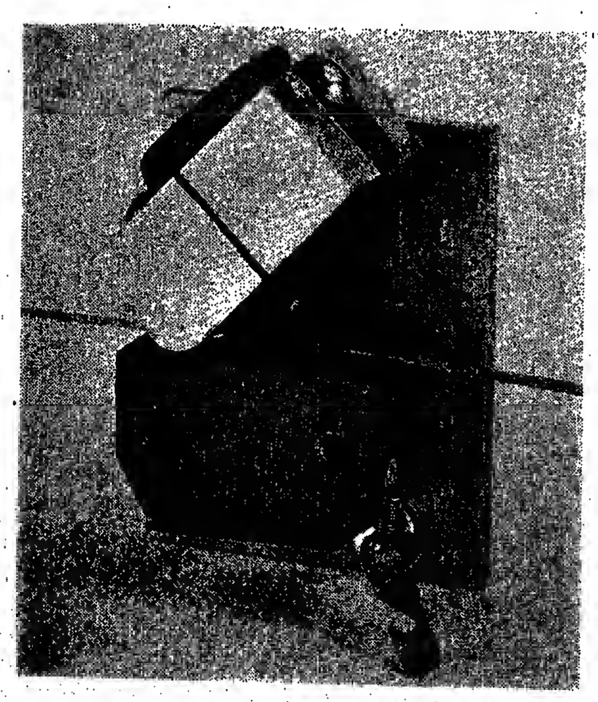


Figure 4. View of recording-reproducing head

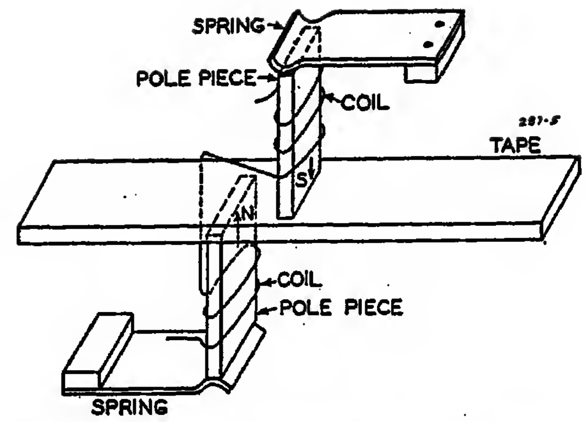

Figure 5. Schematic arrangement of recording-reproducing head

The obliterating is done by a head of novel design. This head consists of two electromagnets oppositely mounted across the width of the tape and polarized so that the opposing ends of the pole pieces have the same polarity, thus producing a diffused magnetic field. This diffused field allows the magnetic-field strength to decrease slowly and gradually as the tape passes by, and since a-c is supplied to the obliterating coil, the magnetic tape emerges completely demagnetized. The obliterating head is shown in Figure 2 photographically and in Figure 3 diagrammatically.

For recording and reproducing, a single standard magnetic head may be used. Such a head is shown photographically in Figure 4 and diagrammatically in Figure 5.

The magnetic-recording method makes it possible to automatically obliterate any previous record and to substitute a new one for it. This unique characteristic of magnetic recording permits continuous carrying on of the recording and obliterating process until a transient phenomenon occurs. As long as steady-state conditions prevail, the record made of them is continuously obliterated, since this can be done without loss of material. The new instrument makes use of an endless magnetic tape on which the signal is continuously recorded and after a short time interval again obliterated. The recording and obliterating process is stopped only when a record of a transient occurrence has been made on the moving tape. The obliterating and recording heads are placed close together in such a way that each portion of the moving tape passes at first through the obliterating head and shortly thereafter through the recording head. The time interval which is required for the tape to complete one cycle, namely to leave the recording head and reach the obliterating head is the available recording time, and this recording time has to be somewhat longer than the maximum duration of the transient to be investigated.

As soon as a transient occurs, a trigger system is actuated which automatically stops the recording process as soon as the tape completes the cycle, as has been just described. The time length of a cycle can be increased by increasing the length of the tape loop. The timing of the trigger circuit is adjustable, in order to conform with this increased time length. Such a trigger circuit is made an integral part of the instrument.

After the transient has thus been recorded on the tape, it will now be periodically reproduced, since the tape is endless. This regular repetition makes it possible to synchronize the horizontal sweep of an oscilloscope with the tape cycle, thus giving a steadily repeating picture on the screen of the oscilloscope, and facilitating observation of the transient.

Figure 6 shows a block diagram of the system. The signal to be investigated is applied to terminals a and b of the modulating circuit (1). The carrier frequency modulated by the signal is amplified by the amplifier (2) and passes then through a filter (3) and switch (4) to the recording head (5). The carrier frequency is generated by the oscillator (6) which also supplies through amplifier (7) an obliterating current for the obliterating head (8). The endless tape (9) moves over the two rollers (10) and (11) so that it passes first through the obliterating head (8) and then through the recording head (5). Any signal which is recorded by the

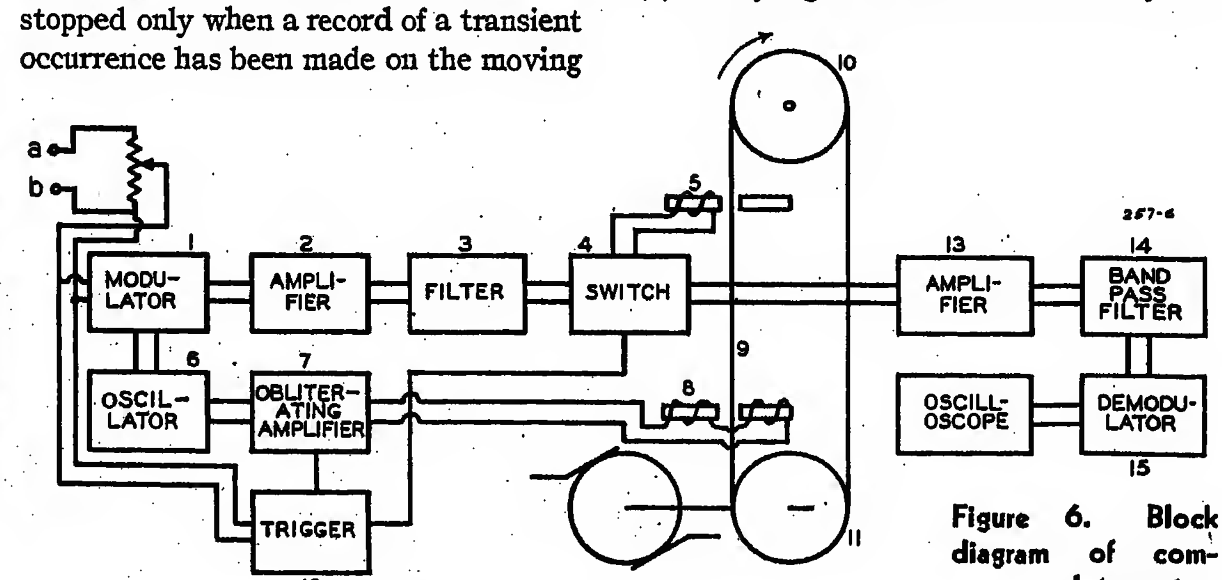

Figure 6. Block diagram of complete system

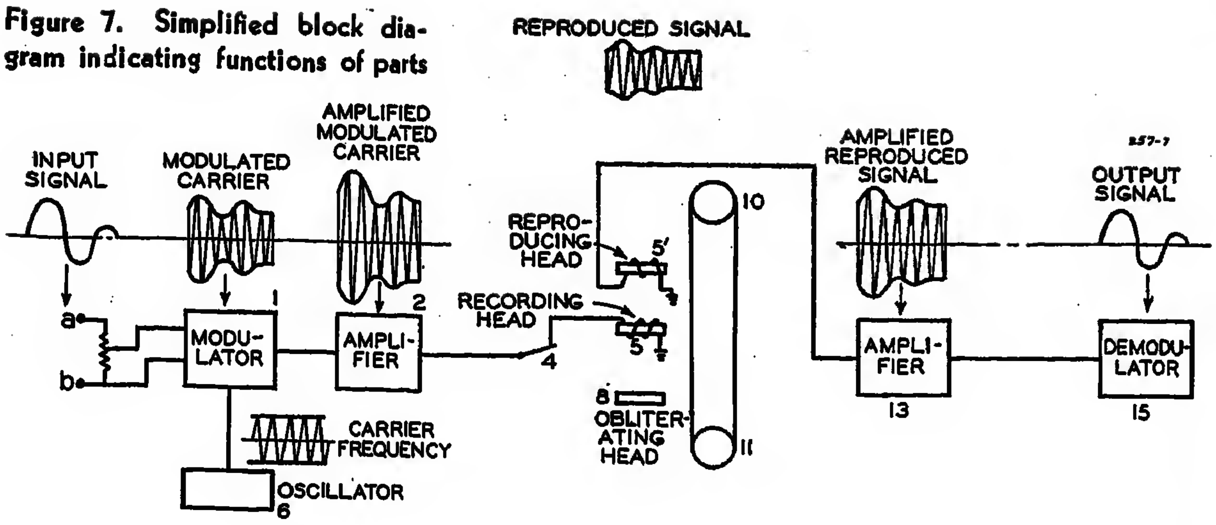
Figure 7. Simplified block diagram indicating functions of parts



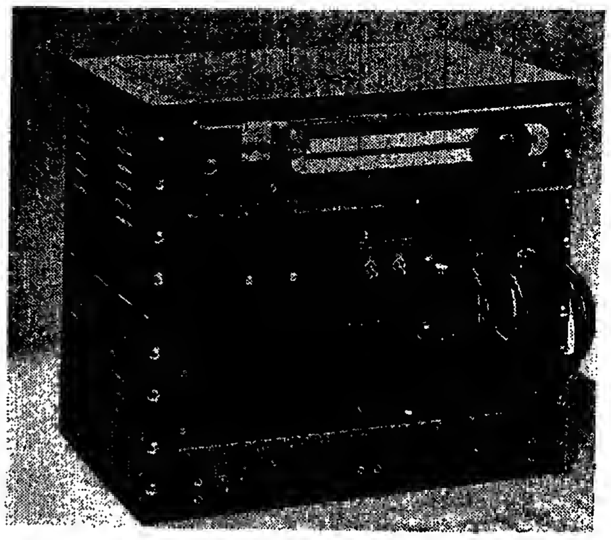


Figure 8. View of the instrument

recording head remains on a given portion of the tape until this portion reaches the obliterating head, which eliminates any previous signal from the tape and prepares it to accept a new recording. The transient signal is also supplied to a trigger circuit (12) which operates with a time delay. As soon as a transient occurs, the trigger circuit becomes energized, and after a short time interval, slightly shorter than one complete tape cycle, it blocks the obliterating amplifier. Simultaneously, the trigger circuit disconnects, by means of switch (4), the recording circuit from the recording head (5). The system is now ready for reproduction. The reproducing head, which is in this apparatus the same as the recording head, supplies the induced signal to the reproducing amplifier (13) which supplies the signal through a band pass filter (14) to a demodulator (15). The demodulated signal is now reproduced on the oscilloscope.

A simplified block diagram is shown in Figure 7 and illustrates graphically the electric functions of the essential parts of the system.

The different filters serve to eliminate spurious signals.

Great care has to be taken to eliminate phase distortion and amplitude distortion. For proper analysis of a transient phenomenon, the visual picture of the reproduced transient must be identical with the original. Because of this requirement, such an instrument is subject to much more severe restrictions than a sound-recording apparatus, where phase distortions are usually considered unimportant. By proper design of the filter circuit and the other circuit components, amplitude and phase distortion is reduced to an inconsequential minimum for a given frequency range.

The transient recorder in its practical form comprises two units as shown in Figure 8. Unit A contains the modulator, amplifier, and the trigger system. Unit *B* contains the drive mechanism for the tape loop, the magnetic heads (5) and (8), and the power supply. In the drive mechanism a synchronous motor propels by way of a belt the drive roller (11). A flywheel associated with the drive roller assures a uniform speed of the tape. The idler roller (10) can be moved in a slot (16) so as to tighten the tape and also make adjustment possible for tapes of different lengths. The recording-reproducing head may be opened for removal of the tape loops. If it is desirable to preserve an interesting transient on the steel tape, the tape may be removed and kept for any length of time with the signal recorded on it.

Unit *A* with the modulator, amplifier, and trigger has only electronic parts. To assure satisfactory operation independent of line-voltage fluctuation, the oscillator for supplying the carrier frequency and the obliterating signal has been stabilized with respect to frequency and amplitude. The carrier frequency which has been selected for this particular unit is 2,200 cycles. The band pass filters are so designed as to permit the transmission of the carrier frequency and side bands necessary to obtain the desired frequency range, namely 0 to 500 cycles, without phase and amplitude distortion.

The new transient recorder was originally developed to meet the difficulties in investigating transients occurring in the different welding processes, particularly in the condenser-discharge type of spot welding. The frequency range of the instrument has been chosen for this particular application, and the limit of 500 cycles takes care of the frequency components to be expected. The maximum recording time is about 0.2 second and the required input transient voltage is about 2 volts.

Much work has been done of late with such an instrument in the investigation of welding processes, and it has proven to be very valuable as a laboratory tool. Undoubtedly it will also prove useful for production processes. The instrument may be easily adapted to many other applications. Among these are transient occurrences in power lines, transient phenomena in loud speakers, illumination patterns of photo flash bulbs, shock-excited vibrations of mechanical parts. Many other applications will undoubtedly be found.

The instrument may be designed for different frequency ranges, depending upon the requirements, but still utilizing the same fundamental principle.

Lightning Investigation on 132-Kv Transmission System of the American Gas and Electric Company

Field Study of Natural Lightning Currents Measured in Towers, Line Wires, and Ground Wires; and Currents and Voltages at Stations

I. W. GROSS
MEMBER AIEE

G. D. LIPPERT
ASSOCIATE AIEE

I. Introduction

THE field study of the characteristics of natural lightning on transmission systems, started some 15 years ago, has been carried on with continued persistence by various investigators up to the present time. On the American Gas and Electric Company 132-kv interconnected system, investigation was started in 1927, and the results obtained have been reported in papers[1–9] before the Institute from time to time, the last appearing in 1937. This present paper presents largely the data obtained from the field work which we have carried on since that time on the above system in an attempt to learn more about the characteristics of natural lightning, particularly lightning currents and rates of voltage rise, as they affect transmission lines and equipment. It includes field data for the past four years, combined in some cases with previous field data in order to make the records complete and inclusive.

II. Purpose and Scope of Investigation

Without attempting to summarize the various phases of the lightning problem to which field research has been directed in past years, it is sufficient to state that the past four years' work in our system has been confined to furthering information along the following general lines of attack:

1. A study of the distribution of lightning currents in parts of the transmission system such as ground wires, line wires, towers, counterpoises, and ground rods.

2. The effect of different methods and technique in grounding, such as with counterpoises and ground rods.

3. Study of lightning voltage, magnitude and wave shapes appearing at stations, as an aid in co-ordination of station insulation and protection.

Incidental to the main purpose of the work outlined above, there are other aspects of the lightning problem on which information has been made available from the field data. These will also be presented and discussed as the data warrant.

III. General Plan of Test Procedure

The general plan of obtaining information outlined above was to install lightning-measuring instruments such as surge-crest ammeters, surge-voltage recorders, and wave-slope indicators on some lightning-infested parts of our 132-kv interconnected system. The lines on which the major part of the data presented and discussed here were obtained are the 132-kv lines of the Appalachian Electric Power Company (Glenlyn-Roanoke), the Indiana and Michigan Electric Company (South Bend-Michigan City), The Ohio Power Company (Philo-Canton), and the Atlantic City Electric Company (Deepwater-Pleasantville).

Instruments

The surge crest ammeter[10] using magnetic links was used to determine lightning currents. At stations the surge-voltage recorder[11] was used for determining lightning voltages and the wave-slope indicator rather extensively to determine the lightning-voltage rates of rise.

The wave-slope indicator is based on the following theory, using the well known elements of the electric circuit q, i, and e:

$$q = ec = \int i\,dt$$

$$c\,de = i\,dt \text{ and } de/dt = i/c$$

Maximum i thus gives maximum de/dt. A wiring diagram of the instrument as used in service is shown in Figure 1A; and field installations in Figures 1B and 1C.

A typical field setup of magnetic links to determine lightning currents at various points on the transmission system is

Paper 42-18, recommended by the AIEE committee on power transmission and distribution, for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 12, 1941; made available for printing December 5, 1941.

I. W. GROSS is electrical research engineer and G. D. LIPPERT is with the engineering department of American Gas and Electric Service Corporation, New York, N. Y.

The field investigation work on which this paper is based was undertaken and planned in co-operation with engineers of the General Electric Company, who furnished the instruments and aided in correlating the data. The authors acknowledge the assistance of the field organizations of the Appalachian Electric Power Company, The Ohio Power Company, Indiana and Michigan Electric Company, and Atlantic City Electric Company, in installing and servicing the instruments in the field.

shown in Figure 2. Therein is shown the approximate general location of instruments as used in the field. It is not to be interpreted that every tower under investigation had all instruments shown, but where used, they were located as indicated in the figure.

A concentration of instruments was made at several sections of the line where counterpoises (500 feet and continuous) were installed on the Glenlyn-Roanoke line, and also at some five substations to determine currents in line wires and ground wires, and the wave slope of incoming voltages to which equipment installed in the stations would be subjected.

The data given and discussed below have been obtained from field records as indicated in Table I. Therein it is shown that some 8,955 instrument years have been involved during the nine years in this investigation and have produced a total of 4,158 records. The distribution of these records among various parts of the tower structure, line wires, ground wires, counterpoises, and so forth, as well as maximum, minimum, and median values is clearly shown in the table.

Throughout the investigation, all instruments were serviced approximately once each two weeks to enable the best possible segregation of records without burdensome field servicing. In addition, instruments were frequently serviced after severe lightning storms which were known to have taken place in the general vicinity of the test stations.

IV. Lightning Records and Data

Current Magnitudes

Lightning-Stroke Current

A determination of current in the lightning stroke has been arrived at in four ways:

1. By multiplying the current measured in one leg of a tower, where only single-leg measurements were attempted, by four (these towers have four legs).

2. By adding the separate currents measured in all four legs of a tower.

3. By direct measurement of the current in a lightning rod placed at the top of the tower.

4. By adding the measured ground-wire currents flowing toward a stroke in midspan.

These data have been plotted in Figure 3 as a magnitude-frequency curve. The measured tower-leg values have been increased by 50 per cent to account for the unmeasured cross-brace current, a procedure previously justified.

Comparing these data with those previously published,[9] the range of indicated stroke currents is in substantial agreement. The maximum current here indicated is, however, 150,000 amperes by the single-leg-measurement method compared with the previously reported maximum of 220,000 amperes by the method of adding adjacent tower currents. Direct measurement of current in the lightning rod showed a maximum of 82,000 amperes and measurement in ground wires 110,000 amperes. As both of these methods of measurement resulted in partially saturated links at high currents, it is believed the maximum stroke current is slightly higher than the above 110,000 but not much in excess of 130,000 amperes, which in turn is only slightly higher than the current measured in a single tower.

It is rather interesting to note that the method of measuring currents in one tower leg and multiplying by four gives results quite comparable to the other methods except that it does show a slightly higher maximum current.

Ground-Wire Currents

Measurements of ground-wire currents were made in the line sections some distance out from the station, as well as at the first tower out from the station, and at the station itself. Some 700 separate current records were obtained on ground wires, 643 being of sufficient magnitude and certainty to warrant analysis.

Figure 4 shows the magnitude and frequency of these currents at the three locations (line, near station, and at station). In the line sections the maximum current was 70,000 amperes; at the first tower from a station, 36,000 amperes, and on the ground wire coming into the station, 12,000 amperes. Where measurements were made directly at the station, they were in all cases on one of three fanned-out ground wires extending from the station to the first tower, where single ground-wire construction over the line started.

That the single-ground-wire and three-ground-wire current curves (Figure 4) cross at approximately 7,500 amperes has no significance and is caused by the fact that the data do not attempt to indicate simultaneous current records on the ground wires, but rather the general magnitude and distribution which may be

II. Currents in one of three ground wires between station and first tower out—30 records

III. In single ground wire on the line side of the first tower from station—22 records

expected where this type of ground-wire construction is employed near a station.

Lightning Currents in Line Wires

The determination of currents in line wires was undertaken for two reasons:

1. In an attempt to correlate the lightning currents and surge impedance of the line with the lightning voltage expected with such currents.

2. To determine the magnitude of lightning currents which might enter a station from the line and would have to be handled by the protective devices.

Over 300 records in line conductors have been obtained, 154 measured at the station and 172 on line towers some distance away. The magnitude and frequency of these currents are shown in Figure 5. The maximum current out on the line is 29,000 amperes and at the station 11,500 amperes. Ten per cent of the measured currents are 6,500 amperes or less at the line towers and 3,000 or less at the station.

Table A

Instrument Location	Amperes: Maximum	Amperes: 10% of Values at or Above	Corresponding Kv of Line Wire: Maximum	Corresponding Kv of Line Wire: 10% of Values at or Above
On the line	29,000	6,500	11,600	2,400
At stations	11,500	3,000	6,600	1,200

If it is assumed that these measured lightning currents can be simply multiplied by the line-surge impedance (taken as 400 ohms), to obtain the conductor voltage, then the voltages of the line conductors would be as shown in Table A.

The line-current data, analyzed as above, give indicated conductor voltages which seem rather fantastic under the conditions of operation. The magnitude of currents in the line conductors at stations, however, correlates quite closely with the measured currents in lightning arresters as has been reported previously.[12]

Currents in Towers, Counterpoises and Ground Rods

Currents in counterpoises as measured at the point where they attach to tower legs were measured in five different types or lengths of counterpoises, namely, 40, 150, 250, 500 feet, and continuous. The continuous counterpoises were installed between towers where the tower spacing was approximately 1,500 feet or less. The counterpoise currents recorded on the above basis are shown graphically in Figure 6, from which it will be noted that the currents carried by the counterpoise increase with length, although not in direct proportion to the length. The most searching type of test would, of course, be one where all these counterpoises of various lengths were attached to the same tower and therefore affected by the same stroke current, but since a setup of this kind was not practical, the comparison of data has been made on actual measured currents. This method does not evaluate the variation of stroke current which initiates current in the counterpoise. However, since the data cover some eight years of field tests, the varying magnitude of stroke currents has probably been averaged out to some extent so that the data given indicate to a large degree the relative benefits of the counterpoise length.

Comparative data on a selected group of towers where 500-foot and continuous counterpoises were installed, and, in addition, tie connections between the four tower legs, are given in Figure 7. The tower currents have been obtained by four-leg readings increased by 50 per cent for the shunting effect of tower bracing, and show a maximum of 79,000 amperes. The 500-foot and continuous counterpoises show maximum currents

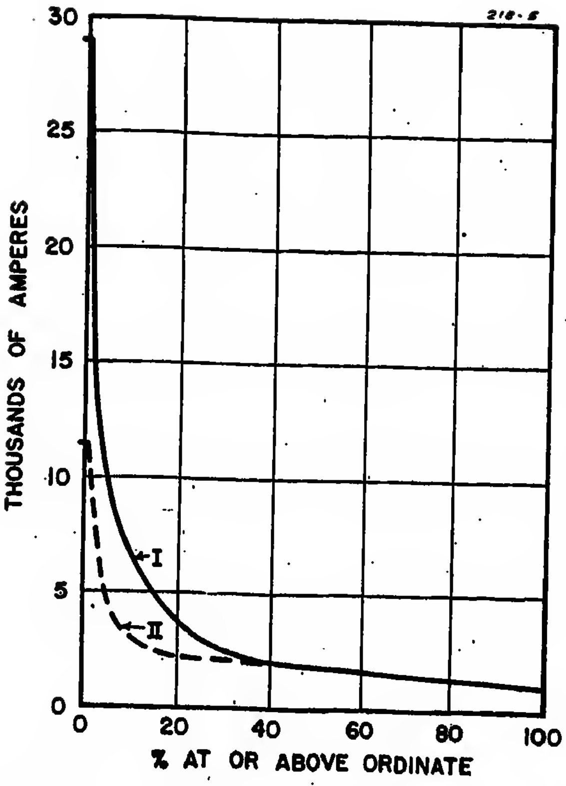

Figure 5. Lightning currents in conductors

I. Conductor currents at line towers—172 records
II. Conductor currents at station entrance—154 records

and frequency distribution of approximately the same magnitude. This would be expected if the continuous counterpoise can be considered as effective only for about half the span (or 400 to 750 feet). In fact, the agreement of curves III and IV seems to indicate that increasing the counterpoise much beyond 500 feet is not particularly effective.

One important feature brought out by these data is the records of currents obtained in the buried ground or counterpoise wire which ties the four tower legs together at the base of the tower. This connection consisted of a $^1/_{16}$-inch by 2-inch flat iron strap buried 18 inches in the ground and extending around the base of the tower, as shown in the sketch of Figure 2. The current carried by these tie connections is shown in curve V of Figure 7, a maximum of 10,200 amperes

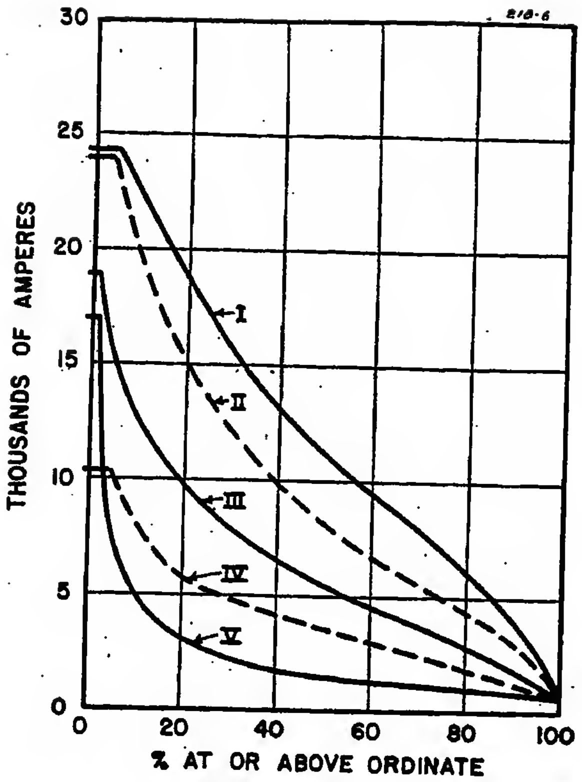

Figure 6. Lightning currents in counterpoises

being indicated. While it might seem, in tying a counterpoise direct to one leg of a conventional four-leg tower, that the tower cross bracing would be effective in quickly distributing the lightning currents to the other legs of the tower, such does not seem to be the case (see also Figure 11). It is strongly indicated that, where counterpoises are used, means should be taken to make direct underground connections to all tower legs to obtain the maximum benefits from an even, uniform, and quick distribution of current to the various tower structural members.

A comparison of tower and counterpoise currents with 40-foot and 150-foot counterpoises attached is shown in Figure 8. Here, the benefits of a number

V. In buried cross-tie connections between tower legs at towers—40 records

of short counterpoises are indicated as compared with using the same length of buried wire as a single counterpoise. Taking the median values in Figure 8, 80 feet of counterpoise in two short sections carry 5,000 amperes, and 300 feet of the 150-foot counterpoise in two sections, 17,000 amperes, or 3.8 times the length, carry 3.2 times the current. When comparing maximum currents, the results show still greater efficiency for the short counterpoise. Again comparing median values for the 40-foot counterpoise (Figure 8) with the 500-foot counterpoises of Figure 7, the ratio of increase in length is 5.9, and the ratio of currents 2, thus indicating considerably less effectiveness with the single long counterpoise. Although these records were not obtained at the same tower under the same lightning condition, the comparison of counterpoise efficiency given above seems justified, as the median tower currents of 30,000 for the short counterpoise and 22,000 for the long single one, and similar maximum currents are reasonably comparable.

Tower-Arm and Arm-Brace Currents

The question has been raised[13] regarding the magnitude of stray currents in the tower such as in braces, arms,

hanger bars, and so on. Some data on this question are given in Figure 9 where maximum currents in tower arms are shown as 26,000 amperes and the median currents in this structural member from 2,000 to 3,500 amperes. Detailed analysis of the records shows that most of these currents, except possibly the highest, are leg currents shunted by the bracing members.

Lightning Voltages at Stations

Magnitudes

In an attempt to correlate lightning effects at stations, surge recorders were located on the three phases at three 132-kv stations and recorded the station bus voltages to ground. Lightning currents on the lines and through station lightning arresters were also recorded. A summary of ten records correlating this information is given in Table II. It will be noted that the highest station voltage recorded was 525 kv, the lowest in this group 224 kv, and the average value 334 kv. At all of these stations, arresters having a gap breakdown and *IR* discharge at 3,000 amperes of approximately 388 kv and 346 kv were installed.

It will be noted that correlation between recorded bus voltage and arrester characteristics for the current measured is rather good, thus indicating, not only that the arresters are affording protection, but also that they are operating with their expected performance characteristics.

In this table are also shown the maximum recorded incoming lightning currents on the line wires. An attempt, however, to use line-surge impedance and current, say 3,000 amperes by 400 ohms, to determine the bus voltage indicates 1,200 kv which requires some further study or interpretation to properly correlate with other records.

Using the recorded bus voltage and line currents in an attempt to determine the line-surge impedance, an equivalent value is given in the seventh column of Table II, ranging from 112 to 236 ohms, with an average of approximately 150 ohms.

Rates of Voltage Rise

The wave-slope indicator used at 26 locations, and coupled to the 132-kv telephone and relay capacitors, in five different 132-kv stations yielded records of some 492 separate voltage occurrences from which the rate of rise of voltage at the station was determined. The data are summarized in Figure 10. The five separate curves shown are based on the rate of voltage rise determined by the individual calibration of magnetic links in the first five positions of the wave-slope indicator (see Figure 1).

After the first records were obtained from this test setup, it was believed that some of the results were affected by switching surges. A field check verified this point, and it should, therefore, be pointed out that links 1, 2, 3, and 4 are affected by switching surges so that the data presented from link readings 1 to 4 inclusive are a combination of characteristics of lightning and switching-surge voltages. The data from link 5, however, appear to be confined solely to lightning-voltage surges entering the station and, therefore, may be taken as indicative of lightning voltages only, coming in from the transmission lines.

It will be noted that the maximum rate of rise of pure lightning surges is 600 kv per microsecond, the minimum 60 kv per microsecond, and the median or 50 per cent value approximately 200 kv per microsecond. While these data in Figure 5 were obtained from only 45 records, it is believed they are the first of their kind giving any actually measured rates of lightning-voltage rise at the stations where protective devices are used extensively to protect the station equipment. It is worth-while in passing to note that the recorded rates of lightning-voltage rise are somewhat less than the generally accepted 1,000 kv per microsecond on which some present-day test work is often predicated.

The rates of voltage rise for switching surges are considerably lower than for

lightning voltages and show a maximum of 325 kv per microsecond, a minimum of 10 kv, and a median value of approximately 50 kv.

V. Discussion of Special Cases

Having obtained some 4,000 individual records of lightning currents and voltages, it has been impossible to present each one separately and discuss it. For this reason, most of the data already presented here have been in curve form, showing the magnitude and frequency of currents which, in many cases, of course, have not been simultaneously recorded with the other correlated data presented. It is, therefore, of interest to discuss a few special cases where readings were obtained simultaneously in various parts of the circuit considered.

Currents in Counterpoises, Ground Rods, and Tower Legs

In Table III are presented the simultaneous readings recorded in counterpoise, ground-rod, and single-tower leg. An attempt has been made to show the comparative value of these three elements in carrying lightning current. The resistances recorded were measured with the customary d-c ground-measuring instrument. (The tower-leg resistance was taken as four times the measured ground resistance of the four-leg tower.) If these three elements are equally effective in carrying current, there should be recorded in each a current in exact proportion to its conductivity. The last column of the table showing the ratio of current to conductance shows the deviation from this law. It will be noted that the counterpoise carries an average current 74.5 per cent of that expected, and deviations from this value in the four cases are not great. The ground rod is very much more erratic, carrying current ranging from 15.6 per cent to 180 per cent of the value based on conductivity alone. This, however, may be accounted for by the lower value being recorded in a 10-foot rod, and the higher value in a 60-foot rod where the earth was not so much affected by the presence of the counterpoise.

In the case of tower legs, omitting the two extreme values of 6.10 and 0.76, the general average is approximately 2.25 times that expected.

The general conclusion to be drawn from these data appears to be that the tower leg on account of the large extent of its exposure to ground is much more effective in carrying lightning current than either the ground rod or the counterpoise. Further, it appears that a counterpoise of 250-foot length, at least, does not carry current in proportion to its conductivity. This is completely in accord with past observations and theory, which indicate that when the counterpoise much exceeds 200 feet or so, its effectiveness does not increase anywhere near in direct proportion to length.

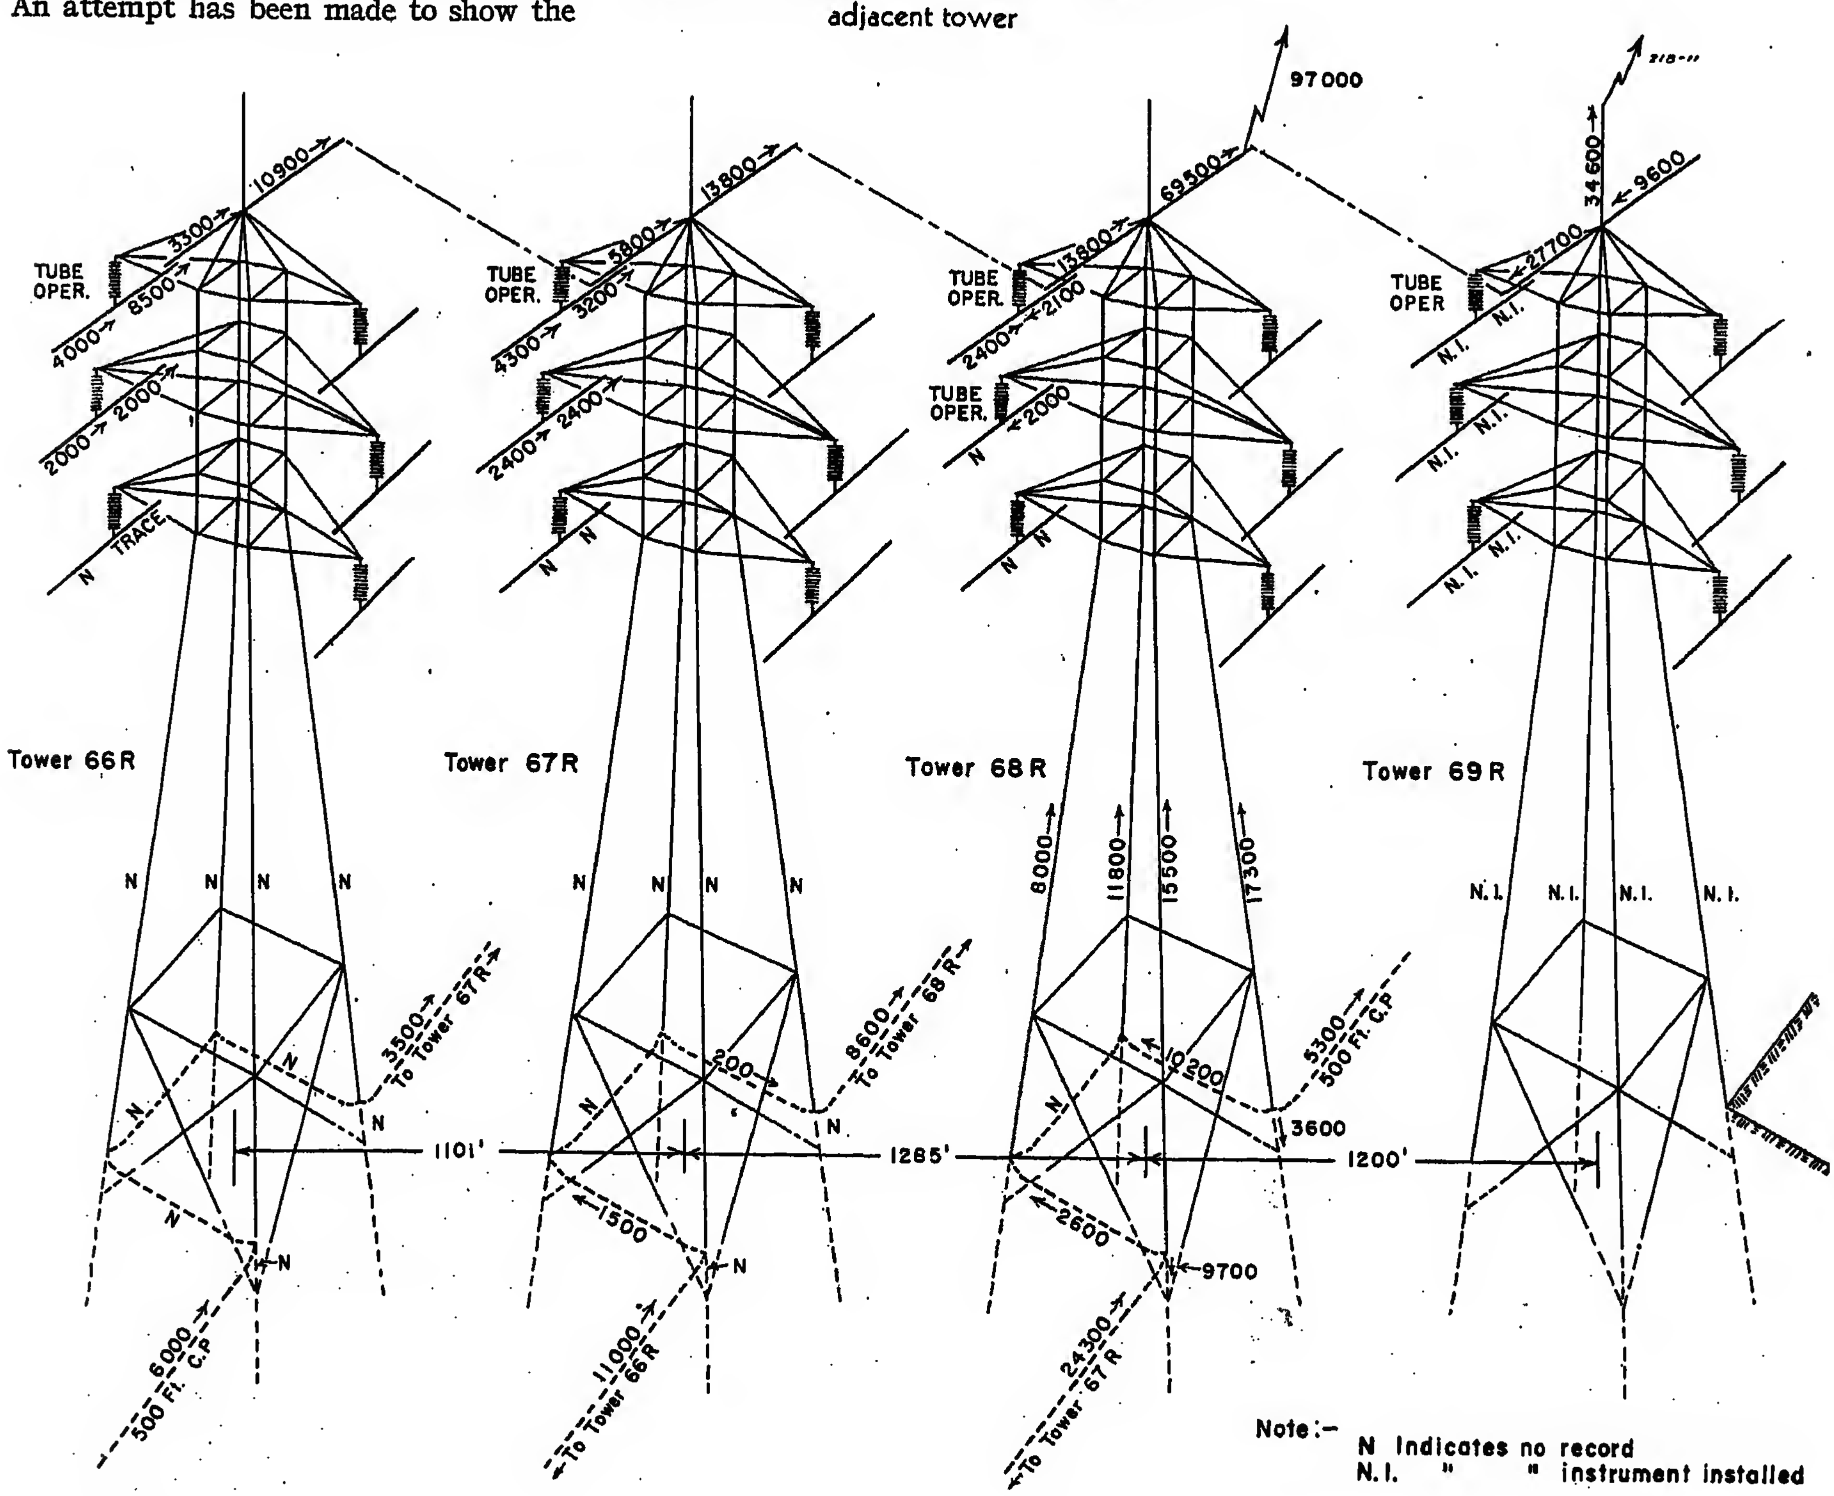

Figure 11. Typical record of lightning strokes to overhead ground wire on 132-kv Glenlyn–Roanoke line showing distribution of lightning currents in grounded structure, counterpoises, and in line conductors

Note that two strokes have occurred, one to the ground wire in mid-span, and one to an adjacent tower

Currents in Towers, Ground Wires, Line Wires, and Counterpoises

A typical case of a severe lightning stroke to the overhead ground wire between towers, and involving a stroke of smaller magnitude to an adjacent tower, is shown in Figure 11. The lightning-stroke current has been determined as 97,000 amperes from the sum of the two ground-wire currents. This is a particularly interesting stroke as it shows currents in the ground-wire on one side of the stroke of 69,500 amperes and on the other side of 27,700 amperes. Assuming that the smaller stroke to tower 69*R* occurred after that to 68*R*, the 69,500 amperes in the ground wire might be approximately half the total stroke current, indicated above as 97,000 amperes, or in other words, the stroke current might have been twice 69,500 or 139,000 amperes. The smaller ground-wire current of 27,700 amperes from tower 69*R* may be accounted for by the demagnetizing effect of ground-wire current flowing into the stroke at tower 69*R*. This sequence of events seems to be borne out by the reversal of current shown in the counterpoise.

Another interesting point shown by this record is the transfer of high current between buried counterpoises between tower legs. A current of 10,200 amperes is shown flowing from one counterpoise tower leg to one non-counterpoise leg. So far as currents in adjacent towers are concerned, these seem to indicate that, in this case at least, the stroke current was drawn through only the tower structures quite local to the point of the stroke.

This record also shows the current in the line wires of some 2,000 to 8,500 amperes. If this is analyzed on the basis of line-surge impedance, extremely high voltage on the line conductors are indicated. The fact that protector tube operations occurred at the four towers further confirms the high voltage occurring at these consecutive towers. As a matter of fact, tube operation occurred in this case at six consecutive towers.

Other strokes to the ground wire similar to the above have been observed showing the same general trend as discussed in the typical case given.

VI. Summary and Conclusions

Based on the data obtained during the past four years in combination with other similar data, much of which has already been published, the following conclusions seem to be warranted:

1. Lightning-stroke currents rarely exceed some 150,000 amperes. It is believed that the method of adding adjacent tower currents (which in the past has indicated stroke currents as high as 220,000 amperes) to determine the stroke current gives results which are probably too high.

2. A total tower current of 150,000 amperes has been indicated as a maximum with 10 per cent above 80,000 amperes. This compares with previous data[9] of 100,000 amperes and 45,000 amperes respectively.

3. The maximum benefits of counterpoises are obtained with several short ones rather than by using the same total length in a single counterpoise.

4. To aid in the transfer of current from the counterpoise to tower legs, the bonding of tower legs together near the ground line (in addition to relying solely on the structural bracing of the tower) seems advisable (see Figure 11).

5. Currents circulating in the tower members such as crossarms, hanger bars, and so on, are comparatively small in each member and are the result of shunting current out of the main tower-leg path.

6. The current shunted from the tower legs by the bracing members in the conventional four-leg tower has been shown to average about 50 per cent of the measured tower-leg current. (Detailed data not presented here.)

7. Based on the measured d-c resistance, the counterpoise is less effective in carrying current than the normal tower leg in the ratio of approximately 1 to 3. The ground rod, on the average, carried more than its proportionate share of current, with the tendency for deep driven rods to be slightly more effective than shorter ones. The data, however, are too limited for one to draw this as a definite conclusion.

8. The correlation of measured conductor currents with probable line-surge impedance gives indicated conductor voltages which appear highly questionable. This situation appears not only on the line proper but also adjacent to stations.

9. Currents measured in line conductors at stations are of the same general order as currents which have previously been reported[12] as measured in lightning arresters, thus tending to indicate that protective equipment at the station is not subjected to high lightning currents unless by direct stroke.

10. In no case has there been an apparent direct stroke to any of the five stations involved in this investigation.

11. The maximum rate of measured voltage rise of lightning surges measured at the entrance to a station was 600 kv per microsecond with a median value of 200 kv per microsecond. Ten per cent of the records showed over 300 kv per microsecond. While it might seem that voltages of 1,000 kv per microsecond are not prevalent, it should be pointed out that the records obtained cover only three years of investigation work, were taken at only five stations, and were not measured at the equipment terminals within the station.

Table III. Division of Lightning Currents Between Counterpoises, Ground Rods, and Tower Legs

Structure	Tower and Leg Number	Length (Feet)	Resistance (Ohms)	Measured Amperes	Per Cent Conductivity	Per Cent Current	Ratio of Per Cent Current to Per Cent Conductivity

Progress in Development of Trolley-Coach Overhead Reflected in Higher Service Standards

L. W. BIRCH
MEMBER AIEE

Synopsis: The expansion of trolley coach operation to include 50 transit systems in the United States and Canada has been greatly helped by the progress made in the development of overhead distribution materials. Beginning with the installation of the first transit-type trolley coaches in Salt Lake City in 1928, the inadequacy and limitations of the earlier designs of equipment were recognized. Since 1928 it has been necessary to add many new devices and redesign many old devices to provide better reliability and permit of greater flexibility of operation. The development of trolley-coach overhead materials has been concentrated mainly on

1. Current collection
2. Hangers and insulation
3. Curve materials
4. Turnouts and crossovers

The improved current collection equipment incorporating the carbon-insert shoe has been responsible for the reduction of wear on fittings and trolley wire. The carbon-insert shoe has also been responsible for the complete elimination of trolley-wire lubrication formerly required for the all-metallic shoe collector.

Improvements in insulated hangers have resulted in a more dependable distribution system and have been responsible for the elimination of considerable secondary insulation formerly inserted in the supporting span wire between positive and negative trolley wires.

The curve segment, available in any degree, is replacing the conventional pull-over arrangement on all trolley-coach overhead systems. Today the conventional pull-over is only installed on curves used jointly by both street car and trolley coach.

Special assemblies for turnouts and crossovers are constructed with the same insulating units. These interchangeable units have been strengthened both mechanically and electrically to meet the severe service on heavy lines. Automatic electrical equipment has been developed for all classes of turnouts and has practically replaced the older types of manually operated devices.

Today's trolley-coach overhead is both mechanically and electrically stronger than the overhead available a few years ago. In combination with the carbon-insert shoe there is less fitting and trolley-wire wear, less dewirements, and less maintenance cost.

Paper 42-51, recommended by the AIEE committee on land transportation for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 12, 1941; made available for printing January 6, 1942.

L. W. Birch is engineer in the transportation department, Ohio Brass Company, Mansfield, Ohio.

A VEHICLE propelled by electric energy collected from a trolley-wire system has this advantage—that power is always available. It is not necessary to refill a tank or tender. Trolley-coach operation is of this type and is successful because the overhead distribution system is capable of delivering continuous power.

As electrical engineers we are all interested in electric transportation. The trolley-coach overhead distribution system is part of a \$70,000,000 trolley-coach investment which, in turn, is part of the mass transportation systems on 50 properties. These systems represent a total investment of \$700,000,000.

Problems of Operation and Design

Primarily a trolley-coach overhead system differs from a street-car distribution system in that there is no rail return. An aerial negative contact wire replaces the rail. The support and insulation of two aerial contact wires for operation with mobile current collectors presented several interesting problems. These include:

1. *The current collector, itself.* Numerous single-pole and two-pole collection equipments have been built and tried on commercial trolley-coach routes.

2. *Building for operating speeds of 30 to 40 miles per hour.* At these speeds the trolley coach may be touring to one side of the trolley wires.

3. *Selecting a trolley wire and collector that would prevent excessive wear.* Experience with street-car current collection demanded that the trolley wire last as long for trolley-coach operation as for street-car operation.

4. *Insulating the positive and negative trolley wires.* At both crossovers and turnouts the positive trolley wire crosses the negative trolley wire.

5. *Providing a touring range to permit of curb loading, also the passing of other vehicles in traffic.* The trolley coach should tour over, at least, three traffic lanes.

6. *Automatically selecting the proper path at a turnout point.* This necessitates the selection of either turnout or main line at the will of the operator, and the selection must be made without the operator leaving the coach.

These problems were not solved on the first installation. Our present overhead system is the result of the development of 20 years of experience. The pioneer systems, such as those installed in Staten Island, Philadelphia, Baltimore, Toronto, Windsor, Rochester, and Petersburg, as well as in English cities, were very simple, but they were responsible for many important developments and standards in use today. For example, the advantages possible with four trolley wires providing two-way operation rather than two trolley wires providing "single-track" operation,

were recognized during the early '20's. Furthermore, considerable additional conductivity was made available for the carrying of electric energy.

The selection of 2/0 and 3/0 trolley-wire sizes was made on the early installations, because the short life of 1/0 and the additional supporting structure necessary for 4/0 were recognized as economically unsound. As early as 1923 the American Transit Association selected a 24-inch spacing between positive and negative trolley wires and recommended a trolley-wire height of 18 feet above the street. These limitations are standard today. After considerable experimentation with a single-pole collector, two individual poles were finally accepted on the Staten Island property as the standard. The general method of insulating the positive from the negative contact wire, the length of insulation, and the location of the contact wires with respect to the curb line are other features developed 20 years ago which have helped to secure a well-standardized overhead design.

Since 1928, when Salt Lake City installed the first modern 40-passenger transit type of trolley coach, each new installation of trolley coaches has added some new features to the overhead system. These new features have dealt chiefly with the improvement and development of new *devices*, the *dimensional* standards and limitations having remained unchanged. It is an interesting thought that without some of the early standards selected for trolley-coach overhead distribution design, we might have had as many different gauges between positive and negative trolley wire as the railroads had track gauges 75 years ago.

Typical Distribution System

The standard tangent distribution system consists of a pole structure either wood, concrete, or steel, which supports four trolley wires with the poles spaced at approximately 100-foot intervals. The trolley wires are attached to insulated hangers and clamps, and, in addition to the insulation placed in the supporting hangers, a secondary insulation, either porcelain or wood, is inserted in the span wire near the pole. The center line of one pair of trolley wires is usually located 13 feet from the curb line thus permitting the trolley coach to load at the curb and to tour around double-parked vehicles.

Development of Collection Equipment

Early collection equipment included a free-swiveling trolley base mounted on top of the coach, a long trolley pole, and a free-swiveling wheel harp for operation under the trolley wire. The trolley base was similar to that installed on street cars, the trolley pole was a lightweight alloy steel pole insulated from the trolley harp, and the harp itself was a wheel collector similar to an ordinary caster. With this combination the trolley coach could tour on either side of a pair of trolley wires, the limitation to the touring range being chiefly the length of the poles. This early assembly of equipment is similar to that employed today except that the wheel collector has been replaced with a shoe collector. Owing to the point bearing of the trolley wheel and to the swiveling action of the device, the wheel collector was subject to many dewirements when passing through frogs and crossovers, and milling action of the spinning wheel on the trolley wire, particularly with the

This lubricant was necessary with an all-metallic shoe

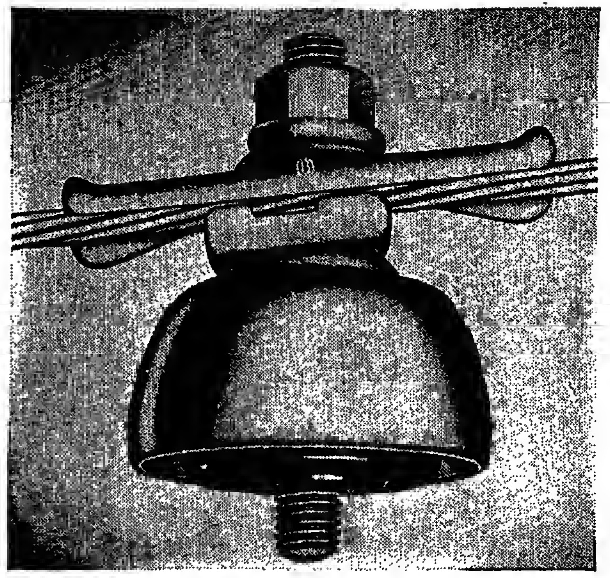

Figure 11. A molded-insulation hanger with adjustable feature for alignment on sloping span wires

trolley coach touring off-center, was quite injurious. These facts were responsible for the development of the shoe.

With the installation of the larger fleets of trolley coaches and the use of higher accelerations and higher speeds, the wheel collector was abandoned in favor of a shoe collector. The history of the development of the shoe collector is interesting. The first shoe collectors were all-metallic, either malleable iron or forged steel. The wearing of a groove in these collectors produced a cutting edge that was injurious to trolley wire, particularly round trolley wire that was supported with a trolley ear encircling the wire. Soft-nosed or bronze-tipped shoes diminished this cutting action but did not prove entirely satisfactory. All of these metallic shoes required lubrication of the contact wires for the prevention of excessive wear to wire and fittings. Usually a graphite lubricant was applied with special roller-type lubricator attached to trolley poles mounted on a line truck or a service truck.

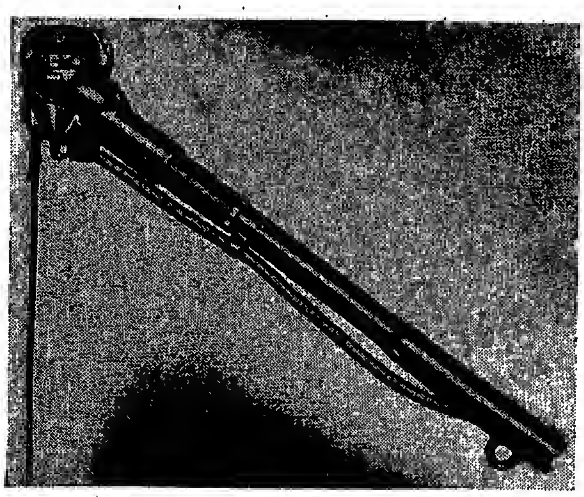

Figure 8. This shoe collector widely used in the United States and England is equipped with a bronze holder in which is clamped a carbon insert

Only the carbon insert contacts the trolley wire

Five years ago a collection shoe consisting of a solid piece of carbon permanently embedded in a bronze shoe was installed on a complete system. This was a real step in the right direction, but trolley-wire lubrication was still necessary since the bronze of the shoe continued to rub the wire. The final step was the development of a collecting shoe consisting of a bronze holder in which is clamped a carbon insert that collects electric energy from the trolley wires and operates in a manner similar to a carbon brush on a commutator. This small carbon insert is replaced when it is worn to the allowable limit. Lubrication of trolley wire has been completely eliminated since the carbon insert lubricates and burnishes the trolley wire.

Effect of Shoes on Trolley-Wire Life

When the metallic shoe was first introduced for collection purposes, dewirements diminished, there was less arcing, and collector noise disappeared, but, on the other hand, the cutting effect of the groove worn in the metallic shoe, and the wear on trolley wire and fittings was greatly increased.

 
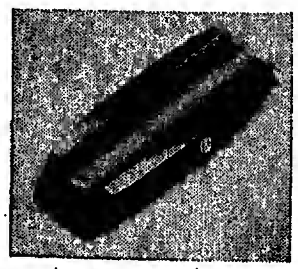

Figure 9 (left). Carbon insert installed in bronze holder

Figure 10 (right). Pregrooved carbon insert

This wear was controlled by the substitution of grooved trolley wire for round trolley wire. All fittings were attached to the upper lobe of the grooved trolley wire, the lower lobe being free of attachments, thus presenting a smooth underrun to the collector. At this time it was estimated that the life of a 2/0 grooved trolley wire would be 500,000 bus passes. Actual experience showed figures as low as 300,000 bus passes. At the present time the combination of a *carbon*-insert shoe operating on grooved trolley wire has increased 2/0 grooved-trolley-wire life to figures varying from two million to seven million bus passes. This is equivalent to saying that 2/0 grooved trolley wire might last on the average line from 20 to 70 years. Most installations today are being equipped with 2/0 wire. The 3/0 wire is selected only where conductivity

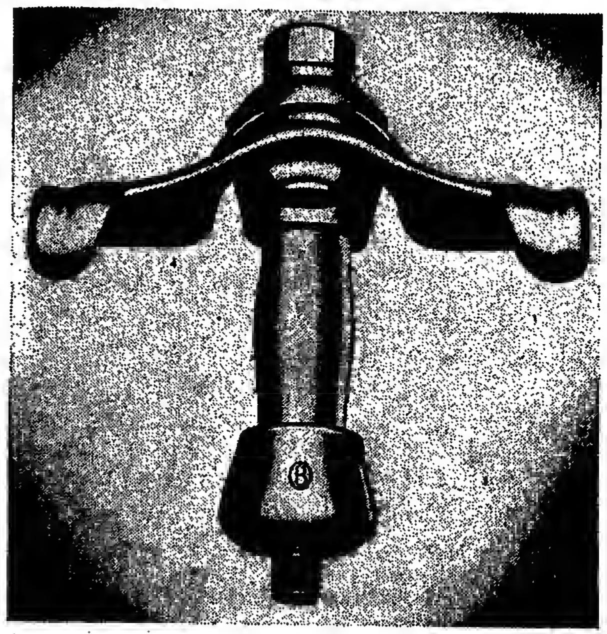

Figure 12. The wood-stick hanger provides a longer leakage path than is possible with most of the hangers equipped with molded insulation

Figure 18. A typical crossover showing a location of insulating units in one line; the other line is not insulated

demands. Bronze trolley wire, because of its greater life and ability to hold sufficient tension, so necessary for good operation, is almost universally used.

Trolley-Coach Hanger

A trolley-coach hanger or insulator used for supporting the trolley wires has been developed for this class of two-wire suspension. The hanger carries sufficient insulation in itself to eliminate further secondary insulation, with the exception of that placed in the span wires near the poles. However, in some instances a secondary insulator, usually a wood stick, is placed between the positive and negative hangers in the supporting span. Insulation in the hanger is usually a molded insulation of high dielectric and has sufficient resistivity to heat, moisture, and mechanical injury to permit of long life. Recently several installations have been made with a wood-stick hanger. This type of hanger provides a longer leakage path than is possible with the molded insulation hanger. Hangers are built with adjustability in order to properly align the trolley clamps to prevent interference with the collecting shoes.

Curve Segment

The usual conventional curve designed for street-railway work requires the frequent installation of pull-overs in order to align the trolley wire of the street car with the curvature of the track. This is necessary because of the type of rigid collection equipment normally used on street cars. In the case of the trolley coach, it is not necessary that the vehicle follow beneath the line of trolley wires since the swiveling action of both the trolley base and the harp permit off-center touring. With this equipment it is not imperative that a trolley wire follow any particular curve except that it must be within reach of the collection equipment.

The conventional curve employing numerous pull-overs has been almost entirely replaced by segment construction where the trolley coach does not operate jointly beneath the same trolley wire as the street car. The segment is a large pull-over built to provide an easy means of aligning trolley wires over the path of the coach and, at the same time, to eliminate many fittings and cables formerly used on the conventional street-railway curve. The segment is built with a comparatively large radius and, of course, connects the several chords on the curve. An adjustable feature reduces

the total number of segments for a given job to a few. This device does not restrict speeds on curves, inasmuch as it has been designed to handle the maximum speeds possible for the various curves. It has been responsible for the elimination of some unsightly pull-over wires and has contributed to considerably less labor cost during installation.

Feeder Span

The frequency of feeder spans for tapping either positive or negative contact wires to aerial feeders is dependent upon electrical loads, cost of annealed trolley wire occasioned by a trolley wire break and the total cost of feed span installation. As a general rule feed spans for the same polarity are located at 800-foot intervals. This means one negative feed span and one positive feed span in an 800-foot section. Since tapping of the positive trolley wire requires good insulation in the feed span because of the closeness of the negative contact wires, special equipment has been designed for making these taps. The most recent arrangement uses the copper feed span as a supporting span, direct taps being taken from the span to the trolley ear as illustrated in Figure 17.

Special Work for Intersections

At locations where one trolley-coach system crosses another trolley-coach system, or where a trolley-coach system crosses a street-car line, insulated crossovers must be installed. At locations where one trolley-coach line leaves another trolley-coach line, or where a street-car line leaves a trolley-coach line, special turnout equipment is required. In all cases the special equipment includes devices to which a trolley wire is attached. These devices may be for the purpose of crossing two lines or for the purpose of taking one line off another line. In any event, the design of these devices has been made so that the cross section of the runner pieces, metallic or insulated, is approximately equivalent to that of the trolley wire. This uniform cross section of trolley wire and fittings reduces bumping and scrubbing and consequent arcing by the collector and also prevents considerable damage and wear. To the trolley-coach rider, it is important, because it is responsible for very quiet collection operation. Even the trolley-wire splicer is attached to the upper lobe of the trolley wire itself, in such a manner that there is no obstruction to the passage of the collector.

There are many types of crossovers and turnouts, most of which are constructed with standard parts. For instance, in Figures 18 and 20, similar crossover pans have been used, and the same insulation unit occurs repeatedly. The tips for connecting the trolley wire to the devices are the same for the same size of wire. In the case of the turnout, the standard arrangement shown in Figure 19 is equivalent to that used on all turnouts, the frog pan itself being the only piece that is selected for some particular type of operation. In these illustrations the standard insulating unit, standard tips, and crossover pan may be seen. Of course it is understood that the degree of turnout may vary the degree of the crossover pan in either a crossover assembly or turnout assembly.

Insulating Unit for Turnouts and Crossovers

The insulating unit used in all crossover and turnout assemblies must withstand the ultimate mechanical loads of the largest sizes of bronze trolley wire. It must provide adequate insulation during the passage of a collection shoe from positive to negative wires and must withstand the repeated arcing caused by the breaking of electrical loads. Structurally, this unit consists of two phenolic tubes, a tension member, and a compression member. The compression member is constructed of insulation only, while the tension member is reinforced with a steel core, properly insulated at the ends, that enables the assembled unit to withstand all mechanical loads transmitted by overhead trolley wires. The unit provides 12 inches of clear insulation between metallic sections, this distance being adequate to prevent the "carry-over" of the 600-volt arcs.

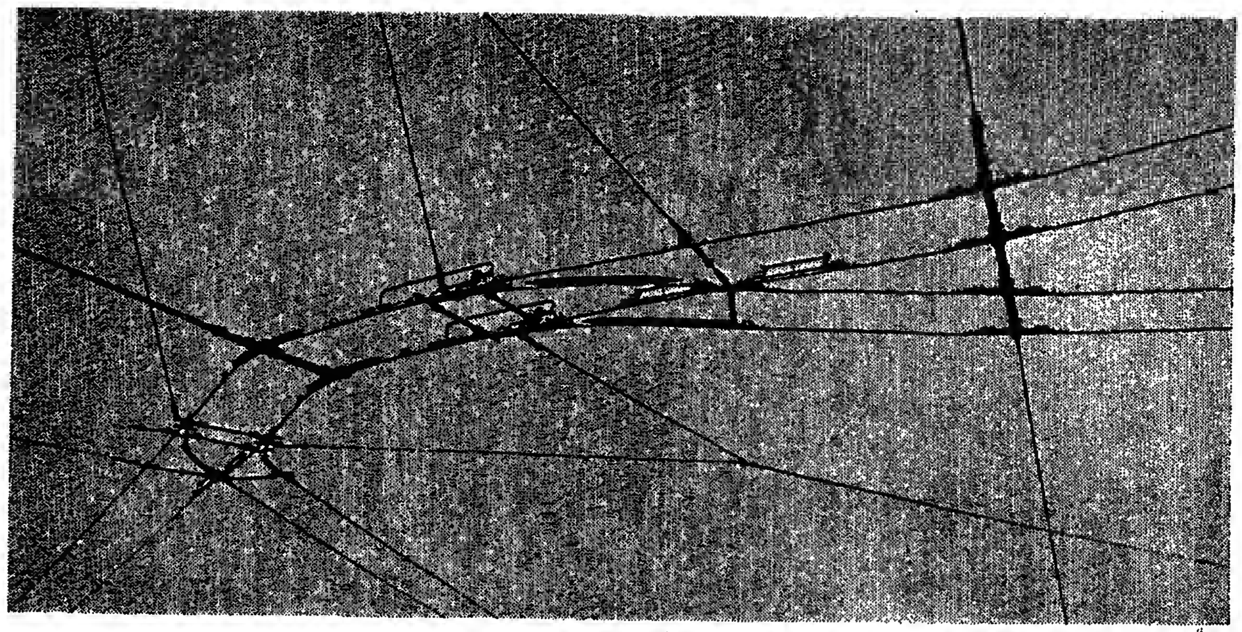

Figure 20. An electrically operated frog installed immediately ahead of a segment

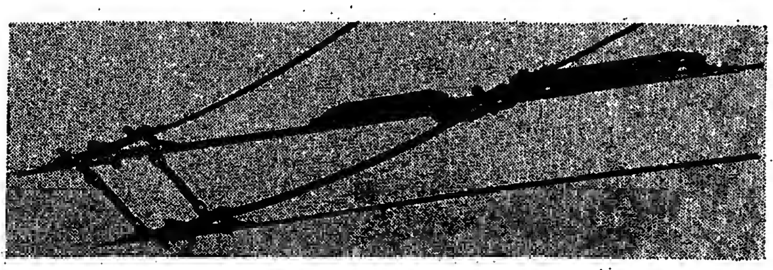
Figure 19. Typical turnout arrangement where one trolley-coach line joins another trolley-coach line



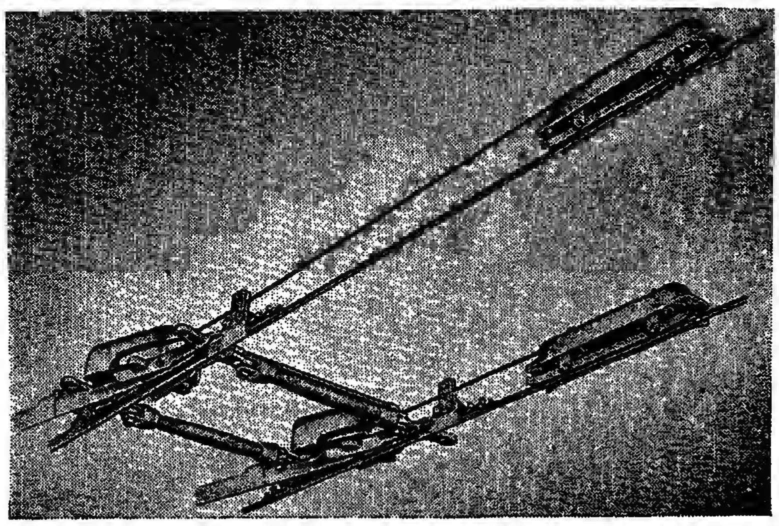
Fiber insulation formerly used between positive and negative wires is shown in this view. Fiber has now been replaced with a phenolic insulation

Types of Turnouts

Again looking at the standard turnout, a set of ordinary cast trailing frog pans will permit a trolley coach to "trail through" this arrangement from either the main line or the turnout, no additional guiding of the swiveling shoe being necessary. If the direction of operation is reversed, it can be readily seen that further guidance of the shoe is imperative, otherwise the shoe may either enter the straight line or the turnout path. Where the trolley coach enters a frog assembly of this type, the shoe must be guided.

One type of turnout where the shoe is guided to one path only, is equipped with a spring frog similar to a spring track switch. If the frog is set for the turnout at all times, the shoe will enter and take the turnout at all times. With the spring arrangement it is possible to trail from either the main line or the turnout, the same as a rail car trails through the spring track switch.

The movable runner of this frog, as well as all electrically operated frogs, is of the "double-tongue" type. A shoe collector



This frog is operated by the two collectors touching the contactors at the same time. In this view one collector is located ahead of the other; therefore, the two contactors could only be simultaneously touched when a trolley coach is turning into a side street. When the trolley coach is taking a turnout, one collector will lead the other collector

Figure 21. Location of contactors on trolley wires in front of Selectric frog

passing through the frog, either over the turnout or over the main line, will travel over one of the runners. Smooth operation of the shoe is accomplished in this way.

There are numerous locations where one trolley-coach line branches away from another line. At these locations it is necessary for the operator to select either the main line route or the turnout route. At these locations electrically operated frogs are usually installed, although in some minor cases, frogs operated with pull ropes have been used.

The electrically operated frog is of two types, the "power-on—power-off" and the Selectric type. In the former type the path at the point of turnout is selected by the operator of the coach by either coasting through the device (power-off) or by taking power (power-on) to actuate the solenoid-operated frog. In this assembly the frog pan is insulated from the trolley wire. It is, however, electrically connected to the trolley wire through a solenoid which operates the frog runners. If a coach passes through this section with the "power off," the runner remains in the main-line position. If, however, the coach passes through this section with the "power on," current passing through the solenoid actuates the frog runner and sets it to the turnout position. Many modifications of this type of frog are in use; however in principle they are similar to this one.

The other type of electric frog depends upon the angularity of the trolley-coach body with the trolley-coach wires. The electrically operated frog used with this combination is also equipped with only one solenoid; however, it is also equipped with a mechanical reset. The solenoid actuates the frog runner, and after a collector passes through the frog, it strikes a trigger and resets the frog to its original position.

Two contactors, one on each trolley wire, are located ahead of the frog. If the two contactors are placed abreast, and a trolley coach is continuing over the main line, the collector shoes will be abreast and will strike the two contactors simultaneously. Since these contactors are a part of a circuit to the coil, the frog runner is actuated as the shoes pass beneath them. After the collection shoe has passed through the frog, it strikes a mechanical resetting device and throws the frog runner back to its initial position, which in this case would be for the turnout. If the coach is to take the turnout, one trolley shoe will lead the other; therefore the shoes cannot strike the two contactors simultaneously and complete a circuit to the solenoid. If the trolley coach is taking a turnout there will be no movement of the frog runner, and since the reset position of the runner is for the turnout, the action is positive.

Other variations of this type of electric frog are in use, the variations being due chiefly to the locations of contactors. In addition to these variations, frequent installations of one half of an electric frog are used where a street-car line either enters or leaves the trolley-coach overhead system.

At the present time, an intersection assembly, turnout or crossover, is ordered and shipped as a unit. Previously, the transportation company selected and erected a multitude of small devices, but the confusion caused by this procedure resulted in an effort by all manufacturers to simplify the selection of the proper assemblies for an installation. Unit assemblies are easily identified.

Research an Important Factor

The design and development of trolley-coach overhead required many laboratory and field tests of materials and assemblies. Impregnated wood beams were first used in crossover assemblies to furnish both mechanical strength and insulation between positive and negative wires. Partially because of bulkiness and weight, but chiefly because of occasional mechanical failures, the wood beam was replaced with a fiber beam. Fiber furnished sufficient insulation for the 600-volt system and provided ample strength, but fiber has one inherent feature that was responsible for the discontinuance of its use. Fiber beams warp. As a consequence, a straight, smooth underrun was difficult to secure. Variations in moisture even produced warping in stock bins before the devices were shipped. The present tubular, phenolic members of an insulating unit do not warp, have good mechanical strength, and furnish excellent insulating qualities over a period of years. Many service tests were necessary during the development of this insulation.

Life tests on the insulation included repeated collector passages over the runners to determine the deteriorating effect of the arc. An insulating unit is tested with a shoe passing under it at speeds corresponding to the speeds of trolley-coach operation in the street. The life of the unit is determined for various values of current at 600 volts. These tests are responsible for the selection of the general design as well as the selection of materials that will withstand constant arcing. It is to be remembered that the auxiliary load of a trolley coach for lights, heaters, and compressor will reach 70 amperes, and this load must be broken at an insulator even when the traction load is cut off.

The development of the current collection equipment has continued for many years. The first carbon inserts used in

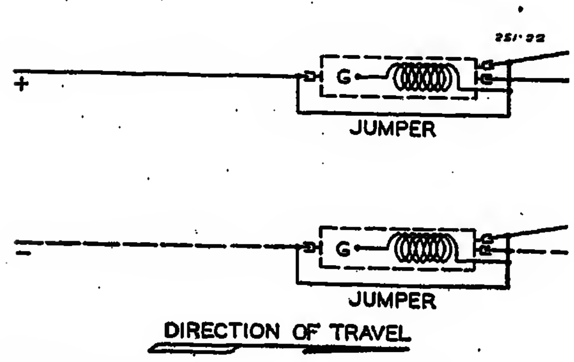


Figure 22. Wiring diagram of a "power-on—power-off" electric frog

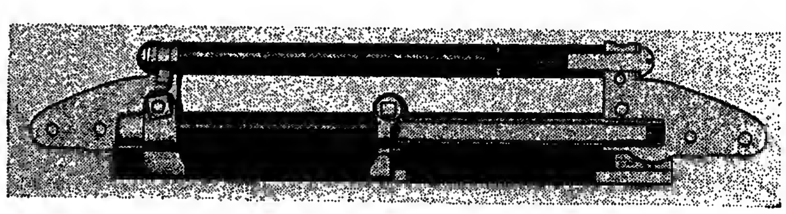

Figure 23. Cut section of the phenolic insulating unit used in crossover and frog assemblies

the present shoe wore out in less than 10 miles, the next carbon inserts in less than 30 miles, and the inserts finally accepted and offered for general use would not last more than 500 miles. The average mileage today for summer and winter, dry weather and wet weather, is considerably over 1,000 miles, and it required four years to secure this mileage. Because of the research conducted by the London Passenger Transport, the present development of the carbon-insert collector was no doubt hastened. Similar experiments were carried out in London and in this country. The exchange of data was very helpful in expediting the production of a satisfactory collector.

The usual problems with lightning and radio interference were encountered, and satisfactory modifications and improvements were developed to provide the degree of reliability demanded for city transportation service. Today, radio complaints are few and there is no record of damage to the traction motors due to lightning.

Reduction in Weight

The weight of the overhead system has always been a problem. A one-pound weight in the overhead system produces from five to eight pounds side load on the supporting structure, either pole or building. The reduction of weight in the overhead system reduces the side loads on the structures and, as a consequence, the cost of the system. Substituting 2/0 grooved trolley wire for 3/0 grooved trolley wire has reduced the weight 20 per cent. The weight of overhead fittings has been reduced 35 per cent since 1934. This weight reduction has permitted the use of many street-car poles that formerly supported two trolley wires. Now they support four trolley wires.

The Picture of Trolley-Coach Operation Today

In addition to the study and development of fittings for overhead design, each new trolley-coach installation has required a field study, a study of the application of the materials. Today, trolley coaches are operating in every climate, almost in every country. They operate at speeds up to 45 miles per hour, accelerate at four miles per hour per second, collect currents as high as 400 amperes, climb 13 per cent grades, run through subways, through congested streets, and over country highways. They do this quietly, swiftly, efficiently, under the overhead distribution system just described.

There are 3,300 trolley coaches now operating in the United States and Canada, 95 per cent of which have been installed within the last 10 years. These coaches, operating over 1,100 miles of route, totaled 100 million coach miles during 1940, and each coach averaged over 1,000 miles for each trolley-pole dewirement.

This is equivalent to saying the trolley coach can run at least five days without a dewirement, a performance that is a measure of the reliability of modern trolley-coach overhead.

The Electrical Strength of Nitrogen and Freon Under Pressure

H. H. SKILLING
MEMBER AIEE

W. C. BRENNER
ASSOCIATE AIEE

Synopsis: Results are given of an investigation of the electric strength of nitrogen, of dichlorodifluoromethane (Freon F-12), and of mixtures of these gases. Sparking voltages are presented as measured between spherical electrodes of brass and aluminum and between pointed electrodes of brass, at various spacings, and in gas at pressures ranging from one to several atmospheres. All measurements are for 60-cycle applied voltage. Dichlorodifluoromethane is found to withstand much higher voltages than either air or nitrogen; this advantage is more marked between points than between spheres, which suggests its use in certain types of insulation applications. A small percentage of dichlorodifluoromethane gas in nitrogen produces an anomalously large rise in the electric strength of the gas, indicating practical advantages of such mixtures.

PREVIOUS studies of the electric strength of air under pressure have been reported by the authors.[1,2] The present paper presents data from a continuation of this work for the primary purpose of studying the electric strength of the gas dichlorodifluoromethane, CCl_2F_2, commonly known as Freon F-12. This gas is readily available as a refrigerant and is known to have unusually high electric strength. It was studied both alone and mixed with nitrogen, and to complete the series of tests the electric strength of nitrogen was also determined.

Paper 42-33, recommended by the AIEE committee on basic sciences for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 17, 1941; made available for printing December 9, 1941.

H. H. SKILLING is associate professor of electrical engineering at Stanford University, Stanford University, Calif. W. C. BRENNER, formerly a graduate student in electrical engineering at Stanford University, is with Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

The work reported in this paper was done under the auspices of the International Telephone and Telegraph Company. The authors are indebted to the company for permission to publish the results of the investigation.

Freon was obtained in liquid form, in a pressure cylinder, and gas from the upper part of the cylinder was released into the test chamber as desired. Nitrogen gas of commercial purity was used; it is guaranteed 95 per cent pure but is believed to be purer than the guaranteed value. It is supplied under pressure, and was released into the test chamber when needed. No purification of either gas was attempted, for it was believed that results obtained with gas of commercial purity would be more significant from an engineering point of view than results obtained with chemically pure gases. In the present investigation no irregularities or inconsistencies of data could be traced to the presence of impurities in the gases supplied.

The apparatus used is described and pictured in a previous publication.[2] The methods of measurement and technique employed in the study of Freon were the same as in the previous work with air, except as the use of mixed gases required special methods.

In order to obtain mixtures of gases of known composition for test purposes, it was necessary to evacuate the test chamber before admitting the gas or gases in which the test was to be performed. Pressure within the chamber was reduced by means of a vacuum pump to a value estimated at one millimeter of mercury before admitting nitrogen or Freon. By this means practically all of the residual gases were removed. This was particularly necessary for the purpose of removing all traces of Freon gas before testing in an atmosphere supposed to contain no Freon. The presence of an extremely small amount of Freon in nitrogen or air was found to be important in determining dielectric strength, sometimes increasing the sparking voltage by fifty per cent or more,

although the amount of Freon could hardly have been more than a fraction of a per cent. The sparking voltage in such cases was highly erratic and undependable. Similar results were obtained when a trace of carbon tetrachloride was present in the test chamber.

After a series of tests with Freon, it was found best for the test chamber to be evacuated and left for several hours or days. Nitrogen was then admitted to the chamber, and it was again evacuated. This process removed all indication of the presence of Freon in subsequent tests.

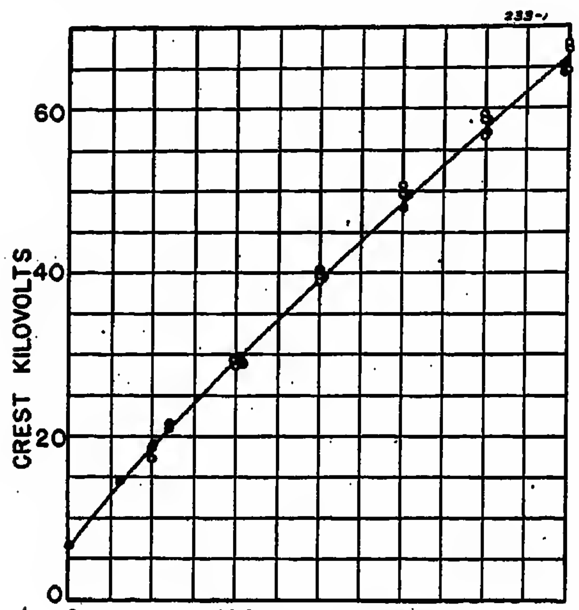

Figure 1. Comparison of sparking voltages in air and nitrogen

Spherical electrodes
Length of spark gap: 0.050 inch
○ Experimental points in air
● Experimental points in nitrogen

In order to obtain satisfactory mixing of gases when Freon and nitrogen were used together, it was found necessary to stir the gases with an electric fan placed within the test chamber. Natural mixing by diffusion did not take place in the course of several hours. When the fan was not used, the heavier Freon went to the bottom of the test chamber and remained partially unmixed with the nitrogen. Results without use of the fan were inconsistent and meaningless. Less than five minutes of operation of the fan was adequate to give thorough mixture of the gases, and results obtained with its use were consistent and could be repeated from day to day.

For test of sparking between spherical electrodes in gas mixtures containing Freon, aluminum electrodes were used in most cases. Aluminum was used because of its greater resistance to corrosive action under such circumstances. Brass was less resistant than aluminum, and steel was less resistant than brass. It is presumably not Freon itself that is harmful to the metal electrodes, for it is reported—in publications relating to its chemical properties—to be noncorrosive, and it is used satisfactorily for refrigeration. Electric discharge in Freon, however, is reported to produce chlorine and other corrosive products of decomposition. It is apparent from the present investigation that the products of electrical discharge in Freon are distinctly corrosive. Moreover, products of electric discharge in a mixture of Freon and air are very considerably more corrosive than those that result from Freon alone or in mixtures of Freon and nitrogen. Corrosion of electrodes in mixtures of Freon and nitrogen was about as severe as in pure Freon, and very much less than in mixtures of Freon and air.

Sparking in nitrogen was remarkably free from corrosion of any kind, and hundreds of sparks would barely tarnish the

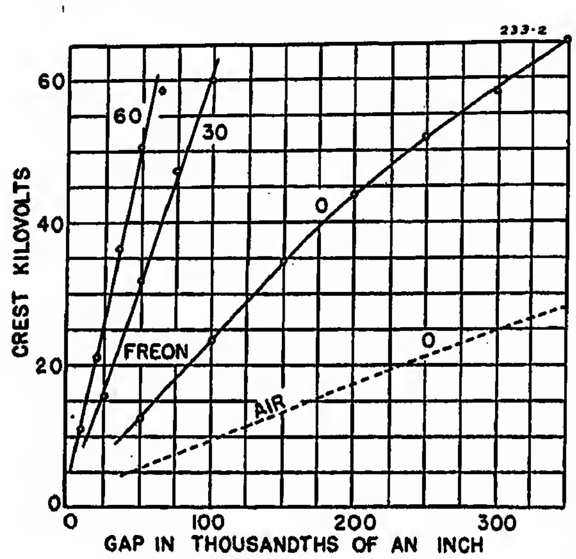

Figure 2. Sparking voltages in Freon

Spherical electrodes
Gauge pressure in pounds per square inch as noted on curves

polished surface of either brass or aluminum spheres. Pointed brass electrodes lost none of their original sharpness after forty or fifty sparks in nitrogen, whereas they were noticeably rounded and measurably shortened in length by similar sparking in either air or Freon.

Results in Nitrogen

In general, sparking voltages between spheres in nitrogen are the same as between spheres in air. This conclusion was checked carefully with an 0.050-inch gap at pressures from 1 to 21 atmospheres; sparking voltages in nitrogen could not be distinguished from those in air (see Figure 1).

A careful study of sparking between spheres at various spacings and pressures had been made in air,[2] and because of the similarity of results this was not repeated in nitrogen.

Despite the general agreement observed between sparking between spheres in air and in nitrogen, there were certain differences in detail. It has been mentioned[1,2] that in air there was a tendency for the sparking voltage to rise slightly as a number of measurements were made in rapid succession. No such result was noticed in nitrogen. It has also been mentioned that a spark would usually result in air if voltage was held for a period of several minutes at a value as much as five to seven per cent below the usual sparking value. This effect did not appear in nitrogen. The sparking values given in this report for nitrogen are average values. Most of the individual sparking values for pure nitrogen lie within one per cent of the average value, the most extreme variations being about five per cent.

It should be emphasized that a slight trace of Freon in the nitrogen would cause very erratic results, but that clean nitrogen was quite consistent.

Results in Freon

Sparking in Freon was investigated at pressures of from one atmosphere to about six atmospheres, with gaps varying from

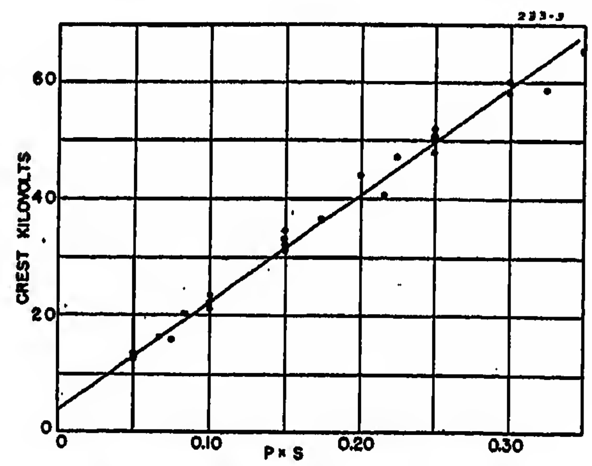

Figure 3. Sparking voltages in Freon

Spherical electrodes

P, absolute pressure in atmospheres
S, spark-gap length in inches

10 mils to 250 mils (0.010 to 0.250 inch) between both brass and aluminum spheres. Sparking between points was also studied (see following). The highest pressure possible at room temperature was about six atmospheres, at which pressure the gas is in equilibrium with liquid Freon. (The vapor pressure of Freon at 70 degrees Fahrenheit is 84.82 pounds per square inch absolute, 70.12 pounds per square inch gauge[5]).

Freon was found to have a sparking voltage between spheres that was, for all pressures investigated, between 2 and $2^1/_2$ times as great as the sparking voltage in

nitrogen or air at the same spacing and pressure (see Figure 2).

The nature of the spark in Freon was not noticeably different from the sparks observed in air and nitrogen, except in color. Sparks in Freon are intensely blue, in nitrogen they are purple, and in air white or slightly yellow. The intensity of sparks in the different gases, however, appears to be much the same when due allowance is made for the amount of current flowing.

Values of sparking voltage obtained in Freon were fairly consistent, although a variation of two or three per cent from the average value was not uncommon. Variations of as much as ten per cent were occasionally encountered, usually below the average sparking voltage rather than above. No "trends" of voltage values, as found in air,[2] were discovered in Freon, and there were no sparks at voltages radically different from the average value.

In general, sparking voltage between spheres in Freon was found to be proportional to the length of gap, and proportional to the pressure of the Freon gas. To be more precise, the voltage-spacing and voltage-pressure relations were found to be linear, but not exactly proportional, taking the same form as Paschen's law for sparking in air.

The breakdown voltage of Freon as determined in the present investigation can be expressed by the formula

$$V = 183PS + 4.0$$

where V is sparking voltage in kilovolts, P is pressure in atmospheres, and S is spacing in inches. It will be seen that this equation gives voltage values for sparking in Freon between 2.4 and 2.5 times the values given by Paschen's law for air.[2]

The preceding formula appears to be reasonably accurate over the range of conditions of test. The values of sparking voltage obtained by experiment, each an average of five to ten individual voltage readings, are all within ten per cent of the value given by the formula. The experimental range of pressure was from one to five atmospheres, and the range of spark length was from 10 to 350 mils, giving a range of the product PS from 0.05 to 0.35 (atmosphere-inch). This is shown in Figure 3. This formula was derived from the authors' results alone. However, it was found to give good agreement with the sparking voltages measured between flat electrodes in Freon by Trump, Safford, and Cloud (see Figures 3 and 4 of reference 9), for pressures up to about four atmospheres (60 pounds per square inch absolute). As the vapor-pressure of Freon is approached (six atmospheres at room temperature) the experimental sparking voltages are lower than would be expected from the formula. Agreement with the work of Trump, Safford, and Cloud appears to extend the range of applicability of the formula to direct voltage as well as alternating, to gap lengths as great as 0.7-inch, and to values of the product PS as great as 2.0 (atmosphere-inches).

Results in Freon-Nitrogen Mixtures

The electric strength of mixtures of Freon and nitrogen gas was measured under a variety of conditions to determine the effect of

(a) Dilution of Freon by nitrogen.

(b) Change of pressure.

(c) Change of spark-gap length.

Results, which will be discussed below, were intermediate between those obtained in pure Freon and those obtained in pure nitrogen. This was the outcome that was to be anticipated. One very interesting relation, however, was discovered. It was found that a very small amount of Freon in nitrogen has a disproportionately large effect in raising the electric strength; this is discussed below.

Considerable difficulty was at first experienced in work with mixed gases, and results could not be repeated from time to time until an electric fan was used to insure thorough mixing of the gases within the test chamber. When the fan was used, however, the difficulty was entirely overcome, and sparking voltages were thereafter obtained with about the same degree of consistency as in pure Freon: that is, individual readings of sparking voltage commonly varied two or three per cent above and below the average for a given condition, while a variation of as much as ten per cent was very unusual.

Mixtures of Freon and nitrogen that were given most attention contained 67 per cent Freon, 50 per cent Freon, 33 per cent Freon, 25 per cent Freon, and 5 per cent Freon by volume. Most of the work was done with a spark-gap length of 50 mils (see Figure 4). To give assurance that the normal relation between the sparking voltage and gap length exists in

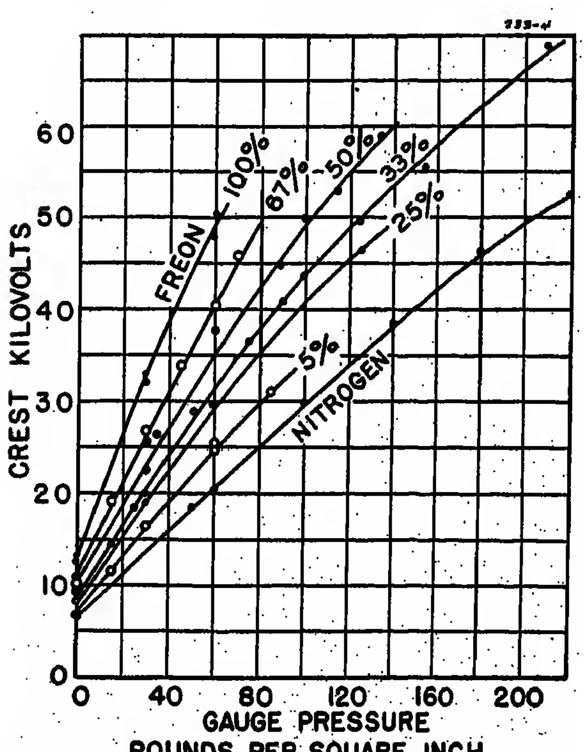

Figure 4. Sparking voltages in mixtures of Freon and nitrogen

Spherical electrodes
Length of spark gap: 0.050 inch
Per cent of Freon by volume as noted on curves

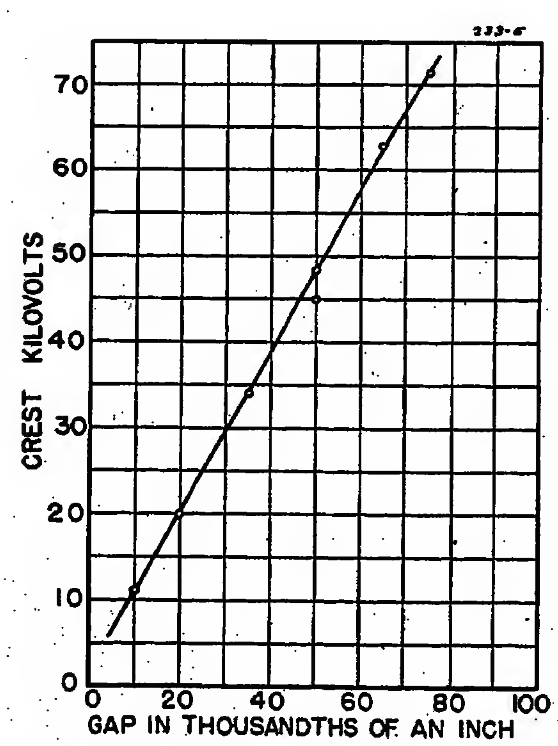

Figure 5. Sparking voltages in a mixture of 50 per cent Freon and 50 per cent nitrogen

Spherical electrodes
Pressure seven atmospheres (90 pounds per square inch gauge)

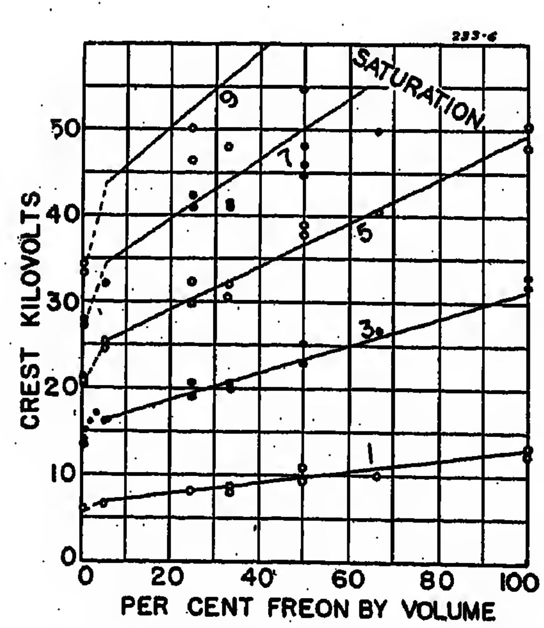

Figure 6. Sparking voltages in mixtures of Freon and nitrogen

Spherical electrodes
Length of spark gap: 0.050 inch
Pressure in atmospheres as noted on curves
Points are experimental; lines are computed from $V = (88PS + 1.9)(1 + 1.08F)$ kv

mixed gases, the gap length was varied from 10 to 75 mils in a mixture of 50 per cent Freon and 50 per cent nitrogen with the results shown in Figure 5. As with pure gases, the voltage-distance relation is linear, and experimental data for this mixture of 50 per cent Freon and 50 per cent nitrogen can be represented by the formula

$$V=132PS+2.5 \text{ kv}$$

(All experimental points lie within 10 per cent of this expression.)

This suggests the possibility of finding a simple equation to represent data for all Freon-nitrogen mixtures at all pressures and spacings. For this purpose the data of Figures 4 and 5 were replotted as Figure 6. In this form it is evident that the relation between the amount of Freon present and the sparking voltage is linear when the concentration of Freon is greater than five per cent. When the concentration of Freon is less than five per cent a small amount of Freon produces a disproportionately large increase in the sparking voltage, as shown in detail in Figure 6 at a pressure of three atmospheres. The linear relation shown in Figure 6 leads to the following equation for sparking voltage in Freon-nitrogen mixtures in which the amount of Freon is greater than five per cent:

$$V=(88PS+1.9)(1+1.08F)$$

where V is kilovolts, P is pressure in atmospheres, S is spacing in inches, and F is the fraction of Freon by volume, in the gas. (For pure Freon $F=1.0$; for half Freon, half nitrogen $F=0.5$; note that for pure nitrogen it is *not* correct to let $F=0$ as the formula does not apply for less than five per cent Freon.)

This equation is proposed with several reservations. As noted, it does not apply for very low concentrations of Freon. Another limitation is that the formula becomes inaccurate at high pressure. The agreement with experimental data is good for pressures up to five atmospheres. At pressures of seven atmospheres and more, the experimental sparking voltage is uniformly less than that predicted by the formula. There are two obvious explanations:

1. It is at about this same pressure that variation from a straight-line relationship becomes evident in pure air or nitrogen.

2. The discrepancies become more marked as the partial pressure of Freon in the gas under test approaches the vapor pressure of Freon.

A condition of saturation is approached when both pressure and concentration of Freon are high, corresponding to the upper right-hand corner of the chart. As the vapor pressure is approached the intermolecular forces become great and the Freon no longer approximates a perfect gas.

Finally, the formula given for mixtures of Freon and nitrogen is based on a limited amount of data. Since there are three independent variables in the equation, it would be an extremely lengthy procedure to determine the voltage for all possible combinations. The data at hand were obtained by recording slightly over a thousand individual sparking voltages, however, and appear adequate to give strong support to the above formula for pressures greater than one atmosphere, for spacings from a few mils to a few hundred mils, and for all concentrations of Freon greater than five per cent.

Some work was done with mixtures of air and Freon, but was discontinued when

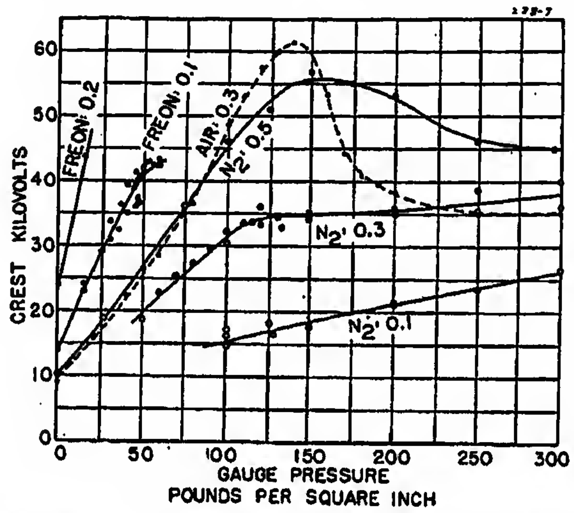

Figure 7. Sparking voltages in nitrogen, Freon, and air

Pointed electrodes
Gas tested, and spark-gap length in inches, as noted on curves

it was found that the products of electrical discharge were highly corrosive and tended to damage the apparatus. In particular, the spheres used as electrodes were tarnished after as few as three or four sparks and rapidly became coated with a grayish deposit. This corrosion, however, had very little effect on the electrical strength of the gap between the spheres. Indications are that the electric strength of air-Freon mixtures is similar to that of nitrogen-Freon mixtures.

Results With Pointed Electrodes

A short investigation was carried out to determine some of the salient characteristics of sparking in air, nitrogen, and Freon, between electrodes with sharp points.

Sparking in air between points was discussed at some length in a previous paper,[1] and present measurements agree, where comparable, with the results which were then obtained. Experimental procedure is difficult because the nature of the results depends to a large extent on the degree of sharpness of the points, particularly for short gaps. In general, however, as pressure is raised, the sparking voltage reaches a maximum; this maximum occurs at 8 to 12 atmospheres pressure. When pressure is further increased, the sparking voltage becomes less—sometimes very slightly less, sometimes by as much as 50 per cent. The large decline of voltage with increasing pressure is obtained with very sharp points, while with blunt points the dip becomes less marked, and there may be no dip whatever if the points are either quite blunt or quite close together. The action is apparently dependent on whether or not corona precedes sparking; observation of corona has been made possible by the windows installed in the present test chamber.

Sparking in nitrogen between points was investigated for three lengths of gap. It was found that the sparking voltage in nitrogen is considerably lower than that in air for the lengths of gap studied. Curves of sparking voltage as a function of pressure are shown in Figure 7. No direct comparison with the strength of air is possible because of the different shape of the curves, but it is seen from the figure that a 0.3-inch gap in air will withstand about as much voltage as a 0.5-inch gap in nitrogen. There is a decided difference in the shape of the curves; the curve for the 0.3-inch gap in nitrogen is practically flat for pressures above ten atmospheres, while the corresponding curve for air has a hump in the neighborhood of ten atmospheres pressure. When the gap is increased to 0.5 inches the curve for nitrogen is also humped, although to a lesser extent. Very short gaps (0.1-inch or less) fail to show any hump in either air or nitrogen, at least for points of ordinary sharpness. It may be mentioned that the sharpness of the points used was such that they would readily scratch the fingernail, and this sharpness was retained during sparking in nitrogen but sparking in compressed air tended to burn and blunt the points.

It is probable that difference between sparking between points in nitrogen and in air results from the high electron affinity of oxygen. Oxygen will allow the attachment of electrons to form negative ions; nitrogen will not.[6] This will greatly affect the mobility of space charge in the gas, and since sparking voltage between points is largely influenced by space charge, it is natural that nitrogen and air behave differently between points al-

though they behave alike between spheres.

The voltage required to spark between points in Freon is considerably higher than for equal distances in air. Curves for sparking in Freon are shown in Figure 7. Again a general comparison is practically impossible, but certain particular values may be compared in air and Freon.

The voltage required to spark 0.1 inch between points in Freon is for all pressures (from normal atmospheric pressure to the vapor pressure of Freon) greater than the voltage required to spark 0.3 inch in air or 0.5 inch in nitrogen. Over most of the pressure range the voltage required for the shorter gap in Freon is very considerably greater than for the longer gaps in air and nitrogen. It was found that a gap of 0.2 inch in Freon will support voltage comparable to published values for a gap of 30 to 50 millimeters (1.2 to 2.0 inches) in nitrogen.[7]

Since this paper was submitted, G. C. Nonken has published[10] sparking voltages for longer gaps in Freon. His curves for sparking between points (square rods) show the typical hump. A hump is just beginning to appear in the curve of Figure 7 of this paper at the highest pressure obtainable in pure Freon, and with longer gaps it appears at lower pressure. At gap lengths of six and eight centimeters this maximum sparking voltage is at almost atmospheric pressure, and voltage declines as pressure is raised.

At atmospheric pressure comparison may be made between results obtained in Freon and the AIEE standard needle-gap sparking voltages for air, as shown in Table I.

Table I

Voltage Kv Crest	Length of Spark (Inches) In Air (AIEE Standard)	In Freon (Experimental)
14.3	0.47	0.10
24.0	0.82	0.20

It will be seen that in general the increase of electric strength gained by the use of Freon is greater with pointed electrodes than with flat or spherical electrodes. The apparent reason is that with pointed electrodes, sparking is preceded by corona discharge, while there is no corona between spheres. The conclusion is that formation of corona is greatly impeded by Freon gas.

One of the more important and useful aspects of the behavior of Freon is the following. The maximum sparking voltage between points in Freon is greater than the sparking voltage of the same point-gap in air or nitrogen at any practical pressure of air or nitrogen. With a gap of 0.1 inch, for example, between points, Freon will withstand about 40 kilovolts at 50 to 60 pounds gauge pressure. According to data given by H. J. Ryan[8] a gap of the same length in air will not support more than 35 kilovolts even though the pressure is raised to 1,500 pounds. With longer gaps the advantage of Freon appears to be even greater.

This advantage is peculiar to pointed electrodes. In nitrogen or air the sparking voltage between points reaches a maximum at a pressure of a few atmospheres and thereafter decreases with increasing pressure, or at the most, rises very gradually. When the gap in which sparking occurs is between smooth surfaces—between spherical electrodes, for example—the maximum strength of Freon may be equaled and exceeded in either air or nitrogen by sufficiently increasing the pressure, but this is not possible if the spark occurs between points.

These facts appear to make Freon potentially more useful to prevent electric discharge from points or projections than to prevent sparking or breakdown in a substantially uniform electric field. On the other hand, it must be remembered that corona or other electric discharge must not ordinarily be allowed to take place in Freon, because the decomposition products are corrosive and somewhat poisonous.

Conclusions

1. The electric strength of nitrogen between smooth electrodes is almost exactly equal to that of air.

2. Sparking voltage between sharp points is higher in air than in nitrogen. See Figure 7.

3. Freon gas (dichlorodifluoromethane) between smooth electrodes will withstand about two and a half times as much voltage as air or nitrogen at the same pressure, but it cannot be used at pressures above about 70 pounds per square inch, gauge, as that is its approximate vapor pressure at ordinary temperatures. See Figures 2 and 3.

4. Mixtures of Freon and nitrogen are intermediate in characteristics between the two gases used alone. See Figures 4 to 6. The most interesting characteristic of mixtures is the large increase in electric strength produced by a very small amount of Freon in nitrogen. See Figure 6.

5. Freon gas between pointed electrodes increases the strength of the gap very greatly, the sparking voltage being found in some cases to be of the order of magnitude of four times that in nitrogen. The maximum sparking voltage in Freon is greater than the greatest sparking voltage that can be attained in air or nitrogen at any practicable pressure.

6. The greatest advantage in the utilization of Freon between smooth surfaces is where the pressure of gas that may be used is limited by mechanical considerations. For most purposes, nitrogen at 300 pounds per square inch pressure is superior to Freon, for it has as great an electric strength, is more consistent in behavior, and does not become corrosive in the presence of electric discharge. But if the gas pressure is limited by mechanical design to 150 pounds per square inch, or less, the possible use of Freon should be carefully considered.

7. The possibility of adding a small percentage of Freon to nitrogen, and thereby increasing its electric strength by 15 to 25 per cent appears to be a practical consideration.

Lightning Investigation on Wallenpaupack—Siegfried 220-Kv Line of Pennsylvania Power and Light Company

EDGAR BELL
NONMEMBER AIEE

F. W. PACKER
MEMBER AIEE

THE Wallenpaupack-Siegfried line, the pioneer 220-kv circuit in the eastern United States, was completed in 1926.[1] Little information on lightning, and most of it incorrect, existed at the time, and the design chosen proved inadequate to cope with the severe lightning conditions encountered. Partly because of this fact an investigation was started that year by the General Electric Company, the Electric Bond and Share Company, and the Pennsylvania Power and Light Company, to learn the facts about natural lightning and means for protection against its disastrous effects. This investigation has been continued for 15 consecutive years.[2–8]

During 1926 the prevailing theory of lightning involved a bound charge on the earth due to cloud field, the sudden release of this charge, and generation of steep wave-front and high-voltage surges.[8] Because of this general conception overhead ground wires were not considered worth their cost, and tower-footing grounding was seldom talked of. The only investigational work up to this time had been carried out in laboratories, and was based on conjectured lightning strokes. Knowledge of the characteristics of natural lightning was very meager. By 1930, the direct stroke theory[10,11] was pretty well proved, and data on the remarkable effectiveness of overhead ground wires and buried tower footing grounding cables were being accumulated.

The lightning investigation which was in very large part conducted on the Wallenpaupack-Siegfried line had several closely interrelated aspects, namely:

1. Increasing insulation strength of line insulators and terminal equipment against flashover.

2. Spillway gap performance at terminals of line.

3. Dynamic current measurements at times of faults and estimation of fault locations.

4. Addition of means for shielding against lightning.

5. Lightning-arrester operation and performance.

6. Lowering structure-footing resistance by adding buried metallic cable.

7. Collection of detailed operating records relating to time of occurrence of flashovers and tripouts and to line construction in use.

8. (*a*) Field measurements at many locations along the line of magnitude, polarity, and wave front of surge voltages appearing on line conductors.

(*b*) Locations of structures hit by lightning and polarity of stroke current.

(*c*) Magnitudes and polarity of lightning currents in overhead ground wires, lightning rods, tower-structure members, and buried grounding cables.

(*d*) Instantaneous and integrated measurements of atmospheric voltage gradients and field strength, and induced voltages on aerial conductors.

9. Field measurements of lightning voltage and current wave shapes at attended laboratories located along the line, and which were equipped with cathode-ray oscillographs and surge-voltage recorders or rotating prism cameras.

Table I lists the principal measuring devices used. Since data obtained from these various sources usually have been from 5 to 15 years duration, and since additions and improvements to the line have been made in steps, and since careful analysis and detailed reporting of data have been made, a wealth of unique information exists, reliable in general to within 15 per cent.

The principal measuring devices used in large quantities in the field included:

1. The surge voltage recorder,[12,13] a clock-driven Lichtenberg figure camera used in conjunction with insulator string voltage dividers to indicate polarity, magnitude, and wave characteristics of lightning voltages on line conductors, and voltage-measuring antennas.

2. A simpler instrument without clock called a lightning-stroke recorder[14] was later used in large numbers to indicate surge polarity and location of strokes to structures.

3. A superior device using small magnetizable links called a surge crest ammeter[15,16] has given a wealth of information on lightning current magnitudes and polarity. Thousands of magnetic links have been employed on overhead ground wires, lightning rods, structure members, buried grounding cables, and lightning-arrester leads.

4. Other devices, such as the lightning severity meter and field intensity recorder. In addition, field laboratories[4,17,18] have been operated adjacent to the line during 1928 and 1929 near Wallenpaupack, during 1930 42 miles south of Wallenpaupack, and during 1939, 1940, and 1941, 12 miles south of Wallenpaupack on High Knob Mountain.

Table II lists magnitudes or range in value of various quantities measured on this line.

Table I. Principal Measuring or Counting Devices Used on or Adjacent to Wallenpaupack-Siegfried Line

Name	Purpose and Brief Description	Max. No. Used in Any One Year
Surge-voltage recorder	Lichtenberg figure camera with clock-driven film. For measuring polarity and magnitude of surge voltages on line conductors and elevated antennas	42
Cathode-ray oscillograph	Electron beam in vacuum chamber recording time-voltage graph on photographic film	2
Lightning-stroke recorder	Small and inexpensive surge-voltage recorder using stationary film	378
Field-intensity meter and rate of change of field meter	Light-beam recording on moving film, for recording atmospheric electric-field intensity, or rate of change of field	3 1
Lightning-severity meter	Modified Kodak recording on photographic film an integrated measure of light from neon lamp energized from antenna and recording atmospheric voltage. Not all used adjacent to Wallenpaupack-Siegfried Line	9
Surge indicator (flashover indicator)	Semaphore device with frangible link exploded by voltage drop across tower bridge, such as occasioned by insulator flashover. Exposed target easily visible to patrolman on ground	1,062
Surge-crest ammeter	Small laminated alloy steel cartridge held by wooden bracket in magnetic field surrounding conductor carrying lightning-surge current	1,000 Approx.
Graphic ammeter high-speed (Hall) recorder, or magnetic-oscillograph element	For recording dynamic current or voltage at line terminals at times of line faults	29

Paper 42-74, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 10, 1941; made available for printing December 19, 1941.

EDGAR BELL is engineer, system planning division, and F. W. PACKER is transmission engineer, both of the engineering department of Pennsylvania Power and Light Company, Allentown, Pa.

The success of this investigation has been due to the careful correlation between records of operating experience and the research measurements. One essential part of this investigation has been detailed information on insulator flashovers. During the fall of 1927 it became apparent that flashed insulators were not being properly recognized and reported, and so during 1928, 1929, and part of 1930 tower climbing patrols were made after every storm at every tower. In 1930 the surge indicator[4,14] had been invented. This was a device showing a large target to indicate insulator assemblies which had been subjected to high voltages. The surge indicator permitted overhead patrolling to be reduced to reasonable amounts and yet enabled practically all of the flashed insulator assemblies to be promptly found.

Table II. Maximum Magnitude or Range in Value of Lightning-Research Measurements Obtained on or Adjacent to Wallenpaupack–Siegfried Line

Potentials due to lightning	
Steel tower lines, conductors to ground	3,000 kv
Across 40 to 50 feet of vertical length of tower	50 kv approx.
Across 5 feet of earth near tower footing	Greater than 50 kv
Potentials due to switching	4.9 × normal crest line to neutral voltage
Attenuation of voltage surges	Proportional to ϵ^2
2,000-kv surge	to 1/2 value in 3.1 miles
1,000-kv surge	to 1/2 value in 6.2 miles
500-kv surge	to 1/2 value in 12.5 miles
Traveling waves due to lightning	
At end of line	
Time of crest	1 to 80 microseconds
Time to 1/2 value on tail	4 to 160 microseconds
At middle of line	
Time to crest	0.1 to 15 microseconds
Time to 1/2 value on tail	0.3 to 50 microseconds
Direct lightning stroke to line	$i = 300\epsilon^{0.8t}$ i = amperes t = microseconds
(Calculated from voltage oscillogram)	
1 microsecond	Current, 700 amperes; Rate of rise, 600 amperes per microsecond
5 microseconds	Current 16,000 amperes; Rate of rise, 13,000 amperes per microsecond
8 microseconds	Current 200,000 amperes
Atmospheric potential gradient	
Near earth at time of lightning strokes	Positive 180 kv per meter; Negative 270 kv per meter
Current due to lightning stroke	
(By surge-crest ammeter measurements)	
In tower structure*	Up to 140,000 amperes (approx.)
Probable stroke current**	Up to 218,000 amperes (approx.)
Polarity negative (neglecting trace records and very small strokes)	99 per cent

*Two other next highest records 102,000 and 108,800 amperes.

**Summation of 5 adjacent and associated records of 20,500, 57,700, 108,800, 14,800, and 16,500 amperes.

Another equally essential result of the investigation has been the obtaining of complete information on individual line tripouts, including time, relay operation, fault location, estimates from magnetic or cathode-ray oscillographs, actual fault locations, insulators flashed, surge voltages measured, lightning-stroke-recorder records, surge-crest-ammeter measurements, structure-footing resistances, and so forth.

The original 64.7-mile line without overhead ground wires operated very poorly for 1 1/2 seasons with 27 lightning tripouts.[18] In addition lightning caused a Wallenpaupack transformer to fail within 3 1/2 months, and a second transformer failed three weeks later. The line was then operated at 66 kv and all transformers at Wallenpaupack and Siegfried were rebuilt at the factory. All were found to be well along the road to failure, but since rebuilding and the installation of protective spillway gaps at their terminals, no more failures have occurred. During 1927, 24 line miles were equipped with conventional 184,000-circular-mil ACSR overhead ground wires spaced ten feet six inches above conductors at towers. Figures 1 and 2 show the general construction design. Lightning flashovers still occurred on the "protected" section, and the 1928 record for the entire line was 15 lightning tripouts, at least one of which was on the overhead ground-wire section. By this time other interconnected 220-kv lines, completely equipped with similar overhead ground wires were used, and during that year these circuits experienced 5 lightning tripouts.

It was evident and has since been thoroughly proved that overhead ground wires are very desirable but are not necessarily fully effective. The next move was to lower the resistance of tower-footing grounding. As an experiment a 2.6-mile long continuous 2/0 copper cable, buried where possible, and connecting 14 towers over High Knob Mountain,[5,18] was installed early during 1929. This region had still experienced flashovers, and during subsequent years lightning strokes of large magnitude have been measured to steel structures and overhead ground wires, and the effects of lightning strokes have been observed to nearby poles and trees. No insulator flashovers have occurred since this pioneer installation of continuous counterpoise was made, and it has proved to be an excellent investment, as well as serving as a model for other lines and other utilities.

By 1930 the single season's record was not accepted as proof that continuous counterpoise, averaging in length 1,040 feet per tower, was necessary, and so each structure in 16.8 miles of line having overhead ground wires was equipped with four 50-foot-long cables (crowfeet). During 1931 the remaining 4.6 miles of line having overhead ground wires were similarly equipped. Results to date have been excellent but not perfect. During 1936, 24 towers having the higher resistances had one cable per structure increased in length by 200 feet or to 400 feet of cable per tower, but these installations likewise have not had a perfect record of complete lightning protection. Figure 3 shows schematic plan views of tower-footing-grounding cable design.

During 1930 again as an experiment a 3.8-mile section of line was equipped with nonconventional elevated shielding wires,[18,19] insulated from the tower top and supported by 40-foot-long wood poles and four to six guy cables per structure, which were bonded to the tower base by long crowfoot-type cables. These "diverting cables" have had a perfect record for lightning protection, but experienced one mechanical failure, due to imperfection in a cable socket. Figure 4 shows the general design employed.

During 1938 and 1939 the 36.9 miles of line still unequipped with overhead ground wires were provided with buried galvanized three-eighths-inch steel continuous counterpoise cable, and the resulting low tower-footing resistances apparently avoided a few line flashovers. During 1940 and 1941 this section of line was also provided with two overhead ground wires of conventional configuration and elevation above line conductors.

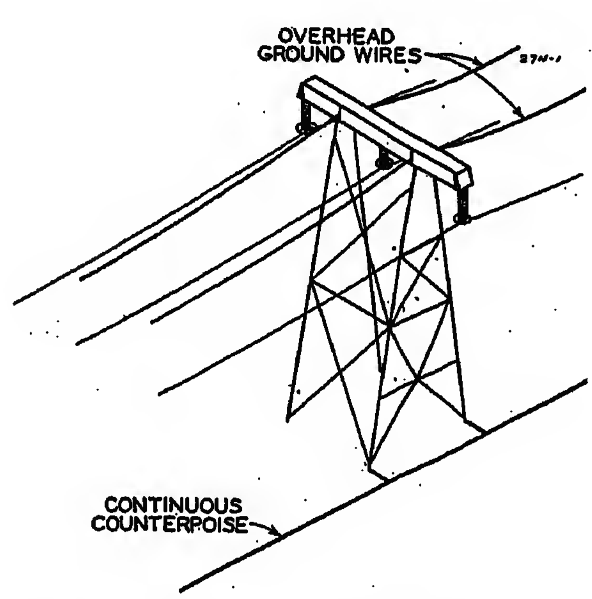

Figure 1. Configuration of conventional overhead ground wires and continuous counterpoise at standard suspension structures of Wallenpaupack–Siegfried line

Figures 2 and 5 show the design employed to support the overhead ground wires at standard suspension structures and at mast structures, respectively. Since the completion of the overhead ground wire no tripouts or flashovers have been experienced on the entire Wallenpaupack-Siegfried line. Inasmuch as this line is now completely equipped with overhead ground wires, with 39.5 miles of continuous counterpoise, and all structures in the remaining 25.2 miles having noncontinuous grounding cables which have a record of avoiding all but three or possibly five flashovers during 11 to 12 years, it is anticipated that the future lightning record of this line will be nearly ideal.

Of the references cited number 18 gives an excellent summary of the investigation up to 1938, including history, construction, photographs, measurements, results, and conclusions, and the reader is urged to refer to it.

Overhead Ground Wire and Buried Tower-Footing-Grounding Cable Construction

In Table III are listed data on lengths of line equipped and construction details. Of particular interest is the fact that the 1940–41 overhead ground wires were installed at 40 per cent of the estimated cost of duplicating 1927 construction. This saving was the result of a combination of circumstances. The selection of smaller and lighter conductor resulted in not only a saving in the cost of conductor material, but sufficient reduction in transverse loading on the suspension towers so as not to require any strengthening in order to maintain the desired factor of safety. The conductor selected was also of sufficient mechanical strength to maintain proper sag and clearance characteristics with a normal tension of 16 per cent of the ultimate which was felt to be well within the limits necessary to prevent any damage from high-frequency vibration.

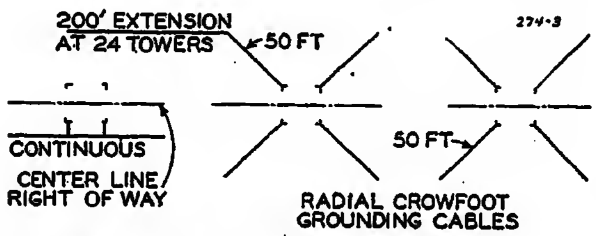

Figure 3. Plan of various tower-footing-grounding cable designs used on Wallenpaupack–Siegfried line. For diverting cables see Figure 4

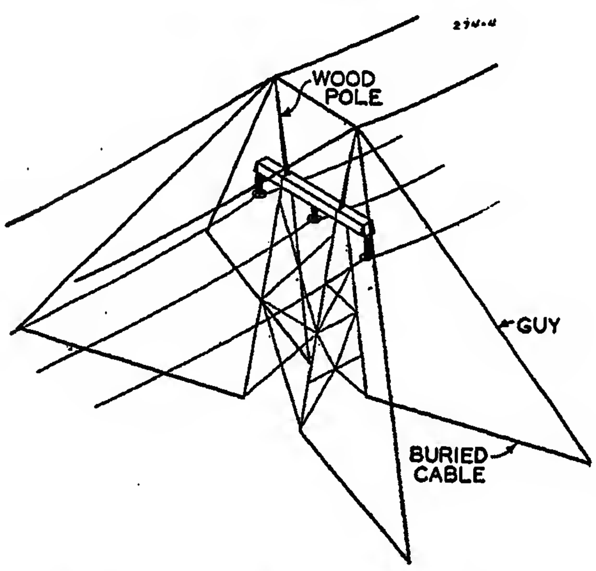

Figure 4. Configuration of 1930 lightning-stroke diverting cables, employing two wood poles to support and insulate the overhead ground wires from the structure

The mast type of structure used at angle locations as well as on very long spans necessitated a special design of additional structure due to the fact that operating conditions made it imperative that the line be restored to service every evening. The existing mast structures supporting the conductors could not be dismantled, lengthened, and rebuilt as was done during 1927. The design finally selected called for a pair of guyed steel masts, installed entirely independent of the existing triple mast structure, and supporting the overhead ground wires in their proper positions by means of a bridle arrangement. These 11 pairs of new steel masts were installed at approximately 40 per cent of the 1927 cost of dismantling and reconstructing existing mast structures. The bridle arrangement also provided excellent shielding over all the dead-end insulator assemblies at these points.

For counterpoise the use of galvanized steel has the advantage of reducing material costs over copper or other acceptable material, minimizing danger of theft (which generally exists where copper or copper-coated steel conductor is used), and providing grounding facilities at least very nearly as good as and possibly better than with smaller-size conductor ma-

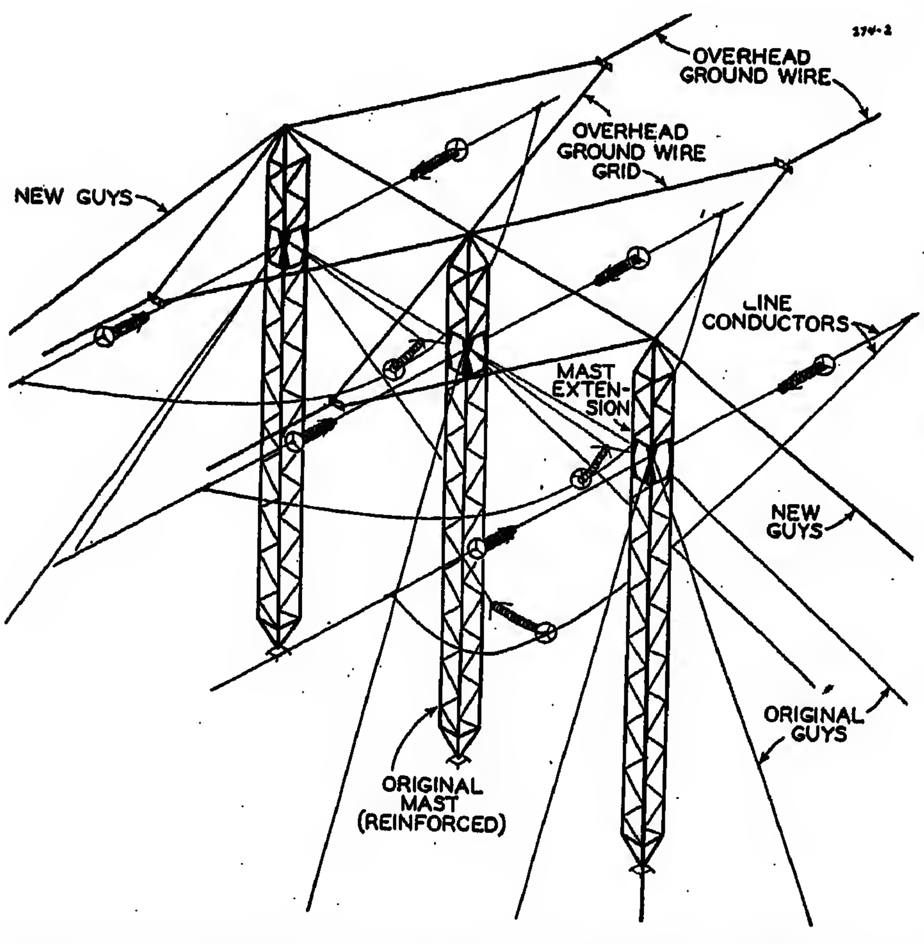

Figure 2. Configuration of overhead ground wires installed during 1927 at mast structures. These structures were rebuilt, strengthened, and lengthened

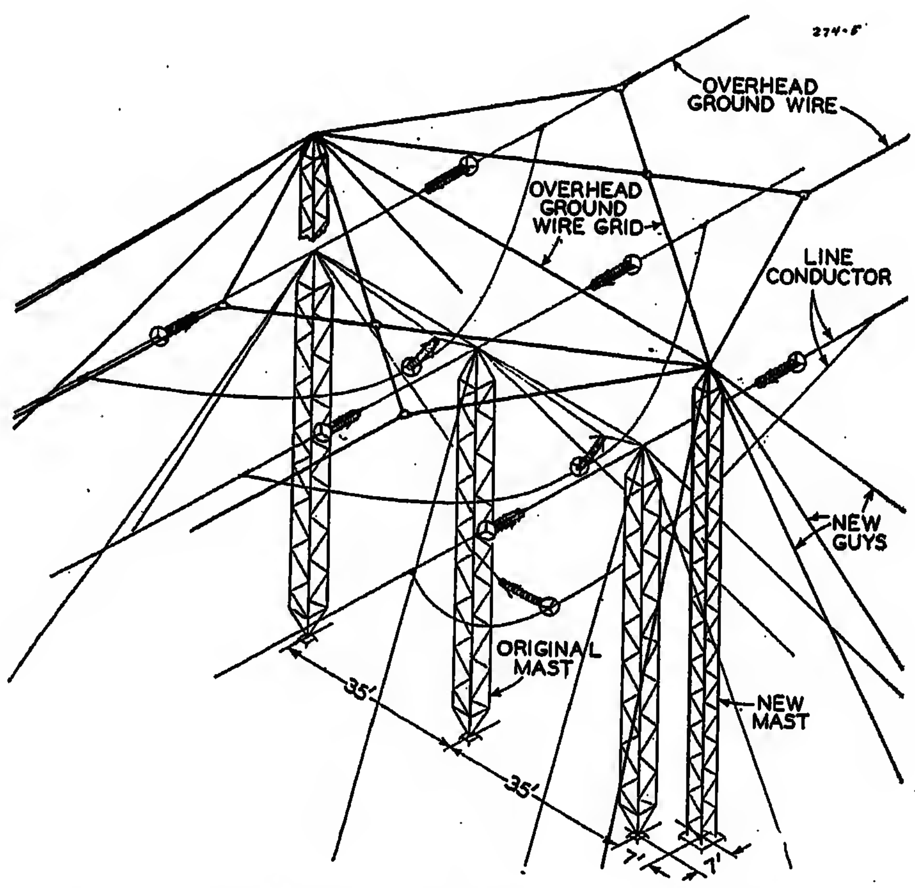

Figure 5. Configuration of overhead ground wires installed during 1940 and 1941 at mast structures. The original structures and guys were not altered. The additional masts and guys are entirely independent and self-supporting structures

terial. It is believed that this steel cable will function adequately for many years.

Tripouts of Wallenpaupack–Siegfried Line

During 1932, 47.1 additional circuit miles were added to the original 64.7 miles. The new circuit extended from Bushkill (roughly midway between Wallenpaupack and Siegfried) to Roseland, N. J. During 10 years, 9 tripouts occurred on the new circuit, and during 16 years, 295 tripouts occurred on the original circuit. Of these latter, 8 occurred on overhead ground-wire sections as follows:

1—Caused by sleet on line conductors (1933).

1—Caused by diverting guy-cable failure (1938).

3—Caused by direct lightning strokes before tower-footing grounding had been improved (1928, 1929, 1930).

2—Caused by direct lightning strokes after tower-footing grounding had been improved (1930, 1932).

1—Same as above, except that it also involved mechanical failure of an insulator assembly (1939).

Of the remaining 287 faults, 20 were caused by incorrect relay operation, operating mistakes, foreign objects against line conductors, system instability, or other causes, and one involved mechanical failure of an insulator assembly caused by a direct lightning stroke. Most, if not all of the rest, totaling 256 tripouts were caused by direct lightning strokes to unprotected line conductors. No permanent damage ever resulted except burns on insulators and occasionally shattered porcelain which was replaced later on a maintenance schedule.

In 1928, 1930, and 1932, other 220-kv circuits, totalling 283.7 miles equipped with twin conventional ACSR overhead ground wires, were placed in 220-kv interconnection service. On these, 98 tripouts have occurred at a rate of 2.7 tripouts per 100 circuit miles per year. The majority of these faults was caused by lightning. For the Wallenpaupack-Siegfried line where overhead ground wires were in use, 3 faults in 3 years were occasioned by lightning prior to installation of improved grounding and 3 faults in 11 years were caused by lightning subsequent to installation of crowfoot grounds. These figures reduce to 4.6 and 1.3 tripouts per 100 circuit miles per year and substantiate the conclusion that the Wallenpaupack-Siegfried line is subject to lightning and that, although once very vulnerable, is now well shielded.

Performance of Buried Tower-Footing-Grounding Cable

In reference 7, Tables II through V, and Figures 1 and 2, data are presented on lightning-current measurements in lightning rods, overhead ground wires, tower-structure members, and buried cables. Measurements have not been made directly of current flowing through tower footings, but measurements of currents in structure members and buried grounding cables show:

(*a*). Continuous counterpoise conducts up to 75 per cent and on the average 58 per cent of the total structure current; noncontinuous crowfeet conduct 11 to 48 per cent of the total structure current depending upon their lengths, and combinations of four crowfeet per structure conduct 42 to 70 per cent of the total structure current.

(*b*). The presence of continuous counterpoise causes 77 to 83 per cent of the total structure current to crowd to that side of the tower. Since the counterpoise conducts 58 per cent of this current, the footings must conduct the remainder or 19 to 25 per cent as compared with 17 to 23 per cent for the other two footings. The presence of one 250-foot crowfoot and three 50-foot crowfeet causes 52 to 58 per cent of the total structure current to crowd to the tower corner having the long crowfoot and leaves 14 to 16 per cent of the tower current in each of the other corners. Since the crowfeet conduct 70 per cent of total structure current, the remaining 30 per cent is distributed among the four footings, and there seems to be no tendency for any one footing to conduct more current than any others.

From these measurements it might be concluded that noncontinuous crowfoot cables are all that are required to produce ideal grounding, and that they are superior to continuous counterpoise. A number of other factors should be mentioned and may help explain why continuous counterpoise so far has a perfect performance record, whereas noncontinuous crowfeet cables have not; why we feel that economically continuous counterpoise is best suited to our conditions; and why we prefer this method of grounding on our 220-kv and 66-kv lines.

1. The 13-year record from High Knob is for continuous cable installed over a stony mountain where lightning has long been known to be prevalent. The cable is not buried at all locations. The inherent tower-footing resistances range from 50 to 148 ohms. The three largest lightning-rod current measurements were 57,000, 62,000, and 65,000 amperes. For this 14-tower section during 1926 (with no overhead ground wire or counterpoise in use) at least 6 insulator assemblies were flashed. During 1927 and 1928, 23 more flashed insulator assemblies were found. Overhead ground wires were in use for about three-fourths of this time and at least two of the flashovers occurred during 1928, while overhead ground wires were in use, but prior to installation of counterpoise. For the seven-year period, 1935 through 1941, at least 25 large lightning strokes have been measured; 21 ex-

Table III. Data on Overhead Ground Wires and Buried Tower-Footing-Grounding Cable Installations

Overhead Ground Wires			
Year installed	1927	1930	1940–41
Length in miles	24.0	3.8	36.9
Conductor material	ACSR	ACSR	Copperweld
Conductor size	184,000 cir mil	184,000 cir mil	7/16 inch special E.H.S. 7 strand
Spacing between cables	22 feet-7 inches	38 feet	22 feet–7 inches
Elevation above conductors at suspension towers	10 feet-6 inches	50 feet	10 feet-6 inches
Percentage suspension towers requiring strengthening	100	100	0
Percentage mast towers requiring rebuilding	100		0
No. suspension towers equipped	115	18	160
No. mast towers equipped	4	0	11
Percentage of towers where Stockbridge dampers were applied to line conductors and overhead ground wires	100	0	0
Tower-Footing-Grounding Cable			
Year installed	1929	1930–31	1938–39
Length in miles of line equipped	2.6	25.2	36.9
Number of structures equipped	14	123	171
Conductor material	Copper	Copper	Galv. steel
Conductor size	2/0 Stranded	2/0 Stranded	3/8″ Stranded
Nomenclature	Counterpoise	Crowfeet	Counterpoise
Configuration	Continuous along one side of line and bonded to 2 tower footings	4 50*-foot-cables perpendicular to each other	Continuous along one side of line and bonded to 2 tower footings
Depth buried	About 1 foot	About 1 foot	About 1 foot in wooded areas, and 1½ to 2 feet elsewhere
Extensions added**	None	To 24 towers	To 5 towers

*At 18 structures equipped with 1930 diverting cables, crowfoot cables were much longer in order to connect with the guy-cable anchors. Two structures had 6 guys and 6 cables.

**Extensions added to crowfeet consisted of 200 feet of cable added to one of the 4 existing cables. Extensions added to counterpoise consisted of two 250-foot-long crowfeet per structure.

ceeded 20,000 amperes, 8 exceeded 40,000 amperes, 2 exceeded 60,000 amperes, and the highest was 70,000 amperes.

2. The record of noncontinuous crowfoot-type cable shows three flashovers during two years before cables were installed and five flashovers during the 10- to 11-year period since cables were installed. Three of these latter flashovers caused line tripouts, but two apparently did not. In no case are lightning-current measurements available. In the last case (1939), an insulator-assembly failure also occurred at a tower having originally 114 ohms resistance. The failure was due to the spreading of a cracked insulator cap at the time of an unusually severe lightning stroke, but it is not certain that this insulator failure and line tripout would have occurred, had the insulator cap been in perfect condition, and it may be that the long crowfoot cables would, otherwise, still have a perfect performance record.

3. At the time the High Knob counterpoise and crowfoot cables were installed, 2/0 copper conductor was used, and it was all installed by hand labor (pick and shovel). In recent years it has been felt that galvanized steel counterpoise is perfectly satisfactory, and the 1938–39 installation consists of 36.9 miles of three-eighths-inch Siemens Martin stranded guy wire. It was, in general, installed by means of a tractor and special "counterpoise plow," which digs a trench 18 to 24 inches deep, lays the cable, and partly backfills the trench. The labor and material cost of installing galvanized steel radial crowfeet exceeds the labor and material cost of installing such a counterpoise.

4. Since the Pennsylvania Power and Light Company is not confronted with exceptionally dry and sandy soil conditions where deeply driven rods may be superior to buried cable, and since, except in very rare cases, no additional grounding is required beyond that provided by a single continuous counterpoise, we feel that, for our conditions, such installations are both electrically and economically ideal. For towers having exceptionally high footing resistance, supplementary grounding can be added. This was done for five towers over a mountain where the underlying strata are of slate formation and where resistances were 200, 237, 319, 165, and 329 ohms.

Another factor which may help explain the performance of continuous counterpoise is that current measurements are obtained at many towers, even seven or eight towers distant from the stroke, or $1^1/_2$ miles away in both directions. These measurements show a definite division of current at each structure, with part of the incoming current diverted up the structure and the remainder flowing in the counterpoise toward the stroke. At the end of the span, the counterpoise current is increased by current picked up from the earth. This current increase is of the order of 10,000 amperes in the span nearest the stricken tower, and drops to 1,000 amperes three or four spans away. In a similar manner, the overhead ground wire currents increase at each tower by the amount going up the structure, and thus serve to conduct currents as high as 30,000 or more amperes in stricken overhead ground-wire spans, and currents on the order of 10,000 amperes for strokes to structures.

On the other hand, where crowfoot cables are used, measurable currents in crowfeet are usually limited to 3 or 4 structures instead of 12 to 14 structures. Continuous counterpoise thus enables the lightning stroke to be fed by many multiple grounds (for example 10,000 to 14,000 feet of buried cable and 50 or more tower footings) rather than by 1,000 to 2,000 feet of cable and 12 to 16 tower footings. Current measurements obtained since 1933 when plotted on charts similar to Figures 1 and 2 of reference 7 are very striking. They confirm our belief that continuous counterpoise is a very effective device for conducting lightning currents and keeping tower-footing potentials low, and that continuous counterpoise is adequate for our conditions.

Summarized Results

1. Lightning-surge voltages were early found to be caused by negative strokes in almost every case. Practically every positive-voltage record was found to have occurred at time of insulator flashover at the tower and line conductor to which the surge-voltage recorder was connected. Such positive voltage records were caused by the recorder and earth being temporarily positive with respect to the stricken line conductor. Many thousands of surge-crest-ammeter records have likewise rarely indicated positive lightning strokes and never any of large magnitude.

2. Measurements of induced voltages, or usually failure to obtain measurements of induced voltages and absence of flashovers which were not clearly associated with direct lightning strokes, showed 12 to 15 years ago that induced lightning voltages are insufficient to cause trouble on lines insulated for 220-kv operation.

3. Hundreds of measurements of voltage across 40 to 50 feet of structure steel seldom indicated voltages exceeding 40 kv, and practically never indicated voltages exceeding 50 kv, and showed that most of the rise in tower potential at times of lightning strokes occurred in the earth surrounding the footings.

4. Twenty-eight measurements of voltage in the earth around tower footings at times of lightning-current discharge indicated that 20 per cent of the potential drop from tower to true earth, exists within five feet of the footings. The voltage across five feet of earth exceeded 50 kv and 40 kv for seven and five cases, respectively. In eight other cases the discharge seemed to be of long continued duration rather than a rapid and violent impulse.

5. Well-defined lightning-current measurements show that strokes either contact structures directly or else one (but not both) of the overhead ground wires between structures. For unprotected sections of line, it was early found that the middle conductor rarely flashed over, but that the outer conductors (and particularly the conductor nearest to approaching storms) experienced frequent flashovers. Furthermore, nearly all flashovers were confined to one conductor with two flashed assemblies (one at each of two adjacent structures) being the usual condition.

6. No flashovers are known to have occurred to overhead ground-wire structures of the Wallenpaupack-Siegfried line having meggered tower-footing resistances of less than 13 ohms. For towers of about 20 ohms resistance, strokes up to 50,000 amperes usually if not always are safely conducted, and strokes up to 100,000 amperes have been safely conducted occasionally.

7. Increasing the number of insulator units on outside conductors from 14 to 16 during 1929 and 1930 resulted in no discernible improvement. After the two transformer failures during 1926 and examination of the remaining transformers, all eight single-phase units were rebuilt, and spillway protective gaps set at $42^1/_2$ inches were installed on each phase conductor near their terminals. No transformer failures have since occurred, and periodic examination has disclosed no more lightning damage, but spillway gap flashovers were frequent at Wallenpaupack until 1934 when 220-kv lightning arresters were in successful operation. Since then three spillway gap flashovers have occurred, but none were on the two protected phases. Of 15 arrester current discharges measured, 6 exceeded 1,500 amperes.

8. During 1930 fault location was facilitated by cathode-ray oscillograph measurements of the time between surge reflections from the faults and from line terminals. Since that time fault-location estimates have been made by relating dynamic-current measurements obtained at Wallenpaupack, Siegfried and Roseland substations.

9. Many cathode-ray oscillograph time-voltage records were obtained during 1928, 1929, and 1930 of lightning voltages on line conductors. The first oscillogram of this nature was obtained during 1928 at the Wallenpaupack laboratory. Another was occasioned during 1930 by a typical negative stroke close to the oscillograph, and, contacting the conductor to which it was coupled, and, causing line insulation flashover less than 100 feet away showed a negative rise in voltage exceeding 2,760 kv and with a rate of rise of 1,540 kv per microsecond between the ranges of 750 and 2,760 kv. This record is believed to be the only one of its kind ever obtained.

10. Unfortunately, the High Knob lightning laboratory equipped with a cathode-ray oscillograph and special cameras has failed to obtain any important data. This has been due to failure of strokes to contact the lightning rod on the structure over the laboratory building, or the overhead ground wires within one span, during periods of laboratory operation. The lightning rod

on the laboratory tower was struck during 1936, 1937, 1938, and 1939 by negative strokes measuring 33,000, 62,000, 38,000, and 17,400 amperes, and strokes measuring 15,000 and 47,000 amperes occurred to the overhead ground wires in the immediately adjacent spans during 1936 and 1938. Of the 25 large strokes measured to the counterpoise section of line between 1935 and 1941 13 were to lightning rods on the five towers atop High Knob summit.

11. None of the measuring devices or auxiliary equipment used has ever caused a service interruption, and none has ever failed with the exception of a few lightning-stroke recorders connected to measure voltage near tower footings.

Lightning Investigation at High Altitudes in Colorado

L. M. ROBERTSON
MEMBER AIEE

W. W. LEWIS
FELLOW AIEE

C. M. FOUST
MEMBER AIEE

I. Introduction

THE operation of transmission and distribution lines in the high altitudes of the Rocky Mountain region had indicated that lightning strokes were not so severe as at lower altitudes. Also glow discharges or corona currents from the earth have been observed at high altitudes from pointed objects and rocks. This investigation was made to determine the probable lightning current at altitudes from 6,000 feet to 13,500 feet and to measure corona current. It has been found that the probable stroke current decreases with increase of altitude from sea level to approximately 18,000 feet altitude at which point it appears that no current would be present. The highest mean temperatures at 18,000 feet do not exceed 32 degrees Fahrenheit, and comparison of temperatures in free air at altitudes up to 13,500 feet check temperatures on the earth's surface and indicate that freezing temperatures may limit the formation of lightning.

Measurements of corona current from the earth during lightning storms indicated as much as 480 microamperes with a potential gradient of 94 kv per foot.

II. Description of Line and Territory

The Shoshone–Denver 100-kv transmission line of the Public Service Company of Colorado was constructed in 1908 and 1909 on steel towers and is not equipped with overhead ground wires. However, a single continuous counterpoise wire has been installed from Leadville to Denver and a double counterpoise over the high passes at Argentine and Hagerman. Figure 1 shows a profile of the line and the location of the counterpoise wire and magnetic links. These counterpoise wires are buried in the ground to a depth of approximately one foot wherever possible. The line passes through the heart of the Rocky Mountains starting at Shoshone Plant at an altitude of 6,000 feet and terminating at Denver at an altitude of 5,280 feet, passing over the Continental Divide three times: Hagerman Pass, altitude of 12,000 feet; Fremont Pass, altitude of 11,300 feet; and Argentine Pass, at an altitude of 13,500 feet. The average altitude of the line is about 10,000 feet.

The type of territory varies widely from plains and hills to rugged mountains and includes cultivated lands, sand and gravel, and various rock formations, some of which are mineralized.

III. Measurements and Measuring Equipment

It had long been noted that lightning strokes at high altitudes did not appear to be so destructive as at lower altitudes, as indicated by the operation of transmission and distribution lines and it was assumed that the currents in lightning strokes might be smaller. Measurements were started in 1937 by installing surge-crest ammeter links on some of the towers. The complete investigation was underway in 1938 with brackets on certain towers where past experience had indicated the most lightning activity, and brackets were placed on the counterpoise on most of its length. The surge-crest ammeter links have been described elsewhere.[1] In some cases a complete installation of brackets was made on a tower which included four legs and eight braces. Figure 2 shows one of the typical towers with brackets on one of the legs and two braces.

In 1940 a corona and surge-voltage-recording installation was made on top of Argentine Pass at 13,500 feet elevation, and a similar installation a few miles west of Denver at about one mile elevation.

The installation at Argentine Pass is shown in Figure 3, and the connection arrangement in Figure 4. To measure corona currents at the tip of the lightning rod, a recording microammeter was connected between the lightning rod and the ground. For protection of the microammeter should a direct stroke hit the

L. M. ROBERTSON is transmission engineer in charge of transmission and station engineering, Public Service Company of Colorado, Denver, Colo. W. W. LEWIS is transmission line engineer, central station engineering department, and C. M. FOUST is of the general engineering laboratory, both with General Electric Company, Schenectady, N. Y.

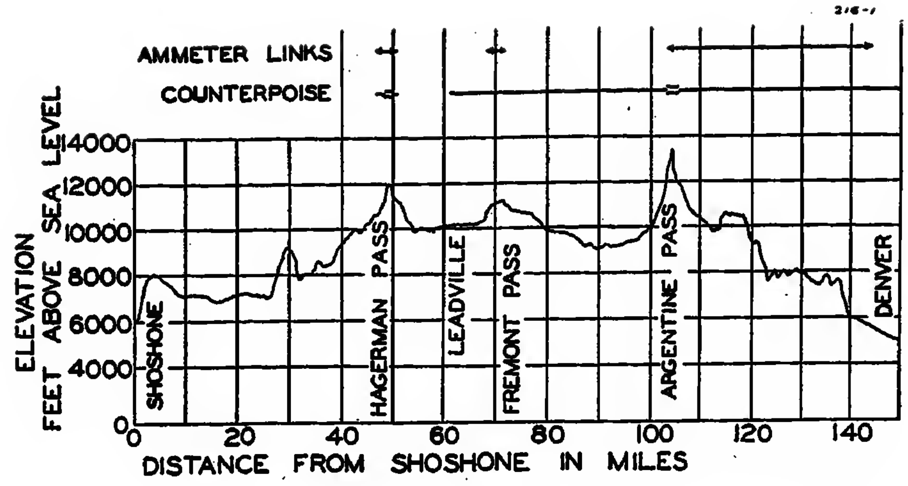

Figure 1. Profile of Shoshone–Denver 100-kv transmission line, showing ground elevation above sea level, and location of counterpoise and surge-crest ammeter links

lightning rod, an inductance was connected in series and a protective gap in parallel. Lightning-rod discharge currents are a measure of cloud field gradient at the earth's surface. Accordingly, current measurements were especially desired immediately before and after direct lightning strokes. To record the time of such strokes and to measure crest-current values a series resistance was inserted in the lightning-rod circuit and a surge-voltage recorder connected across this resistance. Magnetic links were mounted on the lightning-rod down lead to obtain a check reading of crest-current values. The recording microammeter was adjusted to indicate both positive and negative currents. The surge-voltage recorder, because of its double polarity registration characteristics, was capable of measuring crest-current values of either positive or negative lightning strokes.

With one such installation at the high elevation of Argentine Pass, one at the medium elevation of Denver, and a third at a much lower elevation on a line in Eastern Pennsylvania, it was planned to obtain data on discharge levels and polarities over a wide range of elevations. Accompanying this program of field-data taking is a laboratory investigation in which the discharge characteristics of points under different conditions of electric field configuration are being studied.

IV. Direct-Stroke Record

After each lightning storm the transmission-line patrolmen checked the magnetic links, and those which were magnetized were sent into the central office where they were calibrated and each case studied to determine the tower and stroke current. This information was co-ordinated with the patrolman's observations of the time of day of the lightning storms and location along the line. This was checked with the records and oscillograms of Petersen coil operations and line tripouts. In this way it was possible to locate where one-phase-to-ground, two-phase-to-ground, and three-phase faults occurred and to determine tower and stroke current for each case. After the stroke current was calculated the altitude of the tower was determined, and a point was plotted on Figure 5 which shows stroke-current values against altitude. Table I shows a summary of the stroke currents for various altitude groups, namely, 6,000 to 8,000 feet, 8,000 to 10,000 feet, 10,000 to 12,000 feet, 12,000 to 14,000 feet, for the four years 1938 to 1941 inclusive. Each one of these groups was analyzed individually to determine the probable stroke current in the group.

The probable stroke current curves are shown in Figure 6. The upper curve has been presented by Lewis and Foust[2] and was derived from investigations made at altitudes below 2,100 feet. It has been used to represent conditions at low altitudes. The other curves indicate the probable lightning current as derived from the Colorado investigation for three altitude groups as well as a summarizing curve for this investigation, extending from 6,000 to 14,000 feet. The curves indicate a decrease in probable stroke current with increase in altitude. This conforms to observations over 30 years of operation in this district.

The curves in Figure 6 were studied to determine the relation of this decrease of current with the increase of altitude. This was done by selecting the values of current on the five per cent abscissa line for the various altitude group curves of Figure 6. Thus were obtained the four points in Figure 7 marked with circles, including one point at sea level, one at 7,000 feet, one at 11,000 feet, and one at 13,000 feet, and curve A was drawn through these points. The average altitude for each group was used as the ordi-

This also shows the current for various percentages of maximum current at the same altitudes

nate. In obtaining the point in Figure 7 marked with a square, the value of current which the highest five per cent of all observed strokes exceeded was plotted against the average of the altitudes at which occurred the strokes in this highest five per cent. Line *B* was then drawn from the five per cent value for sea level, obtained from the upper curve of Figure 6, through this last point marked with a square. This line intersects the zero current at about 18,000 feet.

It will be noted in Table I that the greatest number of strokes observed was in the group from 6,000 to 8,000 feet altitude. Also, it can be noted in Figure 7 that the five per cent point for this altitude group is the closest to line *B*. This shift of the points in the various altitude groups has been noted from year to year and it is assumed that with a larger number of observations the two lines would approach an intermediate line indicated as line *C* of Figure 7. The same procedure was used for the highest 10 per cent, 15 per cent, 20 per cent, and 40 per cent of the stroke currents, and the resulting curves are plotted on Figure 5. All of these lines of Figures 5 and 7 appear to intersect the zero current at about 18,000 feet altitude. This had been noted in 1938 and has continued through each year of the investigation. It therefore appeared to be of interest to attempt to verify this indicated absence of lightning above 18,000 feet and to attempt to find an explanation.

V. Temperature Observations

Temperature is one of the factors which decreases with increase of altitude, and studies were made to determine the relationship which this might bear to the conclusions previously mentioned. A graphic thermometer was set on top of Argentine Pass during the summer of 1941 to obtain temperatures at 13,500 feet, since the highest altitude for which Weather Bureau information is available is at Leadville which is at an altitude of 10,200 feet. Data were also obtained from the Denver weather bureau of temperatures in the upper air as obtained by balloon sondes and described elsewhere.[3] Data for the year October 1940–September 1941 are presented in Table II. The straight lines in Figure 8 indicate, for example, the variation of temperature with altitude from the balloon readings for three days in July 1941. The corresponding mean temperatures for Argentine Pass, Leadville, and Denver are also indicated. It will be noted that the temperature in free air corresponds rather closely with temperatures at the three locations just mentioned. In Figure 9 are similar average curves for each month of 1941 and for the year, plotted from the data of Table II. This figure indicates that the mean temperatures on the earth at any particular altitude correspond very closely to those at the same altitude in free air, and it appears that the temperature which might exist at altitudes on the earth at 18,000 to 20,000 feet would be as indicated in Figure 9. This shows that at this altitude the temperature never exceeds 32 degrees Fahrenheit, which may be a significant fact.

Minser obtained observations from airplanes,[5] and Figure 10 is a generalized

Figure 6. Cumulative curves of probable stroke currents from 734 strokes on transmission lines at low altitudes,[2] and 145 strokes to the Shoshone–Denver 100-kv transmission line at altitudes from 6,000 to 13,500 feet

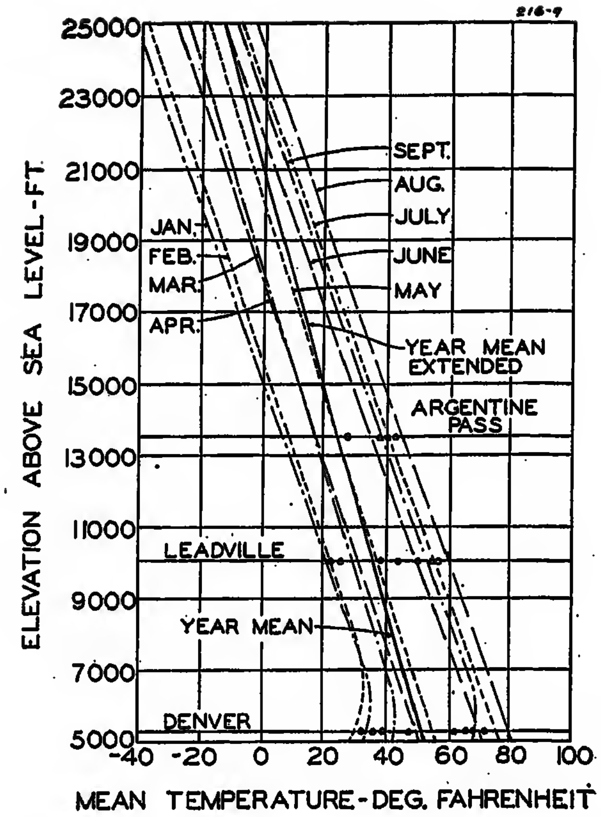

Figure 9. Balloon sonde mean temperatures above Denver for January through September, and for the year 1941, for altitudes up to 25,000 feet, and mean temperatures for same months at Denver, Leadville, and Argentine Pass

diagram showing that at altitudes between 12,000 and 20,000 feet there is a mixture of sleet and water with temperatures between 32 degrees Fahrenheit and −6 degrees Fahrenheit. This region of somewhat mixed charge lies between the upper region predominantly positive and the lower region predominantly negative. From an analysis of a large number of actual cases, he found that lightning discharges to aircraft in flight occur most frequently in the zone adjacent to the freezing isotherm, that is, from 26 degrees Fahrenheit to 34 degrees Fahrenheit. The mean altitude at which discharges to aircraft were encountered was 10,000 feet with a maximum of 18,000 feet and a minimum of 2,000 feet, with no one level predominant.

Simpson and Scrace[6] also found by sending up balloons that a separation of charges in the cloud takes place, the lower portion of the cloud being predominantly negative and the upper portion predominantly positive, and that the region of separation between the negative charge and the upper positive charge occurs at a level where the temperature is between −10 degrees centigrade and −20 degrees centigrade (14 degrees Fahrenheit and −4 degrees Fahrenheit), as shown in Figure 11. The recording thermometer on Argentine Pass near the microammeter showed temperatures ranging from 26 degrees Fahrenheit to 51 degrees Fahrenheit at times when records of corona discharge were obtained.

Transmission line patrolmen have observed for a long time that lightning might occur in a snow storm, but it had also been noted that under these conditions the temperature was near freezing and accompanied by wet heavy snow. This has taken place at all altitudes.

All of these observations indicate some correlation between temperature and altitude and the presence or absence of lightning discharges, but the exact relation is still somewhat obscure. However, the observations do indicate that freezing temperatures may limit the formation of lightning.

Another set of contributing factors pertinent to the decrease of lightning current with altitude are the following: The breakdown strength of air decreases about three per cent per 1000 feet, so that at the altitudes of this investigation the breakdown strength of air varies between approximately 60 and 80 per cent of the sea level value. With less voltage available between cloud and earth, it would be expected that the lightning-current values would be lower. Furthermore, it is possible that in some cases the line itself is very close to the cloud, if not in the cloud. In such cases the difference of potential between cloud and line would be very small. In such high altitudes many discharges would be expected, each of small current magnitude, and further, some altitude would be reached at which disruptive discharges would be of insignificant proportions. This is for the reason that the projection of the mountains into the cloud regions limits the accumulation of charges by increasing cloud-to-ground leakage, at the same time precipitating discharges before cloud charge can build up to average low-altitude lightning proportions.

VI. Effective Counterpoise Resistance

Tower-footing resistance tests were made in 1934, using ground Megger, before counterpoise wires had been installed. This was a very dry year with only 8.93 inches precipitation which was 63.5 per cent of normal. Tests were made on various towers ranging in altitude from 6,000 to 13,500 feet and located in various types of earth including clay or loam, sand and gravel, and rock. The resistances are plotted in Figure 12 against altitude and found to vary from 40 ohms to 950 ohms. The same towers were tested again in 1935 when the precipitation was 17.2 inches or 21.8 per cent in excess of normal. The results are also plotted in Figure 12 and show that the resistance varies from 30 ohms to 360 ohms. These curves indicate that the moisture had a considerable influence on resistance values. The curve also shows that the resistance increases with increase in altitude. This may be accounted for by washing of salts from the ground by rains and snow and by the high-resistance type, of rocky territory encountered at high altitudes.

During the course of observation of lightning strokes and their measurements, the record of the one-phase-to-ground, two-phase-to-ground, and three-phase faults was noted. This was obtained from automatic oscillograph, Petersen coil operation, and relay indications. The line operation was co-ordinated with the stroke measurements to determine what type of fault occurred. For the four years covered by the investigation, 145 strokes were recorded, of which 56 produced single-phase-to-ground faults, 20 two-phase-to-ground and 5 three-phase faults, 64 strokes were observed where no line faults were produced. It is probable that a majority of the strokes occurred to a conductor, thus causing flashover at an adjacent tower, sometimes with very little current in the stroke. If the stroke current were of sufficient magnitude so that the product of current times footing resistance exceeded the flashover of the insulator strings, then one or two additional phases might flashover, possibly influenced by the phase position of the generated voltage. Strokes to towers would flash over one, two, or three phases, if the tower were raised in potential above the insulator string flashover, the number of phases depending on the condition of the individual strings and the phase position of the generated voltage.

Table III shows the length of counterpoise at which readable values of current were read. These distances are plotted against current magnitude in Figure 13. This figure indicates that the greater the lightning current the greater the distance readable current was carried by the counterpoise. A possible explanation for this is that the larger current values are associated with more extensive clouds. The electrostatic field under these clouds covers a large area, and on the occurrence

Triangle points are from Table III

of a stroke, thereby collapsing the field, current flows from the entire area into the stroke. Much of this current makes its way to the extensive counterpoise system, which offers a low resistance path to the tower involved in the stroke. However, since only a portion of the entire counterpoise is involved with any one cloud, the effective resistance of the counterpoise is always somewhat greater than indicated by Megger measurements, which presumably include the entire length of counterpoise.

VII. Cloud-Field Current Measurements

Investigational work on the high altitude Shoshone–Denver line provided an excellent opportunity to study discharge

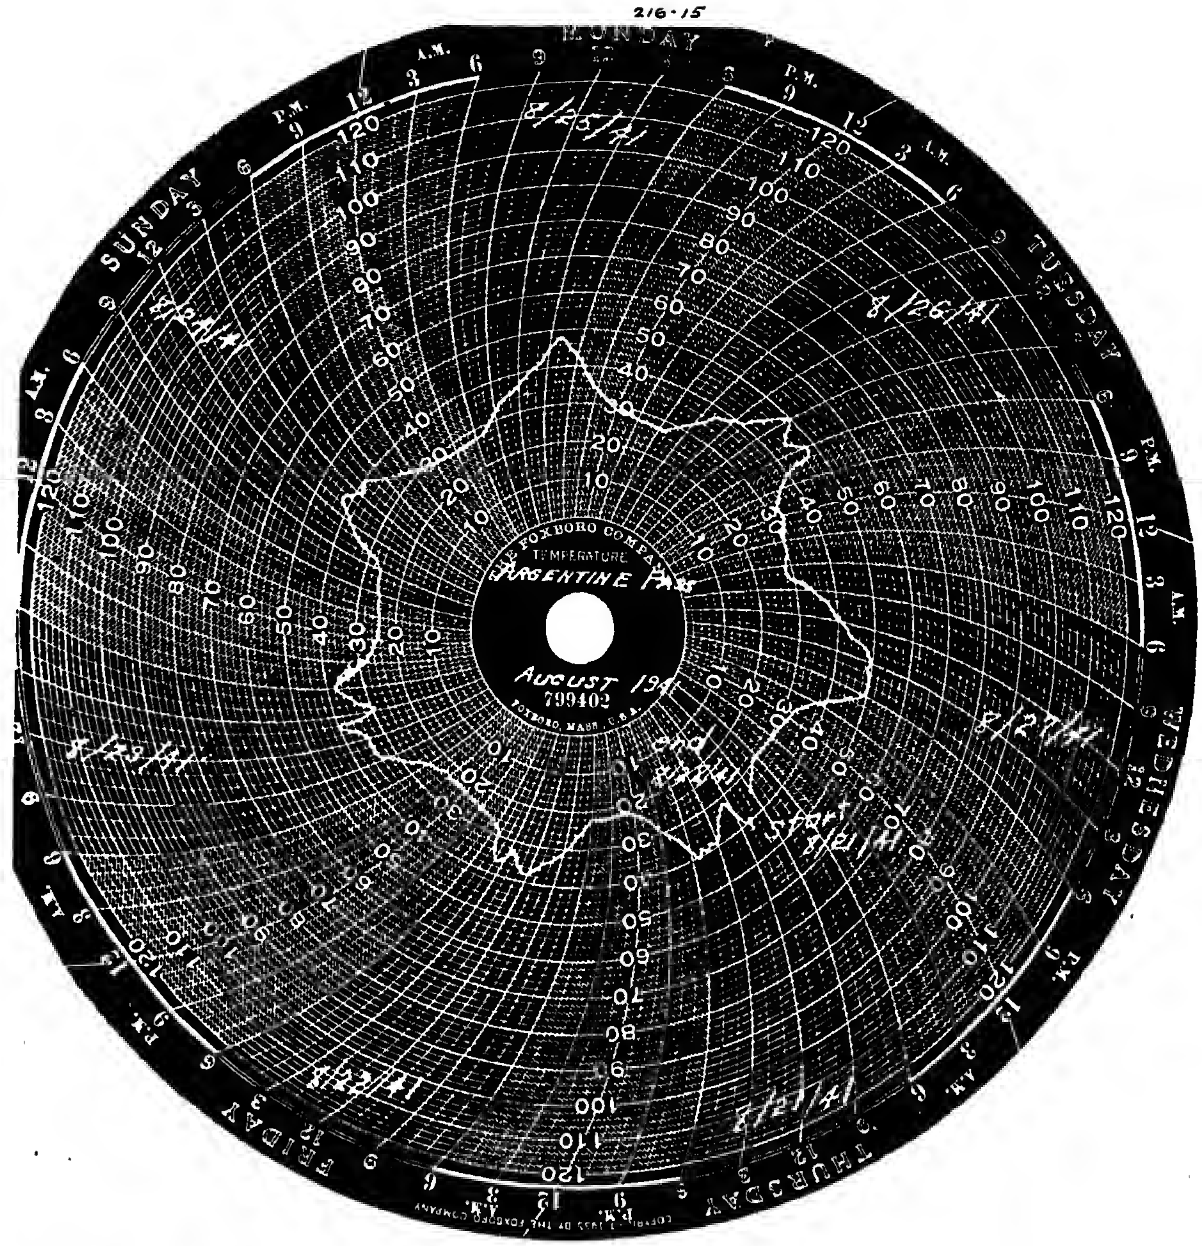

Figure 15. Thermometer record at Argentine Pass during the period corresponding to the corona record of Figure 14

currents from the ground surface during lightning storm periods. Such corona streamers had been observed visually on a number of occasions, but had never been measured. Accordingly, the measuring equipment described in section III was set up at Argentine Pass and near Denver in 1940 and again in 1941. No direct strokes occurred to the lightning rods and no surge-voltage records were obtained.

Discharge-current records for 51 storms were obtained on the Argentine Pass installation during the 1941 lightning season. In Table IV are summarized all records obtained at Argentine Pass and at Denver. The latter are few in number, particularly because the recorder was not in operation during a portion of the period of data taking. This table shows time of occurrence of a storm, the maximum amplitudes of both positive and negative polarity currents occurring in each storm, the temperature at the beginning and end of the storm, and an estimate of the cloud-field gradients at the earth as indicated by the corona current.

In the specimen record of Figure 14 obtained during the storm of August 21 from 9:00 p.m. to 10:30 p.m. it will be noted that beginning at 9:10 and extending over a period of some 20 minutes, sharply increasing corona currents were repeatedly interrupted by discharges, undoubtedly

Figure 14. Corona-current record obtained on Argentine Pass during storm of August 21, 1941

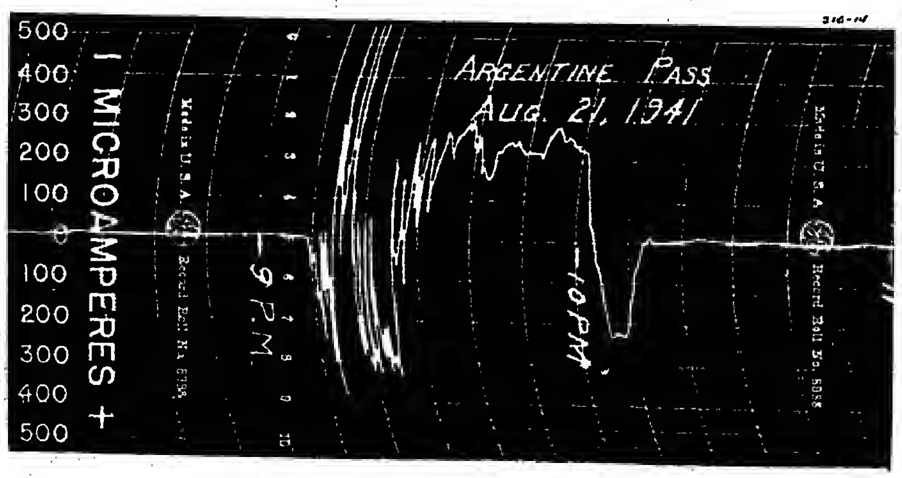

Figure 16. Corona-current record obtained on Argentine Pass, July 15, 1941

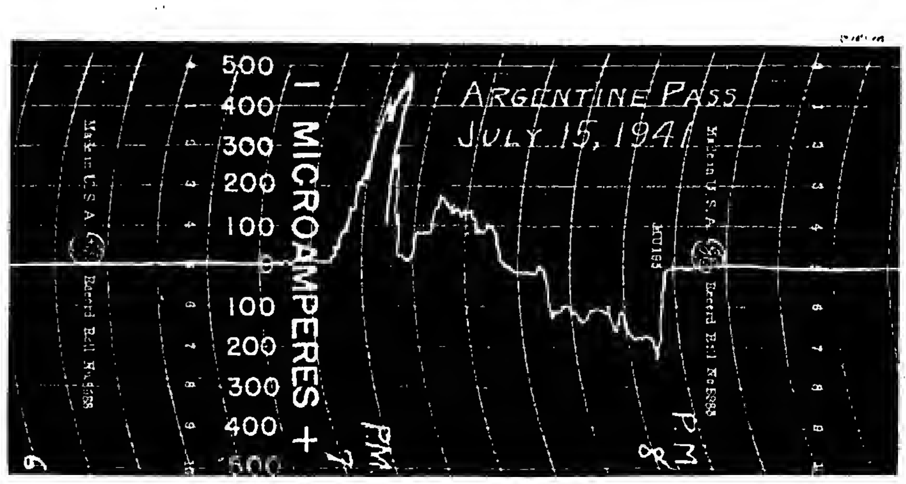

due to nearby lightning strokes. The extreme deflections of the microammeter pointer which leave only single line traces on the record show that a lightning stroke occurred with resulting abrupt change in field gradient. The amplitudes of these wide swings are due partly to sudden release of induced charge in the lightning rod, that is, induced surge voltage and overswing of the sensitive instrument movement. Following this early period of the storm came a steady flow of rod discharge current extending over a period of about 40 minutes and of negative polarity. During the next five or six minutes there occurred a gradual change of cloud field from negative to positive polarity without the sharp lightning stroke changes and apparently due to the movement of a positively charged portion of the cloud to the vicinity of the lightning rod. Several records of this general type were obtained during the 1941 lightning season. In Figure 15 is reproduced the thermometer record at Argentine Pass during the period corresponding to Figure 14.

Typical of a storm not accompanied by frequent nearby lightning discharges is the record shown in Figure 16 and obtained at Argentine Pass on July 15 from 6:50 p.m. to 8:20 p.m. This record shows a gradual increase in gradient beginning at 7:05 p.m. over a period of 10 minutes and reaching a high negative gradient of 94 kv per foot at 7:15 p.m. At this time, a single stroke discharged this high gradient down to about half of its previous maximum level. Continuing, the gradient changed gradually to positive in about 20 minutes, building up to a gradient of 75 kv per foot, which disappeared within three or four minutes time, presumably as this portion of the cloud moved away from the lightning rod.

In considering the records obtained at Argentine Pass, it is well to carry in mind that this elevation places the lightning rod well up into the cloud field on many occasions. Under these conditions the ideal case of a lightning rod projecting from the earth surface up into a uniform field is not obtained. Such an arrangement could, therefore, not be used in the laboratory to calibrate for gradients indicated by the Argentine Pass setup. The tip of the lightning rod at Argentine Pass extends 18 feet above the level of the earth surface and it is presumed that cloud charges may at times be within a very few feet of the rod. Accordingly, in the laboratory calibration, corona currents were measured for a long rod extending more than 10 feet above the grounded plane with the tip located only four feet away from a high potential plane which was some three feet in diameter. Voltage from a continuous voltage-rectifying-type generator providing up to 500 kv was applied to the high potential plane over a wide range of voltage levels of both positive and negative polarity. Corresponding rod currents were measured for each voltage level applied. The figure for voltage gradient was obtained by dividing applied voltage by the distance between rod tip and high potential plane. Correction was made for the relative air density of approximately

Table III. Length of Counterpoise at Which Readable Values of Current Were Read

0.6 at Argentine Pass. The positive and negative current values were about equal for the same voltage levels. The use of such a laboratory setup, of course, involves speculation as to field conditions and means that the gradients indicated are at this time only approximate. However, additional field and laboratory data and its correlation will provide more positive results as the investigation proceeds.

In columns 5 and 6 of Table IV, maximum current values for each storm are tabulated. Both positive and negative values are recorded for about 80 per cent of all storms, the remaining 20 per cent giving either positive or negative current exclusively. Discharge currents ranged up to 480 microamperes both positive and negative. A positive instrument current means that the rod tip is positive relative to the ground and indicates a positive-inducing cloud field. A negative current means that the rod tip is negative relative to the ground and indicates a negative-inducing cloud field. Planimeter surveys of all records show that integrated time and amplitude for positive polarity clouds was 55 per cent and negative polarity clouds 45 per cent.

Columns 7 and 8 of Table IV give equivalent voltage gradients as indicated by the laboratory calibrations previously described. These gradients range up to 94 kv per foot. In 1930 two of the authors reported field-gradient measurements at the ground surface up to 87 kv per foot at about 1,200 feet above sea level.[7] These early results were obtained on an instrument of the ballistic galvanometer type which was connected to the cloud field through a capacitance arrangement and which recorded only on the occurrence of a lightning stroke. The average record was below 10 kv per foot. The new measurements range substantially above the earlier values as would be expected due to the close proximity of the cloud to the lightning rod.

VIII. Conclusions

1. One hundred and forty-five stroke currents were measured at high altitudes, ranging in value from 2,000 to 96,800 amperes, with 64 per cent negative and 36 per cent positive. These figures should be compared with figures for low-altitude transmission lines, in which approximately 95 per cent of the strokes were of negative polarity and 5 per cent positive. It is possible that on the high altitude line, where the line may at times be within the cloud, the positive portion of the cloud may be discharged to the line more frequently than in the normal case.

2. Strokes caused 56 one-phase-to-ground faults, 20 two-phase-to-ground faults, and 5 three-phase faults. The remaining 64 strokes caused no line disturbances.

3. The observed stroke current decreases with increase of altitude from sea level to 13,500 feet.

4. Results indicate that there may be no lightning strokes if the ground level is above an altitude of 18,000 feet.

5. The mean temperature at an altitude of 18,000 feet in free air above Denver never exceeds 32 degrees Fahrenheit.

6. Mean temperatures which would prevail *if* the earth's surface were at 18,000 feet elevation may be the same as that obtained from the Balloon Sondes and may never exceed 32 degrees Fahrenheit.

7. The mean temperature for Leadville (altitude 10,200 feet) and Argentine Pass (13,500 feet) conforms very closely to temperatures at corresponding altitudes in free air as obtained by Balloon Sondes at Denver.

8. This investigation and other observations indicate that freezing temperatures may limit the formation of lightning.

9. The length of counterpoise at which readable values of current were read increases directly with increase of stroke current.

10. Current in tower legs and braces divides approximately as the cross-section area of the steel, although erratic readings were obtained in many cases.

11. Counterpoise wires carried practically all the current with little in tower footing.

12. The microammeter measuring earth discharge at Argentine Pass showed indications for 51 different storms up to 480 microamperes. Potential gradient was calculated from these records up to 94 kv per foot.

13. Polarity characteristics of field gradients at 13,500 feet as determined by the integrated area under the amplitude-time curves, were 45 per cent negative and 55 per cent positive. Comparison of maximum discharge currents per storm also showed positive and negative polarities to be about equal. Particular storms, however, are occasionally predominantly positive or negative.

14. The Shoshone-Denver line passes over an area of differing geological formations but, except for resistivity, these formations do not appear to influence the locations where lightning strokes occur nor the value of current in a stroke. In fact, contour of the ground and its relation to the direction of travel of the storm appears to have more bearing on the location of the strokes than geological formations.

Supplementary Control of Prime-Mover Speed Governors

S. B. CRARY
MEMBER AIEE

J. B. McCLURE
ASSOCIATE AIEE

THE development of interconnected systems has required improvements in the manual and automatic control of load, frequency, and time. The speed governors of the prime movers have always provided the medium for supplementary control of frequency, load, and time. Experience with various types of control devices and the factors influencing their functioning have been discussed frequently in the technical literature. Recently the problem has been given renewed attention[1-5] with an effort to correlate experience with theory and to provide a basis for determining the proper characteristics of governors[2] and their supplementary control.

In attacking this problem, the authors and their associates first made an analysis of the prime-mover governors when performing their essential function of speed control.[1,2] Such an analysis was necessary to provide the required background for the problem of system control of frequency and load by means of supplementary devices. The work on prime-mover governors resulted in conclusions as to their desirable characteristics. This paper presents what appear, from analysis and experience, to be logical conclusions as to the proper characteristics and functions of the supplementary control devices, and, accordingly, is a sequel to the previous paper dealing with prime-mover governors.[2] At the same time this is a companion paper to the one by Concordia, Weygandt, and Shott,[6] presenting the results of an analysis of tie line control. The problems of load, frequency, and time control have usually been treated as related to the operating problems of particular systems. This paper has as its purpose a discussion of the various factors which apply more generally for all types of systems.

System Operation

Economic generation of power, to always meet the demand, to satisfy transmission facilities, and, at the same time, keep frequency and time within certain limits, gives rise to a variety of problems. Every power system or section of a power system is subjected under normal conditions to load changes of rather large magnitude during the course of its daily operation. Most systems have appreciable load "drop offs" and "pickups" during the morning, noon, and evening hours. These load changes may be of the order of one to two per cent of system capacity per minute. Around the average load may be a fringe due to loads which are more rapidly applied and removed. Also, occasionally emergencies arise which will cause sudden changes in loading and frequency.

The characteristics of all the control devices of a system, whether automatic or manual, determine its performance during these changes and readjustments. The co-ordination of the functioning of these devices becomes increasingly important with the number of interconnections and the size of the individual loads which may be applied, and the intelligent solution will necessarily be a compromise among all the requirements involved. After reviewing the factors which appear to be essential for the proper control of generator output, tie-line load, frequency, and time, we have reached the following conclusions:

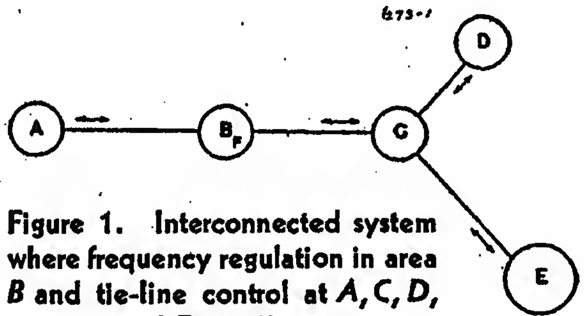

Figure 1. Interconnected system where frequency regulation in area *B* and tie-line control at *A*, *C*, *D*, and *E* is sufficient

1. The duty on the regulating stations can be reduced, for the same allowable frequency deviation, by using more governors which have the proper characteristics.

2. Automatic frequency control may be obtained with simultaneous operation at several stations provided with time-error droop correction.

3. Maintaining absolutely flat frequency, time and tie-line loads is an unnecessarily severe requirement.

4. The required rates of response on the larger systems, with a reasonable amount of regulating capacity, are well within the ability of the prime-mover equipments and controllers.

5. Large rapid load changes are difficult to confine to an area because of limitations in energy supply and of inherent time lags.

The following discussions of the essential factors support the above conclusions.

System Speed Governors

All of the active speed governors of a system tend to support the frequency following system changes in load. Their contribution is made at a rate comparable with the rate at which the loads are usually applied. Parallel-operated machines require some regulation in order to operate properly in parallel. A previous investigation[1] has indicated that the optimum regulation in order to keep the frequency deviation to a minimum, without resulting in undue or unnecessarily long periods for the readjustment to take place, was of the order of about six per cent incremental regulation for steam units. Also, in practice hydroelectric units with droop-correction mechanisms usually end up with an adjustment of around five per cent on the larger systems.

Tests on systems indicate that the composite or effective system regulation is considerably greater than the optimum and may be more of the order of 10 to 20 per cent because of dead band, operation of some machines with blocked governors, and operation at wide open valve points. An approximate characteristic for some systems has been found to be a one per cent load change for a 0.1 of a cycle frequency deviation. This corresponds to an over-all system regulation of 17 per cent. This difference between over-all system regulation and the regulation of an individual unit tends to encourage blocking the governors of the new and efficient units with modern governors so that they will not be able to take more than their share of load changes. This aggravates the situation by resulting in a still larger composite regulation. Experience has indicated that the lower the composite regulation of a system (not so low as to result in too small damping) the smaller will be the frequency change resulting from a suddenly applied or rejected load of a given magnitude. Thus, the more correct solution[8,11] would be to increase the number of active governors and decrease the dead band of all these governors to as small values as is practical.

Paper 42-73, recommended by the AIEE committee on power generation for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted November 12, 1941; made available for printing December 23, 1941.

S. B. Crary and J. B. McClure are with the central station engineering department, General Electric Company, Schenectady, N. Y.

It should be recognized that, until a reasonable percentage of capacity is equipped with governors having small dead band and more uniform incremental regulation, units with improved governors will be doing more than their proportionate share of governing. If a steam unit has a six per cent incremental regulation and no dead band, the load change on that unit for a ±0.1 of a cycle fringe in system frequency will be ± 3 per cent of rating. If the instantaneous frequency deviation is reduced to ±0.05 of a cycle by an over-all improvement in governing alone, the change in load on such a unit will be reduced to ±1.5 per cent of rating, without any increase in regulating station rates of response. Thus, the support of system frequency would be distributed among units having more nearly the optimum regulation, and comprising a greater percentage of the system capacity. This would result in more rapid damping of load oscillations and in more stable operation, with less frequency deviation. Furthermore, the load changes on individual plants which were not assigned the duty of regulating would be so small that they could be considered essentially base-load stations. This improvement in system performance is the reward for reduction of dead band and for the employment of governors having more uniform incremental regulation. It is important, on the other hand, to realize that the regulation of individual units should not be made less than the optimum, for then the frequency fringe may actually be increased rather than decreased. Since there exists an *optimum regulation* it does mean that (even though it is not particularly critical) if the regulation of system is too small, an unnecessarily long time for the damping out of frequency oscillations may be required, while if it is too great, the frequency deviation may not be as small as could be realized otherwise.

Exceptions arise in system operation when it may not be desirable to have all units operating with active governors. It may be desirable to block the governor for small frequency changes (for example, a magnetic pull-out device[9]) of a steam unit at light load in order to prevent variations in output which may be large in comparison with the load the unit is carrying, although small in comparison with its rating. Also, for a base-load unit with high efficiency or with a boiler and boiler control unable to cope with the normal load changes, it may be considered necessary or advisable to operate the unit blocked. These exceptions, however, are less likely to exist when a larger number of units are operating with active governors and the frequency deviations are carefully kept within close limits by supplementary control.

Frequency Control

Allocating the system generation has ordinarily been accomplished among generating stations by communicated dispatches. The control of frequency and the responsibility for holding frequency can, of course, be distributed in this same manner. However, to hold frequency within close limits requires a constant readjustment at the regulating stations. It was a very natural step that this duty should be largely taken over by automatic control and should be assigned to particular stations whose incremental costs, depending upon the system loading, were such as to make them the most economical units for this control. Many systems are operated under a semiautomatic and manual control of frequency. The frequency regulating station is changed during the day or the loading of other units of the system is changed in order to allow the regulating units to operate within their capacity to hold frequency. The use of automatic control at the station or stations which are assigned to the duty of holding frequency at a particular time relieves the operating personnel of a very onerous task. In addition, since automatic control is constantly at work restoring frequency to normal, closer frequency regulation is obtained with the result that there is less tendency for manual stations to contribute by their own initiative. This usually results in better system operation and less unnecessary transfer of load between stations. In general, the loads which are most critical to frequency deviation on a system do not require as close a frequency regulation as is desired, by the system operators, for the best operation of the system.

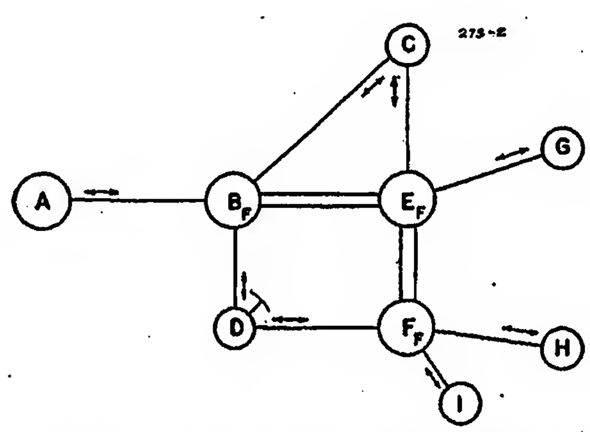

Figure 2. Interconnected system where frequency regulation may be used advantageously in areas *B, E,* and *F* with tie-line control at *A, C, D, G, H,* and *I*

It has become general practice to use one station for holding frequency and time. The other regulated units control tie-line loads. In systems of this type, one station of the whole interconnected group, no matter how large, or a group of closely tied stations, controls frequency. This has come about naturally, it being a fairly easy way to distribute the responsibility among regulated stations and still use the simplest type of control. This type of control is particularly well-adapted to a system interconnected[3,7] as shown in Figure 1, where the other sections of the system are separated from the section holding frequency by only a few tie lines. These other sections can be assigned the duty of holding tie-line loads.

However, for the type of system shown in Figure 2, it becomes more difficult to assign the individual stations or areas to regulate tie-line loads and it may become simpler for two or more stations to be assigned the responsibility of regulating frequency. This is not readily accomplished by the ordinary method used in frequency regulated stations of having a controller which holds essentially flat frequency without any direct control of time error. Parallel operated frequency controllers of this type have been operated when it was possible to have slow rates of response and to keep the two stations in range together by frequent communicated dispatches and manual readjustments. Completely automatic parallel operation can be accomplished, however, by providing the frequency regulating stations with mechanisms which measure accurately the time error and proportion their contribution to the frequency regulation of the system in proportion to their assigned regulating capacity and the time-error deviation. This control principle has been successfully used for many years and provides means for automatically dividing responsibility by what has been termed time-error droop correction,[10] employing a time-error range which is well within practical requirements for electrical time on the systems, that is, one second for complete regulating range.

Accuracy of Standards, Time, and Frequency Limits

Reasonable electrical time accuracy is one of the by-products of automatic frequency control. In fact, it is not difficult to provide acceptable electrical time on manual control with a master clock and Arlington time as reference.

In their enthusiasm, some operating groups, when operating as independent systems, endeavored to maintain very close to flat time. In principle, this

means that following each interval of low frequency a forced high-frequency interval is required and vice versa, resulting in much unnecessary correction at the regulating station. This principle of operation is particularly troublesome in an interconnected area and imposes an unnecessary transfer across tie lines and an unnecessary burden on the regulating stations. Most systems have abandoned this ideal objective and are content with keeping time within ±1 to 2 seconds which is relatively easy to obtain, providing the regulating stations are always kept within range.

Flat frequency-control devices employing resonant circuits are not inherently good time standards. A continuous error of 0.01 of a cycle will integrate 14 seconds error in a 24-hour period. Thus, it is customary to supplement this type of control with some form of time standard, such as master clock, tuning fork, or crystal oscillator. The ultimate in time standard, of course, is a common continuous master frequency or time.[4] At present, the cost of the necessary equipments is the only obstacle to a widespread adoption of a common master standard.

Any of the available time standards is sufficiently accurate for backup purposes, as a supplement to straight frequency control so far as system time is concerned. Ordinary master clocks have an accuracy of one second per day; tuning forks one-half to one second per day; crystal oscillators about 0.1 second per day, and even Arlington time sends out its correction log sheets at the end of each month—revealing that its daily time signals may be off as much as 0.1 second. With any of these time standards, it will still be necessary for a system to have a correcting period, probably during early morning hours, to correct for drift in time standard or for system errors which may have accumulated when the controlling stations were not kept within range.

In appraising the value of a continuous master frequency, it should be kept in mind that it does not improve the parallel operation of flat frequency regulators. It merely applies equal amounts of calibration to all controllers in terms of the differential between system time and master time with the result that system time is maintained within prescribed limits and load equalization must still be accomplished by communicated dispatches and manual readjustments.

In contrast to this, the application of a master time standard to frequency controllers using the time-error droop principle results in perfect parallel control. Thus, the several frequency-control areas shown in Figure 2 may be used in any combination without frequent communication and without readjustment, except to satisfy changing system conditions.

The advantages of time-error droop control will be recognized as interconnections become more widespread and the number of frequency-regulating stations increase.

During the steady load periods the larger interconnected areas are able to maintain frequency within ±0.05 of a cycle and these limits may increase to approximately ±0.15 of a cycle during the rapid load changes. On smaller systems the steady fringe is more nearly ±0.1 of a cycle and the swings may reach ±0.25 of a cycle during pickup and drop-off intervals. The sudden load changes that are applied to the larger systems are necessarily smaller in proportion to the total capacity than may occur on the smaller systems—thus causing smaller frequency deviations for similar governor performance.

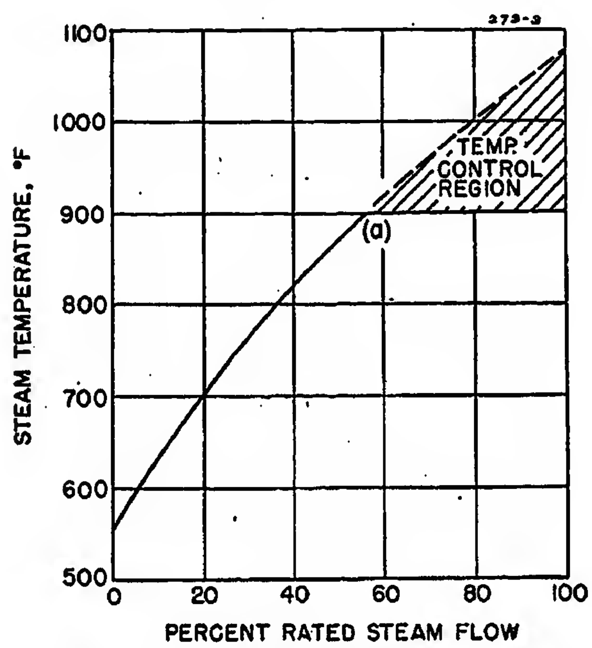

Figure 3. Typical temperature-flow characteristic of modern boiler with convection-type superheater

Tie-Line Controllers

The control of frequency on an interconnected system is ordinarily a comparatively easy assignment and does not require a particularly fast rate of response. The tie-line controllers, on the other hand, are required to hold the tie lines within certain limits in order to prevent pulling out of step, overloading, or too great or long a load deviation from the assigned tie-line loadings, and it is logical that the tie-line controllers should have a proportionately faster correction rate than that of frequency-regulated stations. This also results in a more quickly balanced system after a load change occurs in that the generating capacity within the area in which the load change has taken place quickly picks up the load without requiring an unnecessary change in the frequency regulating station. As the regulated capacity responding to tie-line control increases, it is important to reduce the amount of unnecessary correction. This may be accomplished by employing the well-known principle of frequency bias.[3] Briefly, by combining frequency deviation and tie-line watt deviation, it is possible to determine the location of the net load change associated with these deviations, that is, whether it is internal or external to the area, and the tie-line controller thus responds for the portion of the load change within that area, and when properly adjusted allows the tie line to contribute to external load changes, by an amount equal to the composite governor regulation of that area.

In a closely knit system operating with a frequency control alone, the control may be as rapid in response as is permissible for frequency stability provided there is sufficient energy supply. In the limit this type of system could approach a single unit with a governor having zero speed droop and having as small a droop-correction time lag as may be obtained with stability.

The kilowatt transfer between two systems is not a steady quantity. Load changes in the several areas are continually being applied, and system constants, together with existing governor dead bands, do not produce critical damping to the original oscillation. Before the tie line has steadied down following a load change, another load change has appeared with the result that almost a continuous oscillation exists. This oscillation in watts may be as much as ten per cent of the tie-line capacity and occurs at a period varying between one and five seconds, depending upon the system inertias on either end and the synchronizing coefficient of the tie line. Thus, the watt sensitive element in a tie-line controller need not attempt to follow the instantaneous watts but rather the average of the fringe watts associated with this relatively fast oscillation.

Types of Tie-Line Controllers

A controller which is in equilibrium only when the controlled quantity has been returned to its desired value is called "the floating type." A controller which is in equilibrium when the controlled quantity has been returned to a value which deviates from the desired value by an amount proportional to the controlled quantity is called "the proportional type." In terms of regulation "the float-

ing type" is a flat controller having zero regulation, while "the proportional controller" has a definite positive regulation.

Practically all supplementary controllers of turbine governors are of the floating type. The synchronizing motor receives impulses, either continuous or intermittent, until the controlled quantity has returned to the desired value. The proportional controller may be a device which exerts a pull on the governor arm in proportion to the deviation of the controlled quantity.

The analysis presented in the companion paper[6] shows that equally good performance may be obtained from the two types of controllers if they are properly designed. The proportional controller requires a sufficiently long time lag between the deviation sensitive element and the resulting proportional force that it exerts on the governor. The floating type requires a sufficiently slow rate of correction to allow for stable operation. Since the latter type is the most easily obtained, it is most generally used.

For quick response a continuous controller, either floating or proportional, is better than an intermittent type. A controller whose rate of correction or correcting force is proportional to the deviation is capable of better performance than one which does not have this proportional feature. In all cases, stability may be obtained by providing the controller with a sufficiently slow rate of correction or long time lag. Rates of response considerably greater than those generally used now may be obtained by proper design and do not necessarily require the use of a stabilizer. For best performance of a steam unit, with optimum controller design, the governor incremental regulation should be fairly uniform at a value of about six per cent, with small dead band.

Telemetering

In many cases the tie line to be controlled is not adjacent to the regulating station, and the watt indication is then telemetered. Except in a few special cases, relatively slow types of telemetering now are being used successfully for indication and control purposes. For these special cases continuous and instantaneous types of telemetering have been successfully employed.[12,13]

Rate of Response

Systems operating with a large number of active governors in good condition and with supplementary control will have but small frequency deviations for the usual load changes. The loads are absorbed by the active governors, and then the supplementary control may be used to return the average frequency and tie-line loads to normal. Under such conditions the supplementary control need not be particularly fast in response, corresponding only to the rate at which the average system load changes. This then allows for a relatively slow change in the output of the frequency-regulating station. It has been found that within limits the greater the allowable frequency departure, the less is the required speed of response of the frequency-regulating stations. Also, the greater the number of active governors, the less is the required speed of the response of the frequency-regulating station in order to prevent the frequency departure exceeding that which is tolerable. Operation in this manner relieves the frequency-regulating units by taking advantage of the diversity of load changes and allows them more opportunity to correct the frequency at a rate consistent with their steam and hydraulic energy supply conditions. The governor mechanisms and their control ordinarily are capable of allowing for increases in load at a rate which exceeds that allowed by the steam or hydraulic conditions.

The steam units of a station, because of the smaller time lags of steam than of water, are capable of providing a quicker response than hydraulic or hydrogenerators, if not limited in prime energy supply. However, steam plants may be so limited in their steam rate and steam storage capacity that many steam-generating units are limited at the steam-generation end. Hydraulic units may, however, have sufficient storage capacity but may require an appreciable time lag depending upon ability to change the hydraulic power to the turbine rapidly. When all these circumstances are considered it may well be that a low head hydraulic plant provides a more rapid means for regulating than a steam unit.

Steam and Hydraulic Limitations

The prime-mover energy storage and rate at which it may be changed are very often the most important limitations of the rate of response of a regulating station. In some instances slow boiler-control response may be an unnecessary restriction on the amount of load which can be quickly picked up. The control of the boiler should be such as to allow for as rapid change in steam flow as is possible without resulting in undue stressing of boiler or turbine. Most of the experience to date with regulating stations has been obtained using lower temperature boilers and turbines; some having chain grate stokers and others slightly faster underfeed stokers. Limitations in re
rates are established under these
tions largely by fuel bed condition

frequency regulators operating in parallel can be used to advantage. Thus, there is every justification for believing that the number of regulating units will increase, thereby reducing the burden on any one unit, just as the active participation by all units on governors reduces the burden.

On some present-day systems the regulating capacity is so distributed as to limit the required maximum rate to 10 per cent of regulating-unit capacity per minute over a limited range. This may be considered a moderate regulating rate in comparison with load changes encountered on some smaller systems with rough loads. For a system which has a rate of load change of one per cent per minute this would require a regulating capacity of at least 10 per cent of system capacity.

It will be recognized that in case of emergency, a boiler and turbine should be capable of dropping or picking up full load almost instantly if operating temperatures had been previously established following the starting-up cycle. Such operation, although tolerable in an emergency, cannot be considered good practice if done periodically, unless special provision for such operation has been made in the design.

Large Rapid Load Changes

For those systems in which the suddenly applied load changes are an appreciable part of the total connected capacity, it is found that the frequency deviation will be correspondingly greater. If this exceeds what is considered a tolerable limit, it becomes necessary to use supplementary control having a greater rate of response. This then puts a greater burden on the regulating station, and, in order to avoid too great a frequency deviation, it may mean a sacrifice in economy, or a provision for larger energy-storage capacity, or an increase in the rate at which the prime energy is generated. It is evident that, except for the change in system loading with change in frequency, the net load change must be absorbed by generating capacity, at the corresponding rate of load change. For systems where the load change is a large part of the total load this may become a serious problem.

A large strip mill load may have a load increase of 30,000 kw in 5 to 20 seconds. If it were necessary to follow this load change with regulating capacity comparable with present-day practice on the larger systems, over a million kilovolt-amperes would be required. Fortunately, this type of system is the exception rather than the rule. In these systems, experience has indicated that the limitation is primarily in the available steam supply, and when operated as isolated systems, speed governors alone are relied on for speed control resulting in corresponding large frequency changes. Unless special provision is made for steam supply capacity of the prime movers, large fluctuations in steam pressure will result.

Such a system which finds itself subjected to large suddenly applied loads; for example, a strip mill load which is large compared with its generating capacity, may interconnect with another system in order to help absorb the load changes. If this is done, the frequency deviation will be reduced, and a portion of the load change will be transmitted across the interconnecting tie. In general, the reduction in frequency deviation and the load change transmitted across the tie will be in proportion to the capacity of the external system to the total capacity. By interconnecting with another system in this manner, the local system makes use of the additional prime-mover energy capacity of the other connected system, the load changes being distributed among an increased number of actively governed generators. If the frequency deviation produced by the rapidly varying load is within tolerable limits without the use of supplementary control, little regulating capacity is needed to handle such a load because it will be removed as quickly as it is applied. Accordingly, the supplementary control need correct only the average frequency deviation. This provides a very practical and reasonable method for handling such rapidly varying loads.

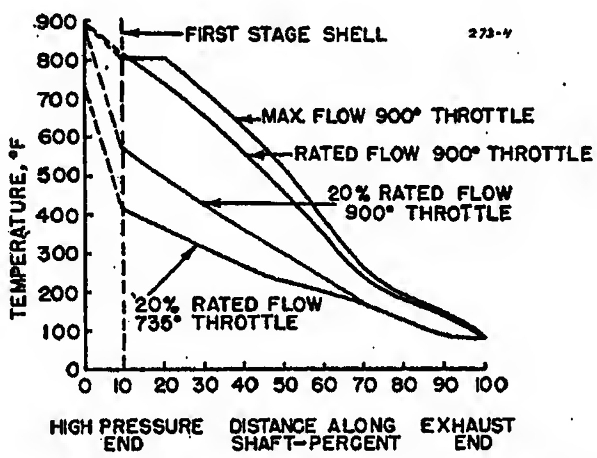

Figure 4. Temperature distribution in a modern high-temperature steam turbine

Occasionally there has been a demand for adequate control of rapid tie-line swings. In this case it becomes necessary to provide special control. The studies which have been made indicate that the limitation may not be in the control equipment so much as it is in the energy supply of the prime movers. From both analysis and experience, hunting or instability between the regulating units is more likely to occur when the rate of response of the regulating units is increased. For units which require a higher rate of response of their supplementary control, it is necessary for their governors to be in good mechanical condition with small dead band and to be stable mechanisms when operating alone. Under these conditions the rate of response with properly designed supplementary control can be further increased before the instability region is reached (see Figure 21—reference 6). The results of the analysis presented in the companion paper[6] indicate that with no limitation in energy supply the tie-line deviation may be held to 15 per cent for a continuous controller and 25 per cent for any intermittent controller for a load applied at a rate of 150 per cent of regulating capacity per minute, the regulated capacity being the total capacity of the local area and tied to the major system by a comparatively weak tie. Both this analysis and experience indicate that the control mechanism is not the limiting factor, since the energy supply limitation makes itself felt earlier.

Summary

It appears that the greatest improvement in over-all system frequency and tie-line regulation will be brought about by further improvement in the composite regulation of the system governing and by more widespread and co-operative application of supplementary control equipments which are already developed.

PCC Car Operating Results in Pittsburgh

W. J. CLARDY
MEMBER AIEE

Synopsis: The problem created by the decline in transit revenues during the depression led the Pittsburgh Railways Company to initiate a long-range service-betterment program. The most important phase of the plan was the use of modern street cars, as developed by the Presidents' Conference Committee, to replace the earlier types of rolling stock on the property. With 301 of these PCC cars in service, and 100 additional units scheduled for early delivery, sufficient data are available to show exceptionally favorable operating results. Actual experience in service has demonstrated that car maintenance comes down 28 per cent, track and roadway maintenance drops 21 per cent, accidents decrease 25 per cent, the number of cars required for specific schedules is reduced 10 per cent, and revenues increase 8 per cent. This favorable outcome has caused continued expansion in the use of such equipment and established a superior urban-transit service.

PEOPLE now have the utility in city transit which is so vital to the conduct of daily affairs. The streamlined PCC car, which gets its alphabetical name from the Presidents' Conference Committee sponsoring its development, provides a degree of excellence in public travel that has established a superior performance standard. Pittsburgh was one of the first cities to adopt this modern transit unit. A fleet of 301 cars is in operation and 100 additional vehicles are under construction. This is the largest installation of PCC cars, and, with a total of 401, there will be sufficient to operate base schedules on all street-car lines. Initial service dates back to August 1936, and the results are enlightening. Car maintenance has decreased 28 per cent, track and roadway maintenance has dropped 21 per cent, accidents per 10,000 car miles have come down 25 per cent, schedule car requirements have been lowered 10 per cent, and gross revenue has increased 8 per cent.

Paper 42-52, recommended by the AIEE committee on land transportation for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted November 26, 1941; made available for printing December 31, 1941.

W. J. Clardy is transportation application engineer, transportation and generator engineering department, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

Operating Improvements Needed

During the lean years of the early '30's, the Pittsburgh Railways Company recognized the need for restorative measures to regain lost gross revenue and to lower operating costs. When the depression began to slow things down, one logical recourse was finding means of speeding things up. This involved re-examination of existing schedules to establish a program that would give service more beneficial to patrons. Coincident with this plan, it appeared essential to reduce maintenance expenditures below the level set up for the more prosperous years of the preceding era.

Many people had attained a critical frame of mind with respect to the street car, and rightly so. After years of seeing and riding in essentially the same noisy uncomfortable vehicle, such an opinion was understandable. Urban passengers responded to this neglect of their needs by transferring their patronage to the public carrier which provided adequate service. Modern street cars were needed to meet the demand for greater usefulness in city travel by providing service superior to any other vehicle for surface mass transportation. Action was required to give fast, convenient schedules, lower the cost of the car ride, relieve street congestion, and handle rush-hour traffic effectively.

Plans for Better Transit Service

Careful analysis of the transit problem led to the conclusion that immediate action was required for speeding up and reconditioning the outmoded rolling stock. Such a plan was put into effect to lower maintenance costs and arrest declining revenues. Motors were rewound for higher speeds, brakes were modified to obtain more effective stopping characteristics, and car interiors were improved.

It was recognized that the most satisfactory operation required modern street cars. However, the immediate benefits of existing rolling-stock improvements could be garnered pending the fulfillment of a long-range program for the procurement of new vehicles. Sufficient cars were reconditioned to handle more than 50 per cent of the mileage operated.

The plan for the purchase of new rolling stock was initiated with the installation of a single trial PCC car in August 1936. The first 100 cars ordered were placed in service from March through May 1937, the second 100 during November 1937, and the third 100 in April 1940. The fourth order for 100 cars will soon be ready for delivery. The type of car procured is shown in Figure 1, and the extent of the installation is illustrated by Figure 2.

Figure 1. Modern PCC car in operation in Pittsburgh

These modern cars have many outstanding advantages which are assisting in meeting transit problems in Pittsburgh. Some of the more important are as follows:

1. Performance is far in advance of any vehicle now using city streets. The speedy quiet-operating trolley car can save from 6 to 15 minutes of every hour's travel time in comparison with the older types.

2. A high degree of agility is attained with comfort to riders. Deep-cushioned forward-facing seats, wide clear-view windows, ample stanchioning, adequate ventilation, uniform distribution of heat, and plentiful indirect illumination conform to the demands of passengers.

3. The control and braking equipment permits attainment of a degree of smoothness of performance that is unexcelled in surface travel.

4. Schedule speeds are higher than any other form of public transportation on congested city streets. It is possible to use

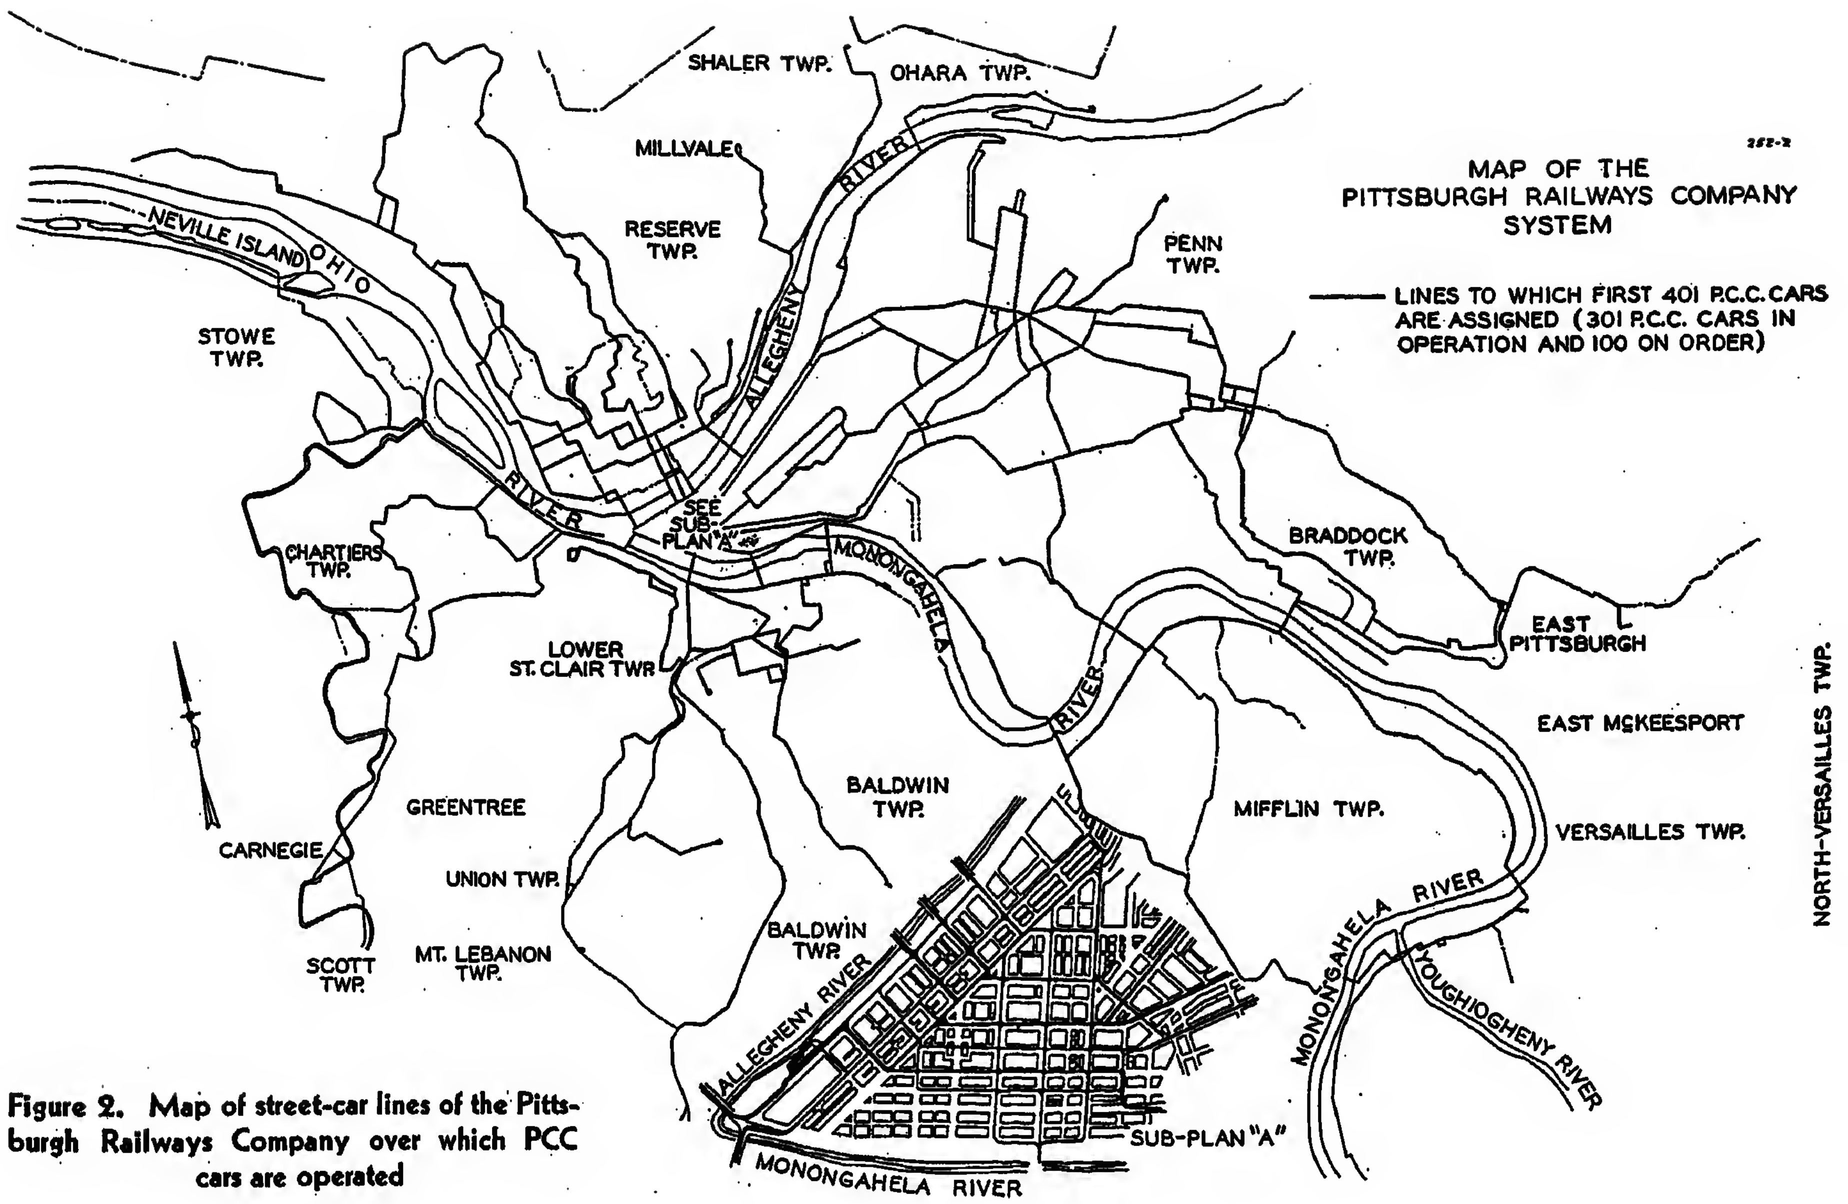

Figure 2. Map of street-car lines of the Pittsburgh Railways Company over which PCC cars are operated

fewer units—10 to 20 per cent—a factor that is reflected directly in the fare cost.

5. Fast schedules and the corresponding reduction in the number of cars minimize traffic congestion and allows the most efficient use of city streets by the greatest number of people.

6. Starting is fully automatic with an unlimited selection of rates—speed of starting—to conform to the particular conditions of street traffic encountered.

7. Smooth electric braking is provided under automatic control. It functions at all times—even if the trolley loses its contact with the overhead wire. In addition magnetic track and air brakes are available.

PCC Car Operating Results

The rehabilitation of old cars to secure higher schedule speeds and reduce maintenance proved quite successful. Results were particularly beneficial in providing better service with lower operating costs. The investment required was more than justified and served to establish a transition to the important part of the program—replacements with modern cars.

PCC car operation has produced some attractive savings in vehicle inspection and maintenance. In comparison with the earlier-type cars, the wheel-grinding period has been doubled (20,000 to 40,000 miles), wheel life is increased from 140,000 to 200,000 miles, brake shoes last 15 times as long, and inspections have gone up from 250 to 5,000 or 10,000 miles, the higher figure being applicable to cars without hand brakes. Parts for PCC cars cost more, but fewer are subject to rapid wear, and the over-all result indicates less expense. Actual labor costs for specific jobs are about the same, so the decrease in replacements means less hours worked.

An analysis has been made of the comparative expenditures for the three-year period from June 1937 to June 1940. Materials are taken from storeroom requisitions and segregated between old and PCC cars. Labor is distributed in accordance with the number of cars passing through the shop—67 per cent earlier-type and 33 per cent PCC. Fixed expenses, such as superintendence, shop equipment, and shop expenses are allocated on a car-mile basis. The total costs for the years studied are shown in Table I.

Table I

Cars	Car Miles	Cents per Car Mile
PCC	32,500,000	1.70
Old-type cars	60,912,000	2.49

These data show a net saving of 0.79 cents per car mile for the PCC cars, which excludes painting, since none had been through the paint shop. A liberal allowance for this item reduces the net saving to 0.7 cents per car mile or a gain of 28 per cent.

Track- and roadway-maintenance costs have been substantially reduced by PCC car operations. The extensive use of rubber and the light weight of the trucks of the new cars are two pertinent factors affecting the action upon track and roadway in comparison with older-type equipment. The principal use of rubber is in the wheels and journal springs. The resilient construction permits normal deflections of one-fourth inch for wheels and two inches for journal springs. The Presidents' Conference Committee directed a program of exhaustive impact tests to determine comparable vertical accelerations of resilient and conventional steel wheels. Based on these data, the earlier-type cars in Pittsburgh impart impact forces to the track structure six times as great as PCC cars incident to track irregularities and vehicle movement. Track damage because of this action loosens the entire structure including the paving bond. Surface water enters, resulting in rapid deterioration and expensive maintenance. Special track work is particularly vulnerable because of the frogs and switches.

The lower impact forces and lighter weight of PCC cars permit a less expen-

sive track structure. With the older-type cars a nine-inch girder rail weighing 134 pounds per yard, wood ties, ballast, and blockstone paving were required at a cost of $12.50 per foot. In the case of PCC cars, it is feasible to use $5^3/_4$-inch Tee rails weighing 100 pounds per yard, steel ties and concrete at a cost of $9 per foot. Experience has shown that track life can be stepped up from 25 to 32 years by the modern cars. There are 394 miles of paved track. The annual reconstruction requirement is 15.8 and 12.3 miles, respectively, for a 25- and 32-year life, a saving of 44 per cent. The system has 54 miles of open track on which there is a reduction of 13 per cent in reconstruction costs. Special work life is lengthened by the use of modern cars. The indicated improvement is 10 years (20- to 30-year life), because the impact pounding is reduced to one-sixth. The special work maintenance has dropped 14 per cent with 301 PCC cars in operation. With 100 per cent PCC cars on the system, the betterment will be 33 per cent. Ordinary track maintenance includes heavy repairs. Such work costs $1 per foot and the schedule has been seven miles per year. An allowance of 2.5 miles per year has proved ample which saves 12 per cent.

During the year ending June 30, 1941, 29,481,000 car miles were operated, with 16,923,000 or 57.3 per cent PCC. A summary of the percentages saved in track and roadway expense is shown in Table II.

Table II

	Per Cent		
PCC Cars in Use	100	80	57
Savings			
Reconstruction—paved track	44.0	33.2	25.1
Reconstruction—open track	13.4	10.7	7.6
Special work	33.3	26.6	19.0
Ordinary maintenance	12.0	9.6	6.9
Average	37.1	29.6	21.1

PCC cars have reduced accidents because of their many safety features and quick stopping ability. Analyses of four comparative 12-month periods show decreases of 24, 25, 25, and 26 per cent of accidents in comparison with earlier-type cars. A typical illustration is the accompanying data for the year ending September 30, 1940 shown in Table III.

The average accident rate for the four years from 1932 through 1936, prior to any PCC car operation, was 2.74 per 10,000 car miles. The 25 per cent reduction obtained with PCC car operation means 0.69 less accidents per 10,000 car miles. Thus, the reduction is 1,167 accidents for 16,923,000 PCC car miles operated during the year ending June 30, 1941. An analysis of the savings incident to the elimination of these accidents is shown in Table IV.

Table III

	Accidents	Car Miles	Accidents Per 10,000 Car Miles
Earlier-type cars	5,166	14,729,129	3.51
PCC Cars	3,531	13,346,580	2.65
Reduction in accidents per car mile with PCC cars			0.86
Per cent reduction in accidents per car mile with PCC cars			25

Table IV

Per cent total accidents resulting in nonlitigated settlement	15.97
Per cent total accidents resulting in litigated settlement	4.66
Saving in nonlitigated settlements (1,167 × 0.1597)	186
Saving in litigated settlements (1,167 × 0.0466)	54

PCC cars provide faster schedule speeds than the earlier types because of their more rapid starting and stopping characteristics, higher free-running speeds, and quicker interchange of passengers. This makes it practicable to give the same frequency of service with fewer units in the case of the modern vehicles. A tabulation is included in Table VI which shows improvements made in schedules with high-speed cars and the first 201 PCC cars. In comparison with the earlier low-speed types the average betterment is 16 and 12 per cent, respectively, for base and peak service.

Considerable improvement was realized when the earlier-type cars were speeded up which meant less schedule speed increase for the system with the introduction of PCC cars. Also, the speeded-up cars are used with PCC cars in peak service, which limits the schedule speeds obtainable with the latter vehicles. A study of the routes on which the 301 PCC cars are now operating shows that improved performance permits replacing 10 of the earlier-type cars with 9 of the new type—a gain of approximately 10 per cent.

Table V

Year	Routes Using PCC Cars (18-Hr Base Service) Index	Routes Using Old-Type Cars Index	Spread Between Two Classes of Routes
1933	100.00	100.00	
1934	104.37	107.09	−2.72
1935	104.94	106.95	−2.01
1936	114.56	114.27	0.29
1937	117.65	112.14	Transition period
Year ending 3/31/39	109.66	102.97	6.69
1939	108.58	103.63	4.95
1940	112.78	104.95	7.83

Average spread in 1934, '35, and '36 =

$$\frac{-2.72-2.01+0.29}{3} = -1.48$$

Average spread in last 3 periods =

$$\frac{6.69+4.95+7.83}{3} = 6.49$$

Total average spread = 7.97%

The increase in schedule speed incident to the use of PCC cars has a direct bearing on the betterment of gross revenues. Performance is highly important and contributes more to attracting passengers than any other feature. Of course, the comfort of the vehicle is of consequence from the "satisfied-customer" viewpoint. The first 201 PCC cars placed in service have been operating a sufficient length of time to show a definite "revenue trend" for the new equipment.

An analysis has been made which indicates the results shown in Table V.

The year ending March 31, 1939, was the first complete 12 months after all of the routes using the 201 new vehicles had been equipped for operation of the 18-hour base service. The gain in revenue shows a spread of practically eight per cent in favor of PCC cars.

PCC Cars Extensively Used

The PCC car is an outstanding city-transit vehicle with exceptional utility. Its success for improving urban travel is demonstrated by the favorable results obtained in Pittsburgh and the 15 other cities which use the vehicle. It serves to reduce car maintenance, lower the upkeep of track and roadway, decrease accidents, raise schedule speeds, and increase revenue. A degree of excellence is established in public travel that is a creditable contribution to the advancement of city transit.

Improvement in Modern Meter-Testing Technique

EDWARD E. LYNCH
MEMBER AIEE

MARK A. PRINCI
ASSOCIATE AIEE

THROUGH more than a score of years a variety of devices has been developed to simplify the procedure and to reduce the hazard of personal errors in the technique of watt-hour meter testing. Of these devices the stroboscope and the photoelectric timer have already become generally accepted tools of the meter-testing art. Indeed, meter-testing problems differ somewhat in the field, in the laboratory, and in the factory, and consequently, no single device nor combination of devices can be considered ideally applicable to all three forms of testing. However, in each case much is to be gained through the use in some form of the many schemes[1,2] which have recently been developed. Such schemes apply equally to single-phase and polyphase meter testing, though in this discussion we shall be concerned only with the single-phase watt-hour meter and the testing problems peculiar to the factory. Briefly these problems are:

1. Removal of the hazard of personal error in testing.
2. Maintenance of closer control of quality.
3. Elimination of errors in portable standards through handling.
4. Reduction of skill required in testing.
5. Shortening of testing time.
6. Reduction of handling of meters.
7. Elimination of storage space for meters awaiting test.
8. Maintenance of a uniform flow of the product from assembly through to packing.

All of these factors contribute to the achievement of greater uniformity and calibration accuracy as well as to a generally improved quality of the product.

The system which was evolved and which is described in this paper is the result of an investigation conducted under actual manufacturing conditions. A small production line was set up which afforded ready means for close study of the factors outlined above and for trial of the several schemes investigated. It became immediately apparent that testing should become as nearly as possible an integral part of the assembly procedure, if the necessity for storing meters for test were to be avoided. That is, the testing procedure must be broken down into operations that might readily be accomplished during or immediately after the assembly of the meter and in synchronism with the cycle of assembly operation. Logically then, the testing procedure must be broken down into these two major steps:

1. Adjustment of calibration at each of the three conventional load points (100 per cent load, unity power factor; 10 per cent load, unity power factor; 100 per cent load, lagging power factor 50 per cent).
2. Verification of calibration accuracy at all three load points.

Conventionally, calibration adjustments at these three load points are made in successive cut and try steps. Usually a rough adjustment of light load is made by applying potential only to the meter being tested and adjusting until the meter disk does not creep. This is the familiar "creep method." Lag-load adjustment, because of the uniformity of controlled manufacturing processes, is set within close limits in assembly. The setting of full load or the location of the damping magnet with respect to the center of the meter disk is done by successive test runs and adjustments until the desired accuracy is achieved. When the accuracy at all three load points called "as found" readings are obtained, a simple calculation enables the tester to make those minor adjustments which will bring the meter accuracy at all points within the desired limits. Obviously, the smaller the spread in the "as found" readings the simpler the calculation and adjustment required on a particular meter. However, many cut and try steps are required before the "as found" readings are within sufficiently small limits to permit a single set of adjustments which will bring the entire calibration within the accuracy required.

In addition to the above limitations of the conventional procedure, long-time test intervals must be taken for each test run if a high degree of accuracy is to be achieved. This is due to the fact that meters are usually tested in gangs of as many as 15, connected to a common load with a rotating standard, for an interval corresponding to a given whole number of revolutions of the rotating standard. The displacement from the starting position of the disk of each meter is a measure of the error at the particular load point being tested. The precision within which these readings of accuracy can be made depends on the length of the test interval. Further, there is the problem of correcting for the error in the rotating standard.

Thus it is apparent, that much manipulation is required, before a satisfactory set of "as found" readings is obtained. It is also evident that, if the preliminary steps could be accomplished less laboriously, and if the entire calibration accuracy could be had at once, the procedure would be tremendously simplified. The discussion which follows, therefore, will describe the usefulness of the devices developed in this investigation to accomplish the desired simplification in procedure.

Calibration Adjustment

Full-Load Adjustment

Consistent with the scope of the investigation, the means provided for making calibration adjustment must be simple and, if possible, render instantaneous indication of changes in calibration. The stroboscope[3,4] is immediately suggested. We must, however, consider its limitations, for its practical value is dependent upon the angular velocity of the object being viewed, a distinct image, and a fre-

Paper 42-71, recommended by the AIEE committee on instruments and measurements for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 27, 1941; made available for printing December 22, 1941.

EDWARD E. LYNCH is meter engineer and MARK A. PRINCI is development engineer in the works laboratory, both with General Electric Company, West Lynn, Mass.

quency of light impulses which is compatible with good vision. The last two of these requirements, over the common ranges of frequency required, are readily met by mechanical or electronic means, or by a combination of both.

The third requirement deals with the angular velocity of the moving element, and an analysis of the conditions required for a stationary image or for a "hunting" image is necessary to understand its influence. Assuming a constant rate of light flashes upon a moving element, any change in angular velocity of this element will produce a change in the rate of displacement of the stroboscopic image with respect to a fixed reference point. When synchronism is achieved a stationary image results.

At synchronism $f = \frac{Nw}{2\pi}$

where

f = rate of light flashes in cycles per second
w = angular velocity of disk in radians per second
N = number of equally spaced elements

If the disk velocity is alternately greater and less than the synchronous speed, the image will be seen to advance and recede according to fluctuations in velocity. This characteristic is called "hunting." It is largely this condition which limits the universal application of the stroboscope in watt-hour meter adjustment, since the operation becomes tedious and time consuming and, in cases of excessive hunting, requires a high degree of skill to achieve accuracy. If observation of image displacement is hindered by hunting, the fluctuating image must be followed through its entire excursion (advance and recession) and the resultant advance and recession noted.

Figure 1 shows the speed-displacement characteristic of a watt-hour meter at both full load and ten per cent load. The magnitude of the variations in this curve is constant at all values of load, so that in percentage this magnitude decreases with increased load. The speed characteristic

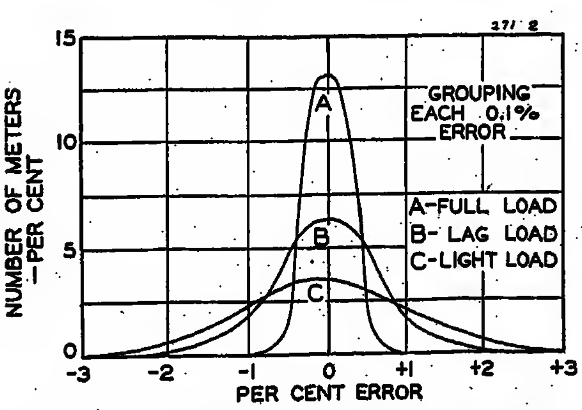

Figure 2. Distribution curves of calibration errors before final adjustment

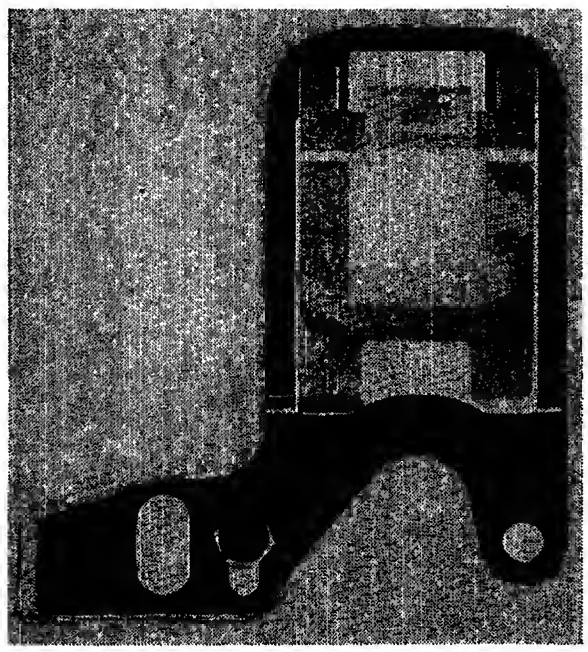

Figure 3. Adjustable-type compensated lag plate

of modern meters is, therefore, quite uniform at the high values of load, but at light loads a large variation in angular velocity exists.

The hunting of the image at these light loads could be eliminated if the flashing rate were made to fluctuate at a frequency corresponding to the irregular angular velocity of the disk and kept in time phase. This condition can be actually achieved only with difficulty and it is more practical to utilize a uniform flashing rate.

With the above facts in mind, a quantitative consideration of the angular velocities of the disk at various values of load on the meter, together with the desired limits of accuracy at each value of load, will define conclusively the limits of stroboscopic application to meter testing. A modern watt-hour meter such as that from which the characteristics were determined for Figure 1 has 720 equally spaced elements on the edge of the disk. At nominal load its speed is 1.745 radians per second, and it would, therefore, require a flashing rate of 200 per second to synchronize it at this speed or 20 per second at one-tenth this speed.

The image advance of this meter will be 7.2 elements per revolution of the disk when 99 per cent accuracy is obtained, or 0.72 element per revolution when 99.9 per cent accuracy exists. These displacements can be instantaneously observed if there is no hunting and may not be imperceptible with a small amount of hunting. If, however, hunting produces an image fluctuation greater than about five times the image displacement caused by the inaccuracy in meter calibration, then the personal error becomes large, and the stroboscope cannot be used except by specially skilled workers. This value is arbitrary and is the opinion of the authors obtained through experience.

The hunting magnitude is influenced by various factors which can be conveniently classified as follows:

I. Those that produce an essentially constant hunting magnitude at all loads:

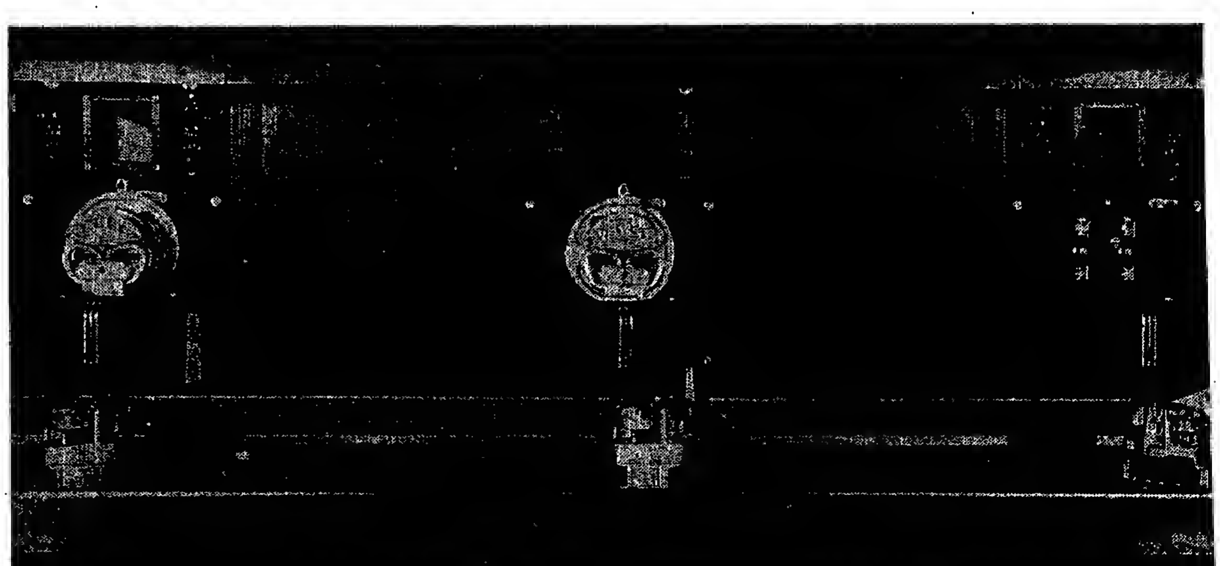
(a). Eccentricity of the disk.
(b). Nonuniformity of flashing rate.
(c). Nonuniformity of disk marking.
(d). Nonhomogeneity of the disk metal.
(e). Bent disks.

II. Those that produce their maximum effect at low loads:

(a). Variation in potential torque with disk position.
(b). Variation in friction with disk position.

Since the maximum total hunting will be produced at lower loads, we can see not only the difficulty of adjusting with small torques such as at light loads, but also the advantage of adjusting for nominal-load calibration with 200 per cent load current. An analysis of tests has shown that nominal-load adjustment can be made at 200 per cent load without affecting the load-speed characteristics of the meter appreciably, and for this reason, the fixture to be described later is designed to operate at 200 per cent load.

Figure 4. Front view of section of conveyor system and calibration-adjusting stations



Light-Load Adjustment

It can be concluded from the foregoing analysis that the stroboscope does not lend itself satisfactorily to calibration adjustment at light loads. Its convenience is also lessened, due to the necessity of alternately and repeatedly adjusting each load until all errors are sufficiently small. This is due to the effect of the light-load adjustment on other loads.

To be most convenient, the light-load adjustment must be accomplished as nearly as possible without influencing the other load adjustments, and the well known "creep" method which adjusts the torque due to potential alone so that the disk will not creep makes this possible.

The method consists of applying voltage to the potential coil and, without any load current, moving the light-load adjustment until the meter disk will not creep in either direction. In principle, it is one used for many years as a rough method of adjusting meters at light load.

Let us analyze just what we accomplish by so doing, for an analysis will show that although we are not fundamentally getting the adjustment we would like, we nevertheless accomplish a very good approximation of light-load adjustment.

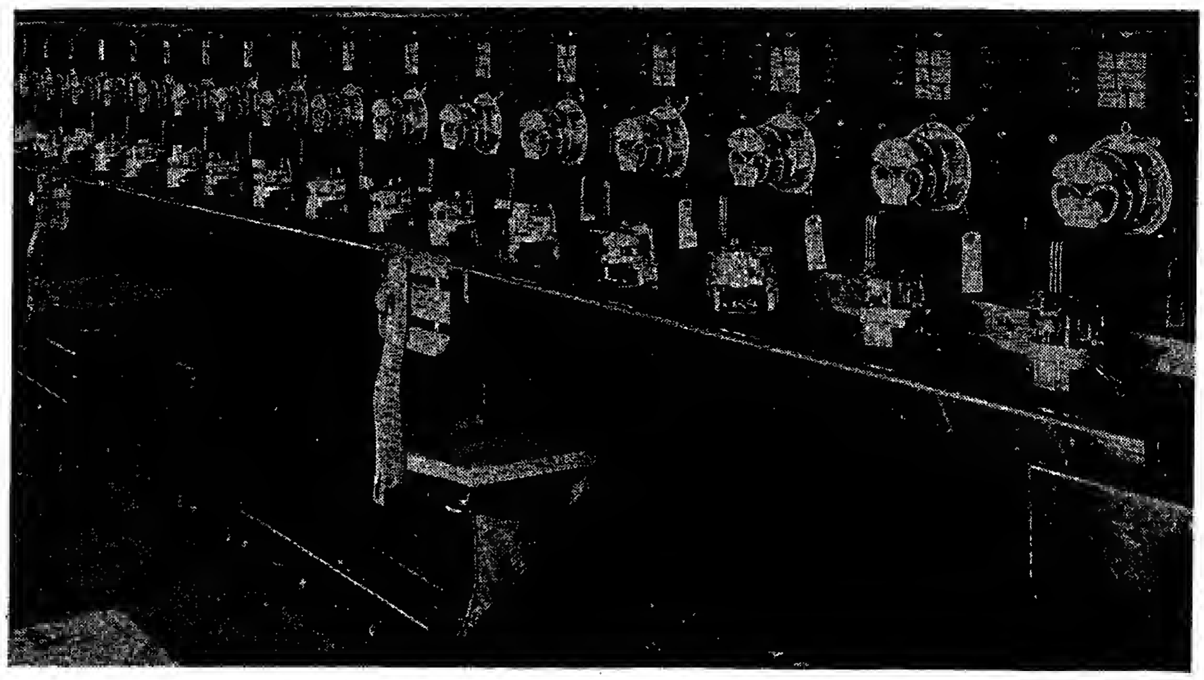


Figure 6. Portion of conveyor system showing bank of verification stations

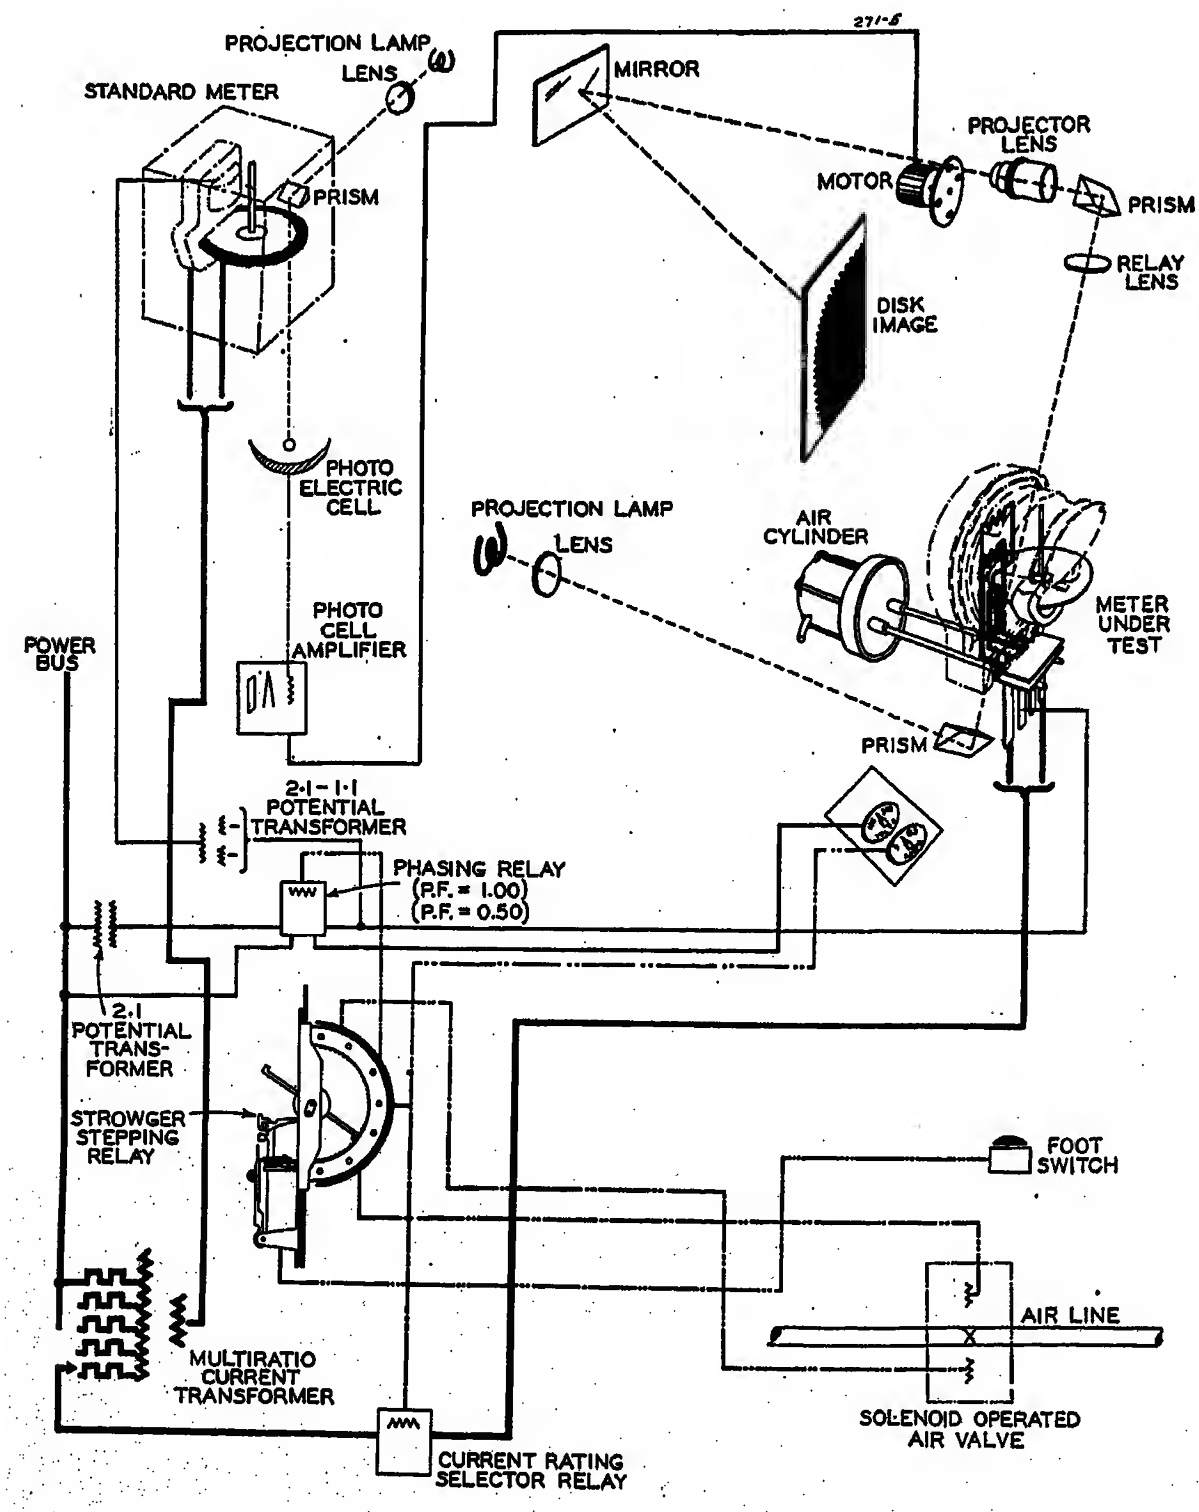
Figure 5. Line schematic diagram of internal connections in adjusting station



A definite but small error is introduced when we attempt to make the potential torque, T_e, equal to zero for, in a meter correctly calibrated at full, light, and lag loads, we find that T_e is rarely zero.[5] This small error will be a variable influenced by two factors shown below.

If we consider a general equation, such as the following, and realize that at the moment of "no creep" with no motion of the disk, the inertia and damping terms (both dependent on disk motion) are not present, and since the balance is performed with no load current, the equation[6] reduces from

$$J\frac{d^2\theta}{dt^2}+(D_m+D_t+D_e)\frac{d\theta}{dt}+(T_{ei}+T_t+T_e-T_f)=0$$

to

$$T_f=T_e$$

which means that the driving torque due to potential flux alone is made equal to the friction torque (see appendix).

This simple equation is complicated by the fact that T_e (similar to Figure 1) is not a simple function but depends on the disk displacement. Therefore, our calibration will depend on what part of the curve T_e we make equal to the friction torque.

By using care to see that the anticreep holes are kept 90 degrees from the element air gap, we can adjust the meter at a disk displacement shown in Figure 1, as 0 or 180, thus attempting to adjust at a point where the average potential torque is zero. This will obviously give the greatest consistency possible, although two factors will tend away from extremely precise results:

1. T_f, the friction torque, can be positive or negative depending on the direction of the tendency to creep.

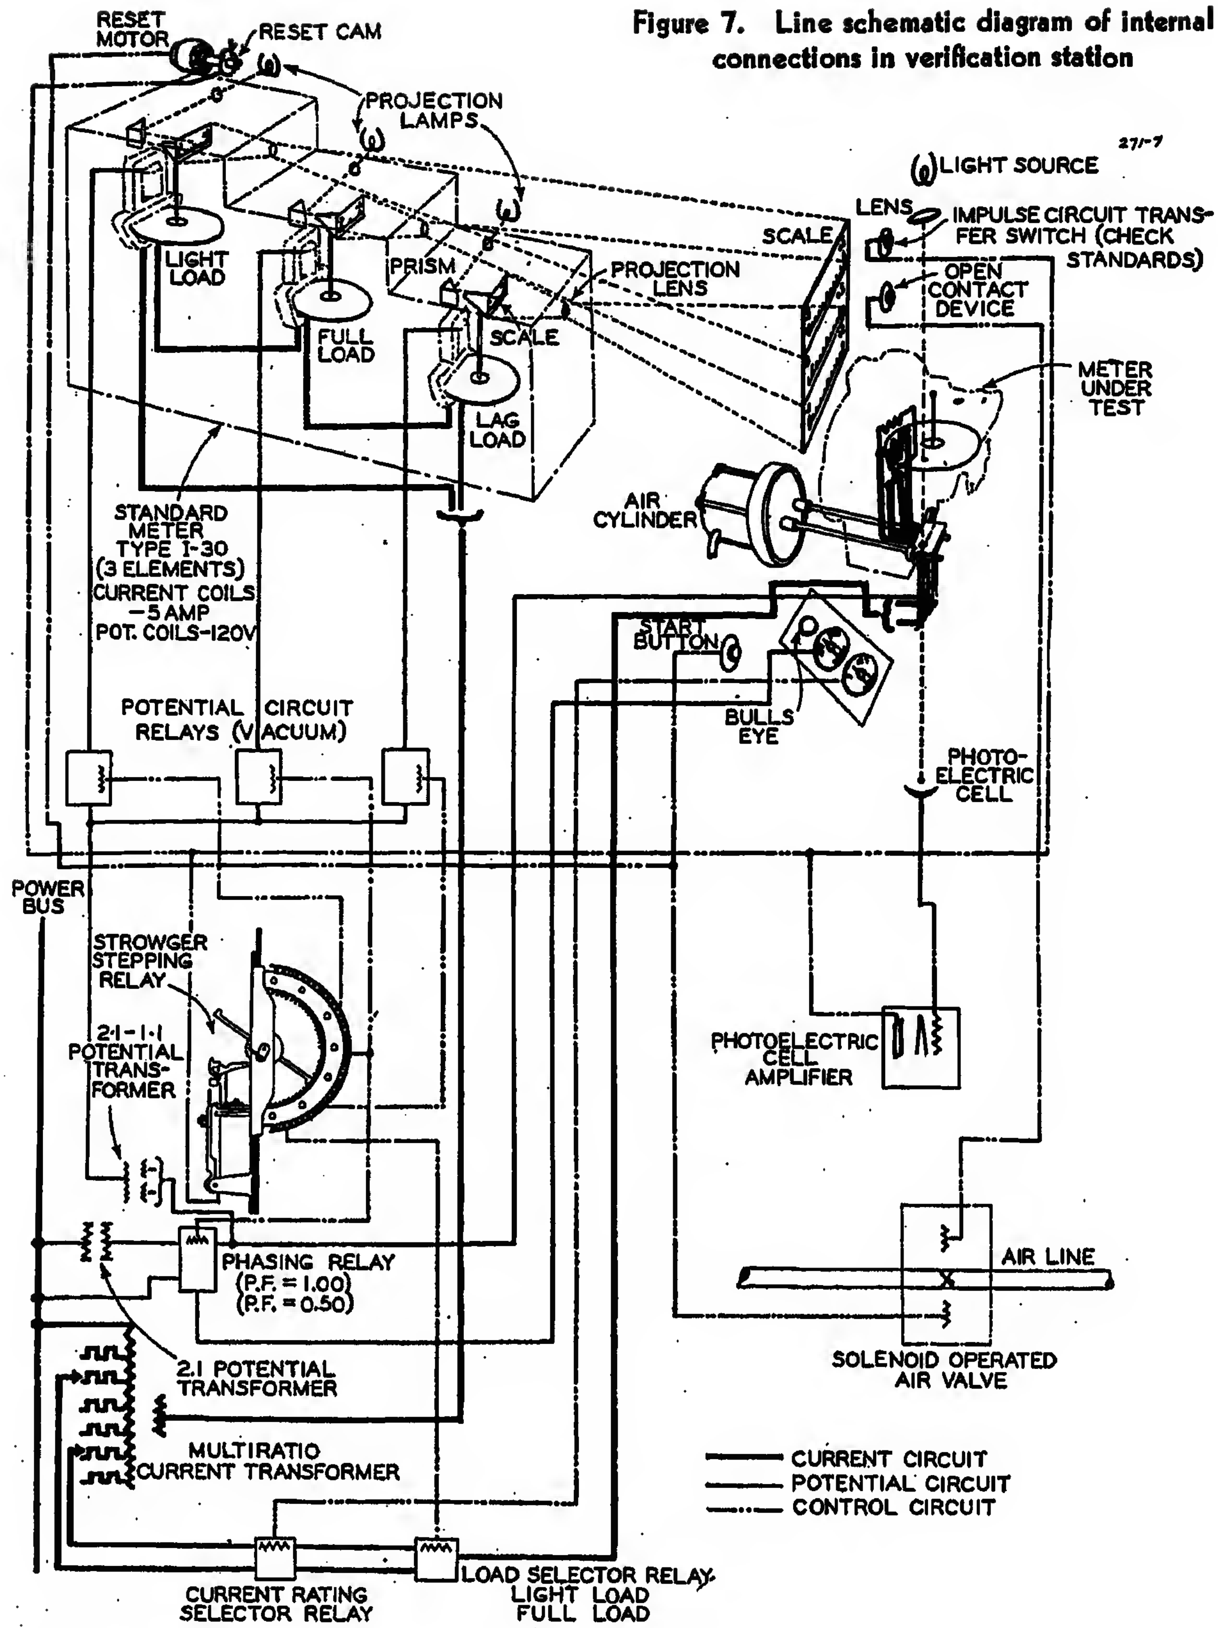


Figure 7. Line schematic diagram of internal connections in verification station

2. The point of adjustment may differ from that at which the shunt torque has its average values.

Although the above discussion might indicate that this method will not inherently give absolutely correct adjustment, a practical application of it has indicated that a very high percentage of meters will be obtained which are within normal allowable tolerance. A curve showing the distribution of accuracies over a large number of meters tested is shown in Figure 2 and is not inconsistent with the above analysis. For a preliminary adjustment there seems to be no better method of setting the light-load adjustment.

Any effort to try to adjust to a slight forward creep to compensate for the average negative error is apt to result in "personal" errors based on "judgment" which will be greater than the above inherent error, and, therefore, it is to be discouraged.

Lag-Load Adjustment

The third load point at which calibration is made consists of setting the lag plate which compensates for the phase angle of the potential coil. Adjustment of this compensator is made at 50 per cent power factor and 100 per cent load current. From the preceding discussion of the stroboscope, it is apparent that reasonable accuracy may be had by using that device for making adjustment. Other methods, such as creep at zero power factor, torque method, or rotating-standard method, are also suitable, and at this juncture, the question naturally arises, why not use one of these methods—for instance, the stroboscope? This might well be accomplished, and many modifications have been developed which make the stroboscopic method convenient. However, any such scheme would require a succession of tests at each of the three loads and a return, until the error at each point has become sufficiently small to to give satisfactory calibration. In our application a "straight-line" procedure was sought, and since such a method involves definite advantages, any one which was not directly applicable to such a straight-line procedure was considered undesirable.

Adjusting the meter not to creep with zero power factor might well be used to accomplish this purpose, but it was found that, with meters equipped with an adjustable lag plate as shown in Figure 3, a quicker and equally satisfactory method is to set the position of the lag plate mechanically.

When this is done with an accurate fixture, a large percentage of meters will be correctly calibrated for lagging loads. A distribution curve of accuracies to be expected are shown in Figure 2b, which summarizes the experimental results on hundreds of meters over a period of several months. Rigid manufacturing control is necessary of the factors entering into the amount of lagging required and that obtained, such as the resistance of the potential coil and the conductivity of the lag plate, and so forth.

A micrometer fixture which can be adjusted from time to time to compensate for the drift due to manufacturing tolerance is an advantage, but for the highest degrees of accuracy, a slight further adjustment will be necessary on a small percentage of the meters.

A device in which this final adjustment can be conveniently made will be described later, but at this point it may be well to indicate the steps necessary to obtain this high degree of accuracy and to show how they fit into the manufacturing procedure.

I. While subassemblies are being made:

(*a*). Set lag plate mechanically.

II. After assembly:

(*b*). Set light-load adjustment by creep method.

(*c*). Set full-load adjustment stroboscopically.

III. After preliminary adjustment:

(*d*). Check calibration at all three loads.

(*e*). If necessary, improve light- and lag-load accuracies.

(*f*). Recheck calibration at all three loads.

Adjusting Device

For best results, adequate equipment must be used for the various operations. A very satisfactory fixture for accomplishing the preliminary adjustments men-

tioned above is shown in figure 4. Its schematic circuit is illustrated in figure 5. Maintenance on such a unit is minimized by conveniently mounting it to slide in or out of a conventional filing cabinet.

Figure 5 illustrates how the standard meter and meter under test are connected in "series-parallel" through multitapped transformers, so that various ratings of meters can be tested without affecting the accuracy of the standard meter which always operates at a fixed load. Selector switches mounted on the panel operate relays to select the desired loads to match the meter being tested, and the testing sequence is accomplished by means of a foot switch which operates a stepping relay so that a predetermined sequence of connections is obtained. The first and last position in this sequence makes and breaks respectively the connections to the meter under test through air-pressure contacts.

The stroboscopic standard is arranged in a convenient manner for setting and maintaining its accuracy at the one load at which it operates. Thermostatic temperature control eliminates any temperature effects in it and is a factor in maintaining this accuracy.

The stroboscopic image is obtained by mechanical means so that a maximum intensity of illumination may be obtained. Figure 5 shows slots cut in the disk of a standard meter. Through these slots a beam of light energizes a photoelectric cell, the output of which is amplified and made to operate a synchronous motor. This motor will operate at a speed proportional to the speed of the standard meter disk. A slotted disk mounted on the synchronous motor shaft interrupts another beam of light which through a suitable optical system projects an image of the teeth on the edge of the disk onto a screen. The standard meter is connected to operate continuously so that when creep adjustment is made, the image, though not

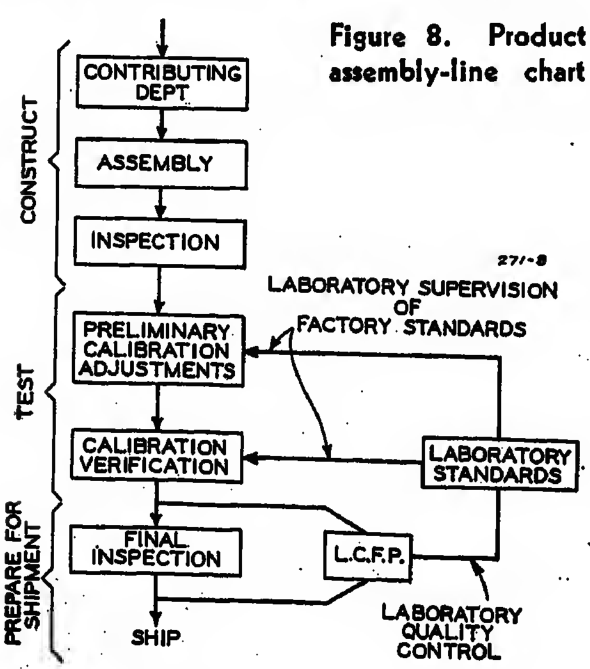

Figure 8. Product assembly-line chart

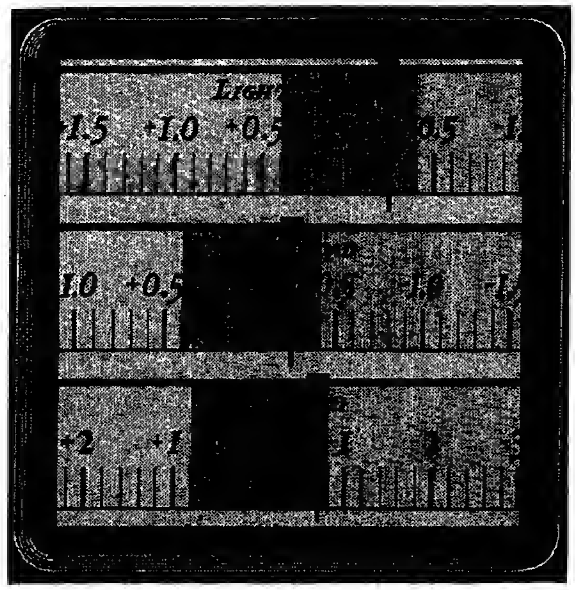

Figure 9. Close-up of scale images as viewed on panel of verification station

Calibration accuracy is read simultaneously at all three load points

stroboscopic, will not be obliterated by the disk on the synchronous motor.

The device is operated in the following convenient manner and in accordance with the previous theoretical discussion. A meter to be tested is placed in the contact-making fixture, and the foot switch is depressed. This operation closes the contact-making fixture and energizes the potential coil of the meter under test. An image of the meter disk will appear on the screen on the panel. This is not a stroboscopic image, but an actual enlargement of the disk teeth. This enlarged view of the disk makes creep adjustment of light load extremely simple. Before making light-load adjustment the disk should be turned manually so that the creep holes in the disk will be located in a plane parallel to the meter element. Then the light-load adjustment may be set so that no motion of the disk is observed on the screen.

The next depression of the foot switch energizes the current circuit of the meter under test, and there will appear a stroboscopic image on the screen. The position of the damping magnet is now set so that the image displacement is equal in both directions, if a slight amount of hunting is present. Having made this full load adjustment, another pressure on the foot switch will de-energize the meter under test and release the pressure on the contact block. The meter is then removed to the verification device where a picture of the calibration accuracy is obtained.

Verification of Calibration

Though for many years precise methods of watt-hour meter calibration have made use of precision instruments and constant load, it has been shown[7] that greater reliability is achieved by means of standard watt-hour meters giving for the first time the standard of watt-hour units. This standard, though maintained in the laboratory, can be readily transferred to the factory, and control maintained. Thus, it was decided to adopt the rotating-standard comparison method for the verification device. Essentially, the device consists of suitable switching and revolution-counting mechanism, together with the familiar portable standard watt-hour meter. The design and arrangement of the apparatus, however, are such as to achieve the results expressed in our introduction, namely, to obtain a direct indication of the complete calibration accuracy of the meter, and, in this respect, we believe that it is unique. The description which follows will deal chiefly with the novel design features and flexibility of the device.

Verification Device

The unit shown in Figure 6 in a multiple group was designed to give simultaneous indication of the complete meter-calibration accuracy. It employs a photoelectric timer which makes its operation automatic. The measurement is made by comparing the speed of the meter under test at each load with the speed of a separate standard for each value of load. This comparison follows automatically in sequence so that, at the end of a given time, the entire calibration appears upon the screen. The line diagram, Figure 7, shows schematically the arrangement of the apparatus by means of which this verification is made. In this figure, a light beam is directed from above the meter under test, through the path of the anti-creep holes and onto a photoelectric cell. The amplified output of the photoelectric cell energizes a sensitive relay. This arrangement is such that for each half revolution of the meter disk having two anti-creep holes, the above relay will operate once. The operation of this relay actuates a stronger stepping relay which in turn energizes relays to perform the following operations in the sequence indicated.

As the starting button is pressed with a meter in position, the standard meters are reset to zero through motor-driven cams, and the meter under test is energized. With the first light impulse after reset, light load is thrown on the meter under test, and the next impulse energizes the light-load standard. After a predetermined number of revolutions of the meter under test, the stepping relay has ad-

vanced to a contact that stops the light-load standard and throws full load on the meter being tested. The next impulse starts the full-load standard which runs until stopped by the stepping relay after a fixed number of revolutions of the meter undergoing test. As the full-load standard is stopped, lag load is thrown on the meter and the standard runs until stopped by the stepping relay. This again occurs after a given number of revolutions of the meter which energizes the photoelectric cell.

After these operations a picture of the meter accuracy at full load, light load, and lag load appears magnified in full view on a screen. This picture is obtained by projecting and focusing the images of transparent indicators which rotate with the standards and which replace the pointers for indicating the displacement of the pointer from zero. The transparent indicators are marked in divisions to represent error in tenths of a per cent and a manually operated index can be set to the point at which the zero position of the projected indicator image should stop if there is no error in the meter under test.

Once the accuracy of the meter has been visualized, the apparatus is ready to function again, or a release button can be pressed to disconnect the meter making it ready to remove the checked meter and replace it with one to be verified.

Conclusions

It will be readily observed that a suitable arrangement of the devices described when operated in the sequence discussed will result in an operating system which permits a uniform and progressive testing routine, readily coupled to conveyorized assembly manufacture. Figure 8 shows how the parts coming from contributing departments can be assembled and adjusted in a simple, uniform routine which moves along in progressive steps until the meter is ready for shipment, and which allows a laboratory check of the product to be made on sufficient quantities and at definite intervals without inconveniencing or upsetting the normal advance of these conveyorized operations. Although less skill is required by the operators, due to less tedious routine and more mechanized operations, more consistent accuracy can be expected, as errors are easily visible on an enlarged scale, and personal errors in judgment are eliminated.

The operation of this straight-line setup will, of necessity, reduce inventories of meters awaiting test and insure better service, since when a meter starts through there is little chance of sidetracking it, unless defects are found during inspection. This improved service means more meters delivered in quicker time and with full assurance of the high quality which any meter organization would be proud to associate with their own work.

Appendix

Single-Phase A-C Electric Locomotives on the Pennsylvania Railroad—Protection and Tonnage Rating

H. C. GRIFFITH
MEMBER AIEE

THE single-phase electric locomotive is thought of quite generally as a piece of motive power for heavy traction service. To an electrical engineer, however, it consists fundamentally of electric motors geared to wheels with means for controlling the applied voltage to handle a variable load at varying speeds.

From this point of view it is interesting to consider the protective features of the motors and their associated electrical apparatus to develop devices and methods which are necessary to guard against the hazards common to the operation of all electrical devices and those special to an electric locomotive. This paper will consider these features as they apply to the electric locomotives operating on the Pennsylvania Railroad.

The Electrical Apparatus

The single-phase a-c locomotive with series motors receives its power from a trolley at a relatively high voltage in order to provide economical distribution and good voltage regulation. The commutator-type motors must operate at a relatively low voltage in order to keep the commutators within a reasonable size because of the limitation of volts between bars.[1] A transformer is, therefore, necessary. Having the transformer to provide the lower voltage, a method for tap changing under load can then be introduced to control the voltage applied to the motors. The motors are permanently connected in parallel groups with the motors in each group in series. This permits a motor group to be cut out of service with no effect on the remaining groups, and the locomotives are occasionally so operated when trouble develops in a motor circuit. The method, Figure 1, of tap changing involves the use of preventive coils and heavy-duty contactors, and, in order to subdivide the voltage steps, a buck-boost transformer is introduced to triple the number of steps.[4] In addition to this, a-c series motors are operated at a low magnetic flux to provide favorable commutation conditions, and in operating at start and low speed when the armature current must be high, the field is shunted, Figure 2, to keep the flux in the same range as at continuous rating. It is also necessary to provide a commutating resistor (or interpole shunt) to produce the quadrature component of the interpole flux, and this shunting must be varied in one or more steps from high power factor at low speed to a lower power factor at high speed to provide adequate neutralization of transformed voltage in the armature coils.[1] The operation of the main-field shunt and the commutating-resistor contactors is controlled by relays, Figures 3 and 4, operating from the voltage across the main field and across the armatures, respectively, Figure 5. Finally contactors must be provided to reverse the main-field connections for operation in the reverse direction.

This equipment comprises the fundamental electrical necessities of the locomotive. In addition, there are numerous electrical auxiliaries, such as forced-ventilation blowers, air compressors, heating boiler, control batteries and charging equipment, lighting and cab signal equipment. The protection of this auxiliary equipment, while necessary, will not be covered specifically in this discussion.

Protection Required

Having the picture of the main features of the locomotive, the next step is to consider against what hazards the electrical equipment must be protected. These may be stated as follows:

1. Overload
2. Overvoltage surge
3. Failure of insulation
4. Incorrect operation of tap-changing switches
5. Excessive field at start
6. Unequal motor speeds—slipping
7. Failure of cooling air
8. Transformer overheating
9. Overspeed
10. Excessive current
11. Overheating of motors

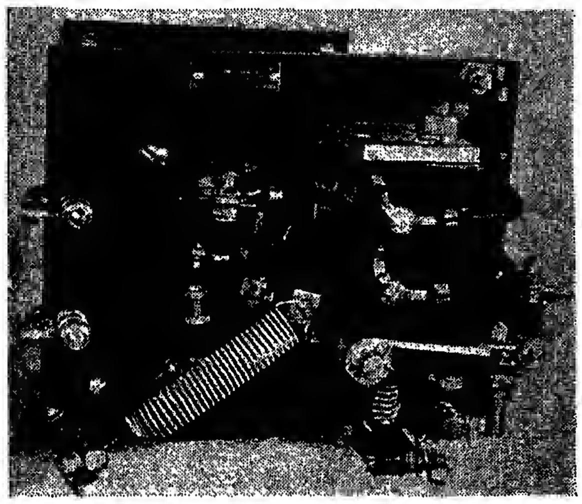

Figure 3. Interpole-field relay

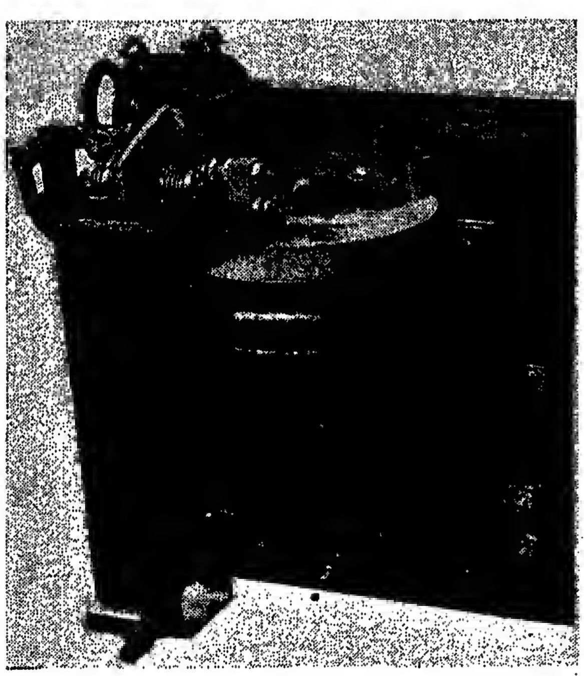

Figure 4. Main-field relay

This is a formidable list, but may be considered by classification of the manner in which protection can be provided.

Fully Automatic Protection

This method is provided for the first five conditions:

1. *Overload.* When the motor current exceeds a value beyond which it is unsafe to operate the motors for even a short period, the motor contactors are opened by the usual overcurrent relay.

2. *Overvoltage Surges.* These surges appear on the high-voltage side of the transformer and require the use of a lightning arrester.

3. *Failure of Insulation.* Faults of this nature are detected by a relay, Figure 6, known as the pantograph relay. In the secondary, or motor, circuits such detection is simplified by the fact that the circuits, Figure 7, are normally free from ground except through a current transformer, so that any secondary ground will cause the relay to operate. The primary winding of the transformer is protected by current differential between the ends of the winding. The operation of the relay first opens the motor and auxiliary switches, and, if this fails to clear the fault, an automatic switch grounds the pantograph collector, throwing the interrupting duty on to the substation circuit breaker. This relay is described in detail in the Luther paper.[2]

4. *Incorrect Operation of Tap-Changing Switches.* Tap changing on main transformer is performed by the introduction of three impedance (preventive) coils, the two smaller of which have their ends connected to four busses to which the taps from the main transformer are connected by the tap-changing contactors. The mid-points of these two preventive coils are connected to the ends of another larger preventive coil, to the mid-point of which is connected the outgoing lead to the motors. In this way four taps on the transformer are used on each of the running voltage steps, Figure 1, and a change to the next step requires the moving of only one of the four tap connections,

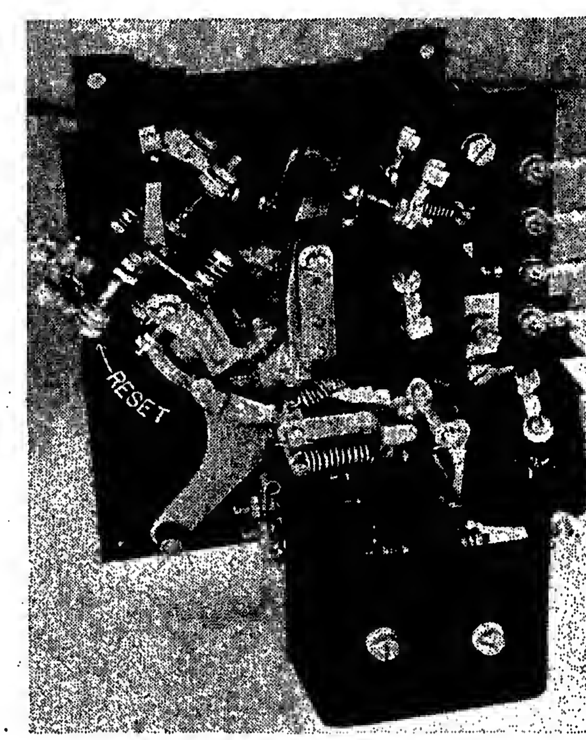

Figure 6. Pantograph relay

permitting smooth and even transition in the voltage change. The impedance of the coils is sufficient to reduce the circulating current between the taps to a low value, while the reactance to the load is cancelled out by the two directional flow to the mid-point leads. In order to prevent two tap-changing contactors from closing on the same bus, thereby short-circuiting a portion of the main transformer, interlocking is used between contactors. This has been extended in recent designs to include a group of interlocking relays, Figure 8, so connected that when a contactor fails to open properly, in addition to the fact that no other

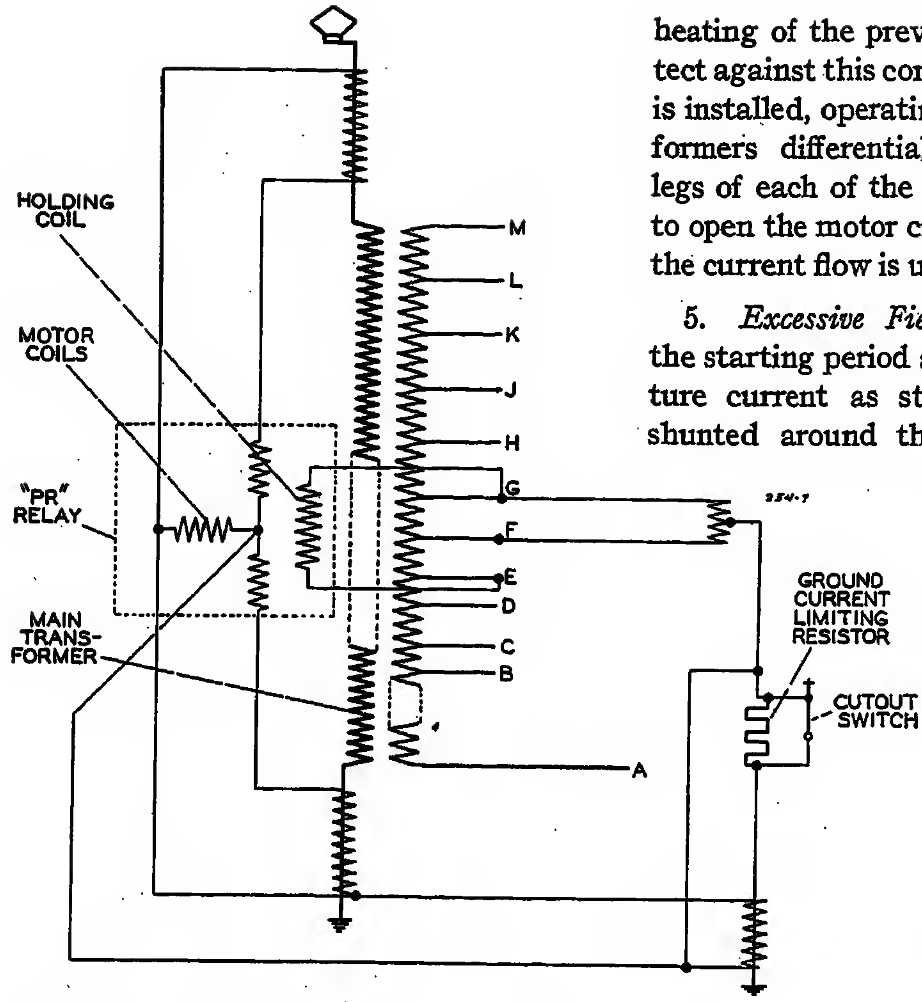

Figure 7. Pantograph ("PR") relay connections

contactor on the same bus can be closed, the contactors on the other busses cannot proceed to the other voltage taps. This prevents a large voltage difference being established across the preventive coils if a contactor on one of the lower steps remains closed while the contactors on the other busses have closed on the higher voltage steps.

This new arrangement of interlocking requires the use of fewer interlocking fingers on the tap-changing contactors and uses instead separate interlocking relays in an enclosed cabinet, Figure 9, providing a cleaner, more accessible and reliable arrangement.

This interlocking is complete excepting under one condition, that is, when a contactor fails to close in proper sequence. Under this condition one end of a preventive coil will be disconnected from the main transformer causing an unbalance of currents which will cause excessive heating of the preventive coils. To protect against this condition a thermal relay is installed, operating from current transformers differentially connected in the legs of each of the small preventive coils to open the motor circuit contactors when the current flow is unbalanced.

5. *Excessive Field at Start.* During the starting period a portion of the armature current as stated hereinbefore, is shunted around the main, or exciting, field to minimize commutation troubles. This function is performed by a relay, Figure 4, operating from the voltage across the main field.

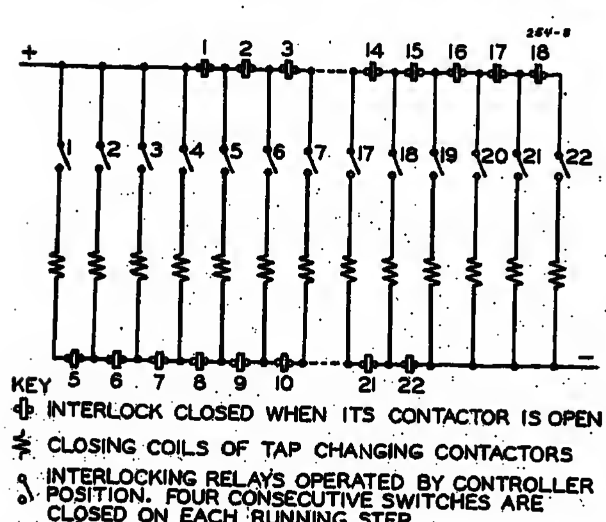

Figure 8. Simplified interlocking scheme for tap-changing contactors

Semiautomatic Protection

6. *Unequal Motor Speeds.* High peripheral velocity is normally designed into the traction motors, and if a pair of driving wheels slips, tractive power is lost, and the motor will soon reach a dangerously high speed. The division of voltage between the motors becomes unbalanced, Figure 4, if one motor slips or two slip at unequal speeds. A voltage balance relay, Figure 10, therefore, is used to indicate this condition to the engineman so that he may reduce the voltage on the motors. This indication is received when the slip differential is approximately 5 miles per hour. If the engineer fails to take the necessary action or is unable to control the slipping, the relay automatically opens the motor switches when the slip differential reaches 20 miles per hour.

7. *Failure of Cooling Air.* The motors and transformers are designed, because of space and economic limitations, to require forced ventilation. Failure of the air supply would permit rapid overheating. A relay in the air stream or a centrifugal relay on the blower shaft indicates such a failure to the engine crew.

8. *Transformer Overheating.* The main transformer is cooled by oil circulated by a pump. This oil passes through a radiator and is in turn cooled by air from the same blowers which provide forced ventilation to the motors. Failure of this cooling scheme to keep down the oil tem-

perature will operate a thermostatic alarm.

Indication

9. *Overspeed.* Speed is indicated to the engine crew by means of a speedometer. Excessive speed is dangerous to the armature windings and commutators. Dependence must be placed on the engine crews to keep the speed within limits safe to the equipment and also within the local speed restrictions of the roadway.

10. *Excessive Current.* Current is indicated by a separate ammeter for each of the parallel motor groups. The rate of acceleration is determined by the current value permitted, limited of course by the weight on driving wheels. A limit is set on the maximum motor current, which limit is appreciably below the setting of the overload relays, and proper attention to the ammeter readings during acceleration is required to prevent slipping and to stay within the range of good commutation.

Indicating Devices

Indicating lights are provided in the locomotive crew compartment to indicate the following:

(*a*). Low water in oil-fired train heating boiler

(*b*). Driving wheels slipping

(*c*). Forced-ventilation blowers stopped, or high transformer oil temperature

(*d*). Motor-overload relay operated

(*e*). Pantograph relay operated

(*f*). Main-motor-field shunting switches closed

(*g*). Fuel pump on heating boiler stopped

In addition to this, a buzzer operates to warn the crew for the first two conditions, that is, low water in heating boiler, or driving wheels slipping.

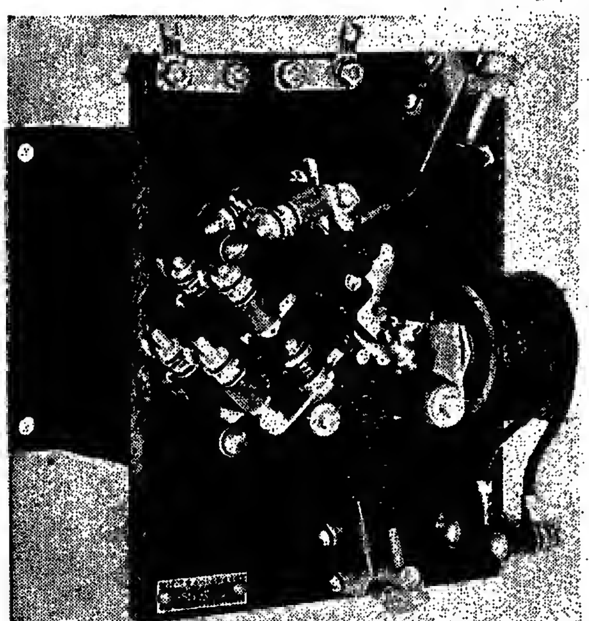

Figure 10. Wheel-slip relay

The indicating light panel, Figure 11, contains a row of amber lenses, on each of which is engraved the designation which it indicates. It is located beside and to the left of the engineman. On this same panel is the series of cab signal indication lights duplicating the aspects of the wayside signals. Here also are located the speedometer, the ammeters for each of the motor circuits, and the usual air gauges for the brake system.

Tonnage-Rating Limitation

11. *Overheating of Motors.* The temperature rise of the motor fields and armatures is the practical limit to the amount of work which the motors can do. These limitations are set by the kind of insulation used and must not exceed the permissible values, or the life of the motors will be materially shortened. Even if it were practical to have continuous indication of the controlling "hot-spot" temperatures, it would still not be practical to send out on the railroad an electric locomotive with a train which, operated under the normal speed and grade requirements of the route, might exceed the temperature limitations of the motors. In fact, no protective device, within the ordinarily accepted meaning of the term, is as yet available for avoiding excessive motor temperatures, without unduly limiting the use of the full short-time capacity of the locomotive.

It is, therefore, necessary to resort to other than electrical or mechanical means of providing this very necessary protection. The obvious method is, of course, so to safeguard the operation of the locomotive as to avoid overheating of the equipment. At the same time, however, the necessity for economical operation dictates that the maximum possible work be performed by the locomotives. To meet these two conditions a tonnage rating, that is, the maximum train which can satisfactorily be handled, is determined for each class of locomotive and each route.

The working out of these ratings requires that complete motor heating and cooling characteristics be available from shop tests of the equipment. The method for arriving at these characteristics has been covered in detail in the paper by Fremont Felix and H. G. Jungk presented at last winter's convention in Philadelphia.[3]

In addition to this, the usual motor-output characteristics for different speeds and voltages are required. Then, with the profiles, alignments, and speed restrictions of the route to be used, it is possible, assuming a weight of train, to determine the motor-output requirements at all points on the runs.[5] The time, distance, and output results are tabulated, and, by using the heating and cooling characteristics of the motors, the temperature rise at each point on the route is determined. If the permissible temperature has been exceeded, the run is recalculated with a lesser weight of train. Similarly, if the maximum permissible temperature has not been reached, a new calculation is made using a heavier train. In this manner, the maximum tonnage which the locomotive can handle over each route, without overheating the motors, is determined.

In addition to these ratings, this protective method requires a thorough education of the personnel to make it effective. Yard masters must be informed of the importance of keeping the weights of trains within the specified limits. Having a proper tonnage, the engineman must learn how to operate the locomotive in a proper manner. This proper operation involves avoiding excessively difficult starts in yards and on grades, avoiding prolonged operation in weak field, taking full advantage of the momentum of the train in negotiating grades, and a general knowledge of the operating characteristics and capabilities of the locomotive.

The results of such predeterminations of tonnage ratings on the Pennsylvania Railroad have proven most satisfactory. After the ratings had been determined by calculation, they were checked by making test runs. In order to make these road tests, thermocouples were built into the windings of several of the motors. A locomotive so equipped was assigned to a regular revenue train which was built up to the predetermined tonnage for the route to be followed, and the train was operated over the road. By means of recording meters a continuous record was made of motor current and temperature. Tests of this nature have been made over all the principal routes, and in all cases the measurements have closely checked the calculations. It has not been necessary to reduce any of the calculated ratings in actual operation.

Conclusions

The electric locomotive is composed of electrical apparatus which is subject to the usual hazards of similar equipment. The methods of protection require some of the usual types of device. The specialized application, however, introduces the factors of loading and operation as protective methods to a greater extent than is usually the case with generally similar equipment in other services. It has been the purpose of this paper to summarize and describe the electrical protection of the equipment, including not only the protective devices but those features of the utilization of the locomotive which become in reality protective methods.

Modern Electrical Equipment for Industrial Diesel-Electric Locomotives

LANIER GREER
MEMBER AIEE

Synopsis: Modern electrical equipment for industrial Diesel-electric locomotives is widely different in many respects from that used five or six years ago. New and improved high-temperature insulating materials and modern synthetic varnishes have been developed and are used extensively today. Also new and improved methods of using these and the older materials have been developed. These, together with new design constants, have made possible a reduction in weight per horsepower transmitted with an improvement in the quality of the product.

The Diesel engine and generator are close-coupled and mounted as a unit, thus assuring proper alignment and, at the same time, reducing the space required for mounting on the locomotive. A new and improved method of generator excitation has been developed which assures positive control of the engine speed and power. This provides a very flexible transmission of power from the prime mover to the rail.

The modern traction motor has a cylindrical instead of a rectangular frame. It is a multipole instead of the conventional four-pole design. It is mounted integral with a double-reduction gear unit which is completely enclosed in an oiltight gear case. All bearings on the motor armature shaft and in the gear case are antifriction except those on the axle, which are sleeve bearings. All bearings in the gear unit are oil-lubricated with the same oil that lubricates the gearing. Both the high and low speed pinions are straddle-mounted to insure proper alignment of the gearing at all times.

Industrial Diesel-electric locomotives are used in slow-speed switching service where high tractive effort is most important. For this type of work, double-reduction gearing with maximum reduction shows much better transmission efficiency than the conventional single-reduction gearing.

FOR many years most of the machinery in American industrial plants has been driven electrically. During the past five or six years Diesel-electric drive has taken a definite place in moving raw materials to and finished products away from the manufacturing plants. This widespread use of electric power for locomotives has been brought about largely by two simultaneous developments.

1. *Modern High-Speed Diesel Engine.* Through standardization and the use of essentially the same Diesel engine for locomotives, trucks, tractors, and stand-by power plants, the cost per installed prime mover horsepower has been lowered greatly. Also, at the same time, the necessity for light weight has been realized and this, together with higher speeds, has resulted in lighter weight engines that still retain their ruggedness and ability to produce power.

Usually these engines are equipped with two-speed governors set for idling speed and full speed. Between these speeds the fuel supplied to the engine is controlled manually by the position of the locomotive operating handle. This is known as an automotive-type governor and is the type used with the equipment described in this paper.

There is another type of governor that is used sometimes in industrial Diesel-electric locomotives and is used on practically all of the larger Diesel engines. With this type engine speed is set by the governor for each position of the locomotive operating handle. In each of these positions the governor supplies the engine with the amount of fuel necessary, up to full fuel, to maintain a given speed. This is known as a variable-speed governor.

2. *Modern Electrical Propulsion Equipment.* During this same period of time, new materials and methods have been developed and adopted for use in this electrical equipment. Through design and research, improvements have been made in, and ways have been found to use, standard materials to better advantage. These have made it possible to reduce weight and cost per horsepower and at the same time improve the quality of the product.

These two developments, together with improved locomotive design, have made a very economical Diesel-electric locomotive. This industrial locomotive has low initial cost, low maintenance cost, low operating cost, and high availability. It has many of the desirable features of a straight electric locomotive but does not require a large investment for plant and equipment. Locomotives of this type weighing from 20 tons to 65 tons inclusive are being manufactured by several locomotive builders.

A unit of electrical propulsion equipment for these Diesel-electric locomotives consists of a d-c commutating pole generator connected directly to a Diesel engine, one or two d-c commutating pole motors geared to the axles, and control to assist in maintaining a smooth even flow of power from the prime mover to the wheels. There are one or more of these units per locomotive, depending upon the weight and performance required.

Traction Generators

Mechanical Features

The generators have only one bearing, either ball or spherical roller, which is located at the commutator end of the machine and carries approximately one half of the weight of the armature. This bearing is mounted in a cartridge type of housing which is so arranged that the armature can be removed without exposing the bearing to dirt and other foreign substances. The use of all-metal labyrinth seals insures that the grease will be kept in and dirt will be kept out of the bearings. The other end of the armature is bolted directly to the engine crankshaft through a flexible steel disk coupling which is mounted integral with the generator fan. This coupling is designed so that it is rigid torsionally and radially. The torsional rigidity makes it possible to use the generator armature and fan for the engine flywheel, which eliminates the conventional flywheel. The radial rigidity is necessary to maintain the electrical air gap on the generator. At the same time the coupling has flexibility in angular and axial directions to eliminate the necessity for exceptionally close machining tolerances.

Figure 1 shows a modern Diesel-electric generator.

Lanier Greer is a designing engineer of the transportation motor engineering department, General Electric Company, Erie, Pa.

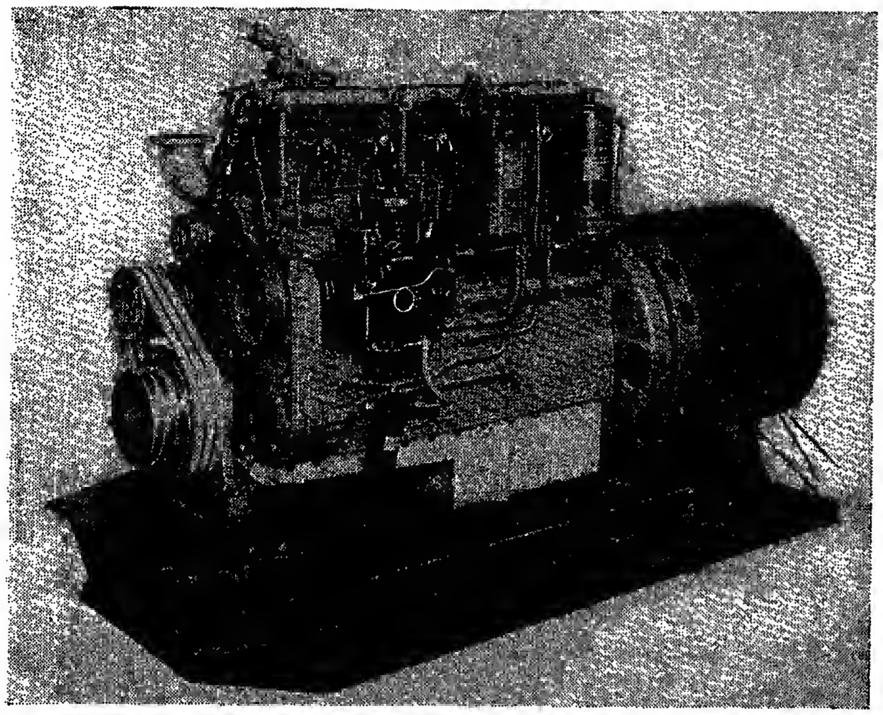

Figure 2. Modern high-speed Diesel engine with directly connected traction generator

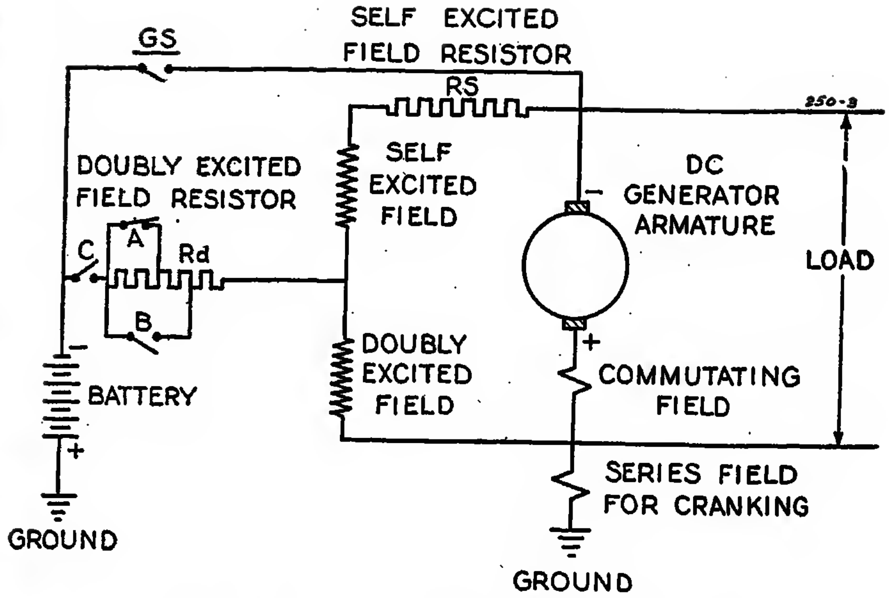

Figure 3. Diagram of connections for traction-generator excitation

The bell housing on the engine has been made special to serve the dual purpose of supporting the generator frame and providing a space in the formed openings for generator-fan discharge. When the generator frame is bolted to the bell housing and the armature to the engine crankshaft through the flexible coupling, the engine and generator become an integral unit and are mounted as such. Figure 2 shows a typical engine-generator unit. The generator fan located in the bell housing provides for multiple ventilation of the machine. One stream of air is drawn over the armature, through the air gap and between the field coils, and the other under the commutator and through the core.

Another important part of this modern generator is the improved brush holder. To collect current properly from the commutator it is necessary to have brush holders that will keep the brushes on the commutator even though it may be slightly irregular or eccentric. This is accomplished by special brush-holder, brush and brush-spring design. Care is taken to keep the brush riding against the trailing edge of the brush holder at all times. This is done by using a trailing brush with a beveled and clip top arranged so that the brush-spring pressure provides a component of force, holding the top of the brush in place, and at the same time provides the necessary radial force to keep the brush in contact with the commutator. The bottom of the brush is held in place by friction on the commutator. Due to the fact that all materials are being worked harder than ever before, brush holders must be spaced and aligned more accurately. This is accomplished by a brush holder designed so that it can be located easily and accurately, one which remains in a fixed position after it is located. These design features improve commutation, give long brush life, and insure generator characteristics that do not change from day to day due to change in brush fit or location.

The commutator must be kept tight and true. This is accomplished by using commutator-design constants which have been developed over a period of years of experience with high-speed equipments. Even with proper commutator design, difficulties occur in manufacture. These are corrected and a good commutator produced by seasoning it after the armature is completely assembled. This process consists of subjecting the commutator to centrifugal forces and thermal stresses in excess of those which are encountered in service, and tightening and grinding the commutator until it operates smoothly, both hot and cold.

In order to provide smoothness of operation, and to reduce noise and vibration to a minimum, it has been found necessary to dynamically balance the complete armature of all modern high-speed Diesel-electric locomotive generators.

Electrical Features

In the past few years insulating materials and methods have been improved greatly. Some of these high-temperature materials are asbestos cloth, asbestos paper, fiber glass, and mica. With the aid of modern synthetic high-temperature varnishes, asbestos and mica, as well as fiber glass and mica, have been combined to form tapes and wrappers. These materials have made it possible to use thinner insulation of a better quality and get a better-insulated machine. This leaves more space for copper and iron and at the same time improves the heat-transfer coefficient through the insulation. Another advantage of these materials is their ability to stand high temperatures and still have long life. By using high temperatures the weight of material per horsepower transmitted is reduced. By the inherent long life of the materials, maintenance costs are kept low.

Careful study of the magnetic circuit has made it possible to so proportion the various parts of the generator that all materials are utilized to better advantage. This also has resulted in reduced weight for a given amount of power transmitted.

The modern locomotive generator is equipped with a series field winding and operates as a motor for cranking the engine from a 32-volt or 64-volt storage battery. This eliminates the starting motor drive and ring gear, and at the same time reduces the amount of apparatus to be maintained. This type of engine cranking has proved to be very successful and reliable.

The locomotive operating character-

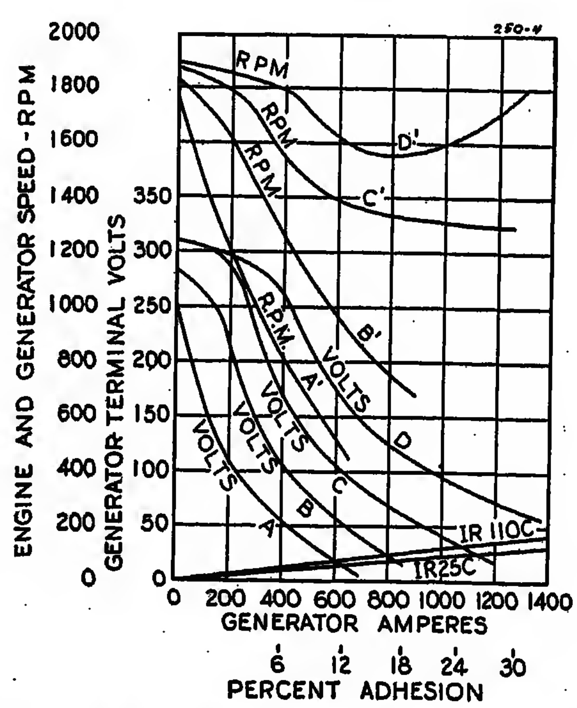

Figure 4. Characteristics of Diesel-engine traction-generator unit

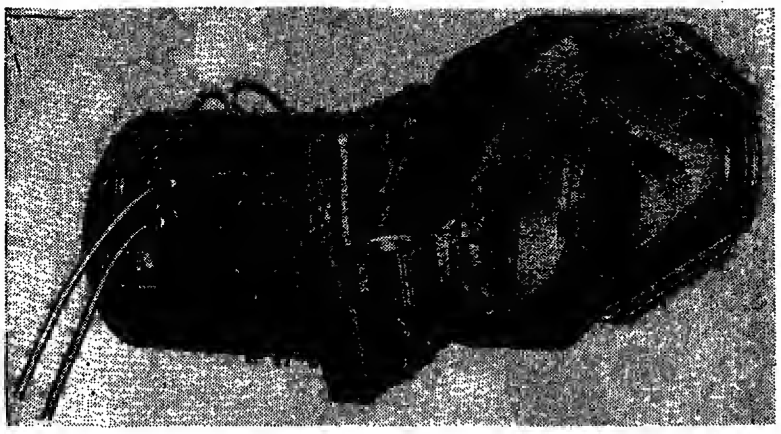

Figure 5. Modern d-c traction motor and double-reduction gear unit

istics are largely built into the generator. For a number of years Diesel-electric industrial locomotives did not have the most desirable operating characteristics. Full advantage was not taken of the fact that electric drive is the most controllable and most flexible of all drives. Recently, detailed studies have been made of various generator-excitation schemes to obtain the very best possible operating characteristics. Some of the more desirable of these are:

1. As the locomotive operating handle is moved from the idling position toward the full throttle position, the locomotive speed increases with the engine speed.

2. As the engine speeds up, the generator voltage increases to provide increased locomotive speed either with or without additional fuel.

3. Smooth acceleration is obtained without jerks or hesitation at all values of throttle opening.

4. The engine must not be loaded so heavily that it does not accelerate rapidly and evenly, nor loaded so lightly that it accelerates too fast and gives the impression of a "slipping clutch."

All of these features have been built into the newest industrial Diesel-electric locomotives by use of a generator which is essentially self-excited. This generator is provided with a doubly excited split field which receives most of its excitation from its own armature and the balance of its excitation from the storage battery on the locomotive. Each section of the field is designed so that approximately one half of the resistance of the circuit is external and does not change with temperature. This minimizes the variation of generator characteristics with temperature change in the windings.

A simple schematic diagram of the connections which are used is shown in Figure 3. The resistor R_s in the self-excited circuit is set to give the proper value of excitation for full power and full speed, Figure 4, curves D and D', and remains set for all other values of speed and power. The resistor R_d in the doubly excited field circuit is varied in three steps by the two switches marked A and B in Figure 3. As the locomotive operating handle is moved from the idling position towards the full throttle position, R_d is set at the three different values which are necessary to insure a full even flow of power at all positions of the operating handle. These changes are made by a cam-operated switch, which is connected to the locomotive operating handle. A double cam switch, which is in the throttle-linkage mechanism between the operating handle of the locomotive and the engine fuel pump, changes the fuel pump setting to provide the proper amount of fuel.

From Figure 4 it can be seen that the speed-ampere and volt-ampere characteristics are very steep. This provides voltage and current which are supplied to the traction motors on the locomotive, causing its speed to follow that of the engine.

Referring to Figure 4, curve A, the first power position on the motor-current resistance (IR) line is at approximately 12 per cent adhesion on the locomotive. This value of adhesion has been proved by experience to be one which gives no jerks but provides a smooth, rapid start. This point will be practically the same at every start, because the volt-ampere curve crosses the motor-current resistance (IR) line at a steep angle, which will change very little as the temperature of the motor windings changes. This is shown by reference to the two motor-current resistance (IR) lines shown on Figure 4, one at 110 degrees centigrade and the other at 25 degrees centigrade. Since there are no notches on the locomotive operating handle quadrant, there are infinite steps of power and speed between the first power position, Figure 4, curves A and A', and the full power position, Figure 4, curves D and D'. Curves B and B', C and C' are shown to illustrate the shape of intermediate power and speed positions. Additional study of the engine-generator characteristics shows that the generator with its controlled excitation is acting to electrically govern the engine at all speeds below that at which the mechanical governor begins to operate.

Further reference to Figure 4, curves D and D', shows that there is a wide range of amperes over which the generator volt-ampere curve is equal to the engine output, less the generator losses and a small loss of power due to the speed of the engine not being held constant. This makes it easily possible and very desirable to use only one motor combination if more than one motor per power plant is required. With a single motor, or with motors in parallel, if two motors are used per power plant, practically full power utilization can be obtained from 30 per cent adhesion on the locomotive to 60 per cent of maximum permissible operating speed. This is very desirable since it simplifies the locomotive control.

Battery-Charging Equipment

Battery charging on industrial Diesel-electric locomotives is done by one of two methods, depending on whether a 32-volt or 64-volt battery is used.

The 32-volt battery is charged with automotive-type equipment. This consists of a 750-watt shunt-wound generator which is mounted on the engine in such a way that it can be driven by a belt or from an auxiliary shaft. A vibrating contact regulator is used in the field of the generator to hold approximately constant voltage over a range of charging current, which is limited by a series coil in the regulator. The generator is self-ventilated by a small fan.

When a 64-volt battery is used, a 1.5-kilowatt shunt-wound charging generator is used. It is mounted on the floor of the locomotive and belt-driven from a pulley on the end of the traction generator shaft. The voltage on the charging generator is held constant by a vibrating contact

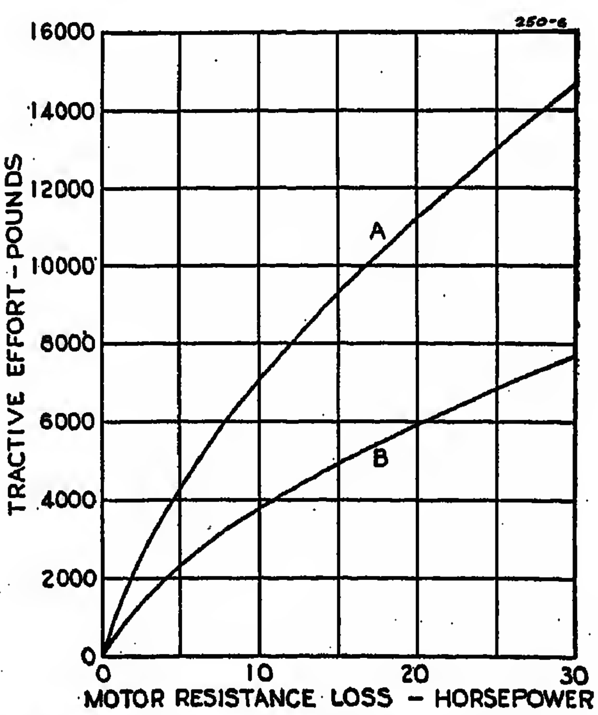

Figure 6. Comparative motor-resistance-loss curves for traction motors with single-reduction and double-reduction gearing

regulator operating in the shunt field. The current is limited by a ballast resistor in the battery-charging circuit. This generator is self-ventilated by a fan mounted directly on the armature shaft.

Traction Motor and Gearing

Mechanical Features

The modern Diesel-electric industrial locomotive traction motor is very different from the conventional railway motor. The new motor has a rolled-steel cylindrical fabricated frame instead of a cast-steel rectangular frame. This new construction has a number of manufacturing advantages and also is more desirable magnetically since casting blowholes are eliminated. The motor is very accessible for original assembly and for repairs. It is equipped with double-reduction gearing instead of the conventional single-reduction gearing.

The commutator is of special design to meet service requirements. In addition to the use of design constants that give a sturdy strong commutator, it is given a thorough seasoning after the armature has been completely assembled.

The armature is designed to withstand the stresses of high-speed operation that go with double-reduction gearing. The coils are held in the core slots by wedges and the end windings are held with binding wire. The completed armature is dynamically balanced to very close limits so that it operates smoothly and with very little vibration at all speeds. It is also equipped with antifriction bearings on both ends. The commutator end bearing housing is designed so that the armature can be removed without opening the bearing housing and exposing the bearing to dirt. This bearing is also arranged with all-metal labyrinth seals to keep grease in and to keep dirt out. The bearing on the opinion end of the motor armature is mounted on the shaft after the motor pinion has been mounted. This forms a straddle-mounting for the pinion. The bearing on this end is housed in the gear case and lubricated with the same oil as the gearing.

The frame of the motor is bolted to the gear case so that the two become an integral unit and are mounted as such. Figure 5 shows the motor and gear unit.

The gear case which forms a part of the motor and gear unit is a rugged steel casting of special design. It is made in one piece except the gear cover which is a malleable iron casting and is bolted to the gear case along a 45-degree line. All bearings and pinions are assembled so that they can be replaced without removing the motor and gear unit from the locomotive. The motor and gear-unit support is so located that, for either direction of motion of the locomotive, there will be no tilting to throw the gear mesh out of alignment or place a twisting load on the axle bearings under the heavy tractive efforts encountered in service. This type of hardened gearing operating in an oiltight gear case has a long life, which should be equal to that of the locomotive. The gear unit is equipped with flood-lubricated sleeve axle bearings and thrust surfaces, and with antifriction intermediate and high-speed bearings operating in an oil bath. Both the high-speed and low-speed pinions are straddle-mounted to maintain alignment. The gearing is straight spur on both reductions.

The motor is self-ventilated. This is found to be practical in a motor which is used with double-reduction gearing, since even in slow-speed switching service, motor speeds are high enough to make the motor fan effective. The fan which is mounted on the armature shaft at the end opposite the commutator provides for multiple ventilation of the machine.

Electrical Features

In the motor use has been made of the various insulating materials, varnishes, and methods used in the traction generator. By this means the best possible quality has been obtained with the smallest amount of insulation. This has made it possible to get more tractive effort rating per pound of material used.

In order to further conserve material, motors have been designed with more than the conventional four poles. The latest industrial Diesel-electric locomotive motor is a six-pole machine. The multipole design reduces length of end windings and commutator. Also the use of multipoles provides for better distribution of field windings. This, in connection with detailed studies of the magnetic circuit, has enabled the designer of modern motors to materially reduce the size and weight of the field structure.

The field coils have also been reduced in size by the use of new insulating materials and methods. Both exciting and commutating coils are edgewise-wound and formed to fit the poles. The completed coils after being mounted on the poles receive a number of dips and bakes in modern synthetic insulating varnish. With this type of coil the heat-transfer coefficients are much higher than for a conventional coil. After the poles and coils are assembled in the frame, the complete assembly is dipped in modern synthetic varnish and baked to fill completely and insulate all connections and joints so that they are sealed and protected from water, oil, and other foreign materials that may enter the motor.

The design constants of the motor have been made such that the motor has a very steep speed curve, and a wide range of field control can be used. These, together with the engine-generator characteristics, Figure 4, make a locomotive with a wide range of full utilization of available engine horsepower.

Since industrial Diesel-electric locomotives are essentially slow-speed machines, and transmission efficiency is an important factor, double-reduction gearing is superior to single-reduction gearing for this service. A much greater reduction can be obtained with double-reduction gearing *than with single-reduction gearing*, and, *at the same time*, clearance under the gear case *can be* maintained, as specified by the Interstate Commerce Commission. This can be done while still having ample top speed for industrial service. Figure 6 shows motor losses at 110 degrees centigrade copper temperature, with an assumed two volts for brush drop, under starting conditions where good efficiency is most difficult to obtain, and where the difference between transmissions is most noticeable. Figure 6, curve *A*, is for the double-reduction motor with maximum reduction.

Figure 6, curve *B*, is for a comparable single-reduction conventional motor with maximum reduction. A study of this curve clearly shows the advantage of double reduction for locomotives that are not required to operate at high speed but are required to provide high tractive effort. Since at the starting point of the locomotive all the losses are in resistance, the difference between curve *A* and curve *B* in Figure 6 shows the additional tractive effort that can be produced with the double-reduction gearing over the single-reduction gearing for a given horsepower loss.

Correction for Saturation

THOMAS C. McFARLAND
MEMBER AIEE

IT is generally agreed that the virtual or air-gap voltage of a salient-pole synchronous machine determines the saturation in the magnetic circuit. Studies have indicated that the major portion of the saturation occurs in the poles of such machines. Consequently, it is logical to apply a correction as a linear addition to the nominal or excitation voltage vector of the two-reaction diagram drawn with unsaturated constants, in order to ascertain the actual per-unit excitation necessary under load conditions which produce a certain air-gap voltage. It is the purpose of this paper to present an analytical method for determining the necessary correction.

Careful tests have shown that the correction for saturation which is to be added to the excitation voltage obtained without saturation can be quite accurately determined for a given condition of loading by moving the zero-power-factor saturation curve for that load so that it coincides with the no-load saturation curve below saturation.[1] In Figure 1 the dashed curve is determined by moving the zero-power-factor load-saturation curve to the left a distance $Od=bc$. The horizontal intercept ab between the air-gap line and the dashed curve is the total per-unit correction corresponding to the condition of loading which produces a per-unit value of i_d equal to the per-unit armature current of the load-saturation curve, and a component of air-gap voltage in phase with the excitation voltage equal to Oe.[1,2]

If a family of zero-power-factor load-saturation curves is available, by moving each curve to coincidence with the no-load saturation curve as explained above, a family of dashed correction curves is obtained. Since at zero power factor $i_a=i_d$, it follows that *the parameter for this family of correction curves is* i_d. Having such a family of curves the procedure would be to determine the excitation voltage by drawing an unsaturated two-reaction diagram in accordance with the equivalent air-gap line drawn through a point on the no-load saturation curve equal to the air-gap voltage for the desired condition of loading. From this diagram i_d could be determined, and from the family of correction curves the intercept between the air-gap line and the curve of parameter i_d could be read corresponding to the direct-axis component of the air-gap voltage.

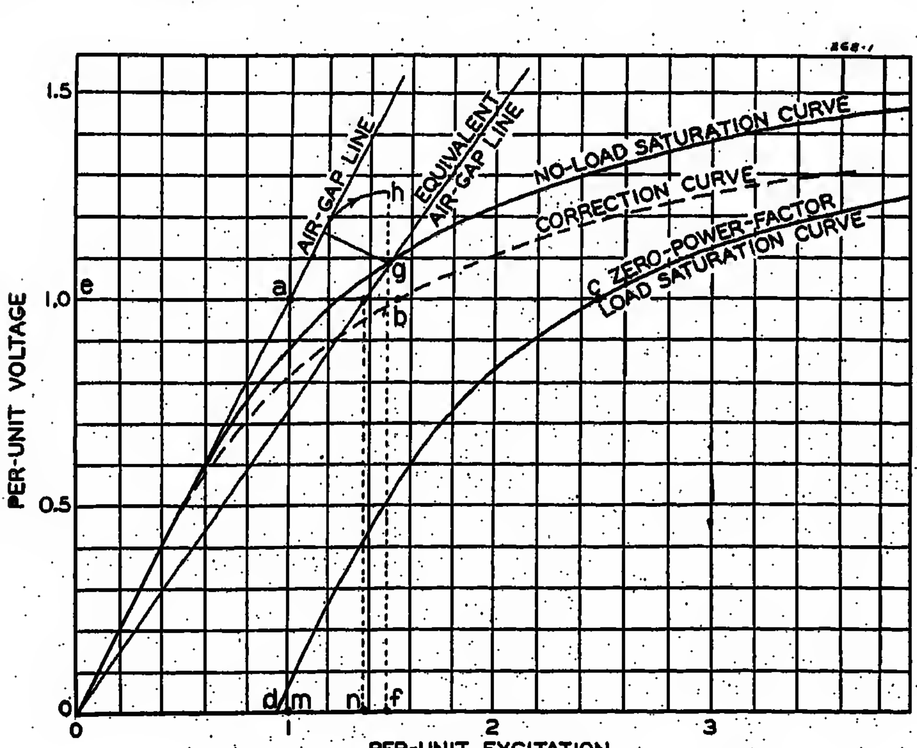

Figure 1. Saturation curves

The foregoing method of correcting for saturation is predicated upon the possibility of obtaining a family of correction curves, and this, in turn, depends on the ease and accuracy of the method used to secure the load-saturation curves. If the machine is already built, it may be possible to get these curves by test methods, but unless these methods involve but a few simple no-load tests the practical importance of the curves is nil. The greatest value of the correction curves would come in designing synchronous machines and in the predetermination of their performance. An empirical procedure which facilitates the application of the above principles is to express the saturation curves by a general mathematical equation and to employ saturation factors derived from the no-load saturation curve.

A modification of Froelich's equation for expressing a family of saturation curves is as follows:

$$V=\frac{A(i-Ci_d)}{B+i-Di_d} \qquad (1)$$

wherein

$A, B, C,$ and D are constants to be evaluated
i=per-unit field amperes or ampere turns
i_d=per-unit direct-axis component of armature current
V=per-unit volts

Solving the equation for field excitation,

$$i=\frac{BV+(AC-DV)i_d}{A-V} \qquad (2)$$

From equation 1 it is seen that when $i=Ci_d$, $V=0$. Hence, by subtracting Ci_d

Paper 42-68, recommended by the AIEE committee on electrical machinery for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 7, 1941; made available for printing December 17, 1941.

THOMAS C. MCFARLAND is associate professor of electrical engineering, University of California, Berkeley, Calif.

from the right side of equation 2 the expression for the correction curve is obtained. As a result, for the correction curve

$$i=\frac{BV+(C-D)Vi_d}{A-V} \tag{3}$$

The equation for the air-gap line, in per-unit values, is

$$i=V \tag{4}$$

The *total correction for saturation* is the difference between the air-gap line and the correction curve. Whence, subtracting equation 4 from equation 3

$$\Delta=\frac{V[V+(B-A)+(C-D)i_d]}{A-V} \tag{5}$$

To evaluate the constants of the preceding equations it is necessary to have the no-load saturation curve, the unsaturated per-unit direct-axis synchronous reactance, and one point on the full-load zero-power-factor saturation curve at about rated voltage. Constants A and B are found by solving two simultaneous equations which are derived by choosing two corresponding sets of values of V and i from the no-load saturation curve and substituting them into the relation

$$V=\frac{Ai}{B+i} \tag{6}$$

which is the expression for the no-load saturation curve, obtained from equation 1 by making i_d equal zero. The values of V and i should be chosen with one set at rated voltage and the other set with considerable saturation.

The constant C is numerically equal to the unsaturated per-unit value of direct-axis synchronous reactance. From equation 1 it is seen that when $V=0$, $C=i/i_d=i$ when $i_d=1$ per-unit. Excitation i is necessary to circulate rated current when the machine is short-circuited. If i is held constant and the short circuit is removed, the voltage of an unsaturated machine will rise to the air-gap line. This voltage is the unsaturated synchronous-impedance drop. By virtue of the definition of unit field excitation as that value which produces unit volts at the air-gap line, the per-unit value of i must equal the per-unit value of unsaturated direct-axis impedance. Hence, neglecting armature resistance, C is numerically equal to the unsaturated per-unit x_d.

If a test point on the full-load zero-power-factor saturation curve near rated voltage is available, the constant D may be found by substituting the corresponding values of V and i for this point into equation 1, along with the values of A, B, and C, letting i_d equal unity.

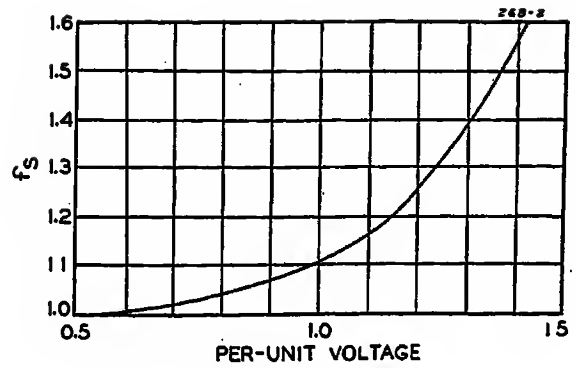

Figure 2. Saturation factor

When no test point on the full-load zero-power-factor saturation curve is available, the following empirical procedure may be used. At zero power factor the per-unit air-gap voltage may be taken equal to the algebraic sum of the per-unit terminal voltage and the per-unit armature-leakage reactance. Through a value of voltage on the no-load saturation curve equal to the per-unit air-gap volts, draw an equivalent air-gap line. In Figure 1 point g represents a per-unit value of air-gap volts. At rated voltage unit field excitation for the equivalent air-gap line is greater than unit excitation for the actual air-gap line by the ratio On/Om. Therefore, the excitation-voltage vector from an unsaturated two-reaction diagram referred to the actual air-gap line must be multiplied by this ratio to refer it to the equivalent air-gap line.

To account for increased saturation due to the presence of armature current a saturation factor[3] may be used. In Figure 1 the saturation factor corresponding to g is the ratio fh/fg; gh is the perpendicular distance of point g from the air-gap line. A corresponding factor for other voltages on the no-load saturation curve may be found in a similar manner. A plot of saturation factors as a function of per-unit volts is shown in Figure 2.

A point on the correction curve corresponding to rated voltage is found as the product of the saturation factor at rated volts and the ratio On/Om. Addition of the unsaturated per-unit value of direct-axis synchronous reactance drop caused by load current i_d gives the desired point on the zero-power-factor load-saturation curve for substitution in equation 1 to determine constant D.

As an illustration of the foregoing principles consider the computation of excitation characteristics for the 40-horsepower, 440-volt, 6-pole, 1,200-rpm, 0.8-power-factor synchronous machine for which test data are given by Robertson, Rogers, and Dalziel.[1] The unsaturated per-unit values of the machine constants are: $r_e=0.04$, $x_e=0.086$, $x_d=1.045$, $x_q=0.55$. The no-load saturation curve is shown in Figure 1.

To determine constants A and B values of $V=1.0$ and $V=1.4$ are chosen. Respective values of i are 1.25 and 3.04. Substitution of these values in equation 6 gives two equations from which it may be determined that $A=1.906$ and $B=1.133$.

C is found from the test data as being equal numerically to $x_d=1.045$.

From Figure 1 the ratio $On/Om=1.38$.

From Figure 2 the saturation factor corresponding to rated voltage is seen to be 1.1.

Applying the procedure outlined above the per-unit excitation for rated voltage at the full-load zero-power-factor saturation curve is $(1.1\times1.38)+1.045=2.563$. Substitution of these values in equation 1 gives

$$1.0=\frac{1.906(2.563-1.045)}{1.133+2.563-D},$$

whence $D=0.803$

By equation 5 the correction for saturation is

$$\Delta=\frac{V(V-0.773+0.242i_d)}{1.906-V}$$

In applying this relation i_d is scaled from the two-reaction diagram and V is interpreted as the projection of the air-gap voltage on the excitation voltage. For leading power factors with generators and for lagging power factors with motors the effect of armature reaction is magnetizing. In these cases the sign of i_d must be taken negative.

When drawing the two-reaction diagram both the per-unit excitation and the power angle are usually desired. It has been shown that it makes little difference in the excitation whether the saturated or unsaturated constant x_q be used, but the power angle is definitely influenced.[1] The saturated value of x_q should be used for accuracy. Since the rate of saturation of the quadrature axis is roughly half that of the direct axis a saturation factor for x_q can be found from Figure 2 as $1.0+(f_s-1)/2$. Dividing the unsaturated value of x_q by this factor gives a saturated value to be used in constructing the vector diagram.

As a check on the accuracy of this method, consider Figure 5 of the paper by Robertson, Rogers, and Dalziel.[1] On this vector diagram $V=1.217$ and $i_d=0.647$. Substitution of these values in the relation for the total correction gives

$$\Delta=\frac{1.217(1.217-0.773+0.157)}{1.906-1.217}=1.06$$

Using the unsaturated value of x_d the excitation voltage for the case shown is 1.85 per unit. Adding the correction gives a

A 2,500,000-Kva Compressed-Air Powerhouse Breaker

I. Introduction

THE use of compressed-air breakers for indoor service has become established by several field installations since the presentation of papers[1,2] describing these devices two years ago. At that time complete tests had been made justifying ratings to 1,500,000 kva. Since then, powerhouse requirements have demanded the development of similar breakers for 2,500,000 kva. During the same interval new laboratory facilities have been provided[3] which are capable of completely testing these large breakers. This paper describes the theory and construction of this new breaker and for the first time presents test results of full 2,500,000 kva under three-phase fault conditions, together with a study of associated voltage recovery rates.

With the completion of the 2,500,000-kva rating, a complete series of indoor air breakers from 500,000 kva up is available which are common in fundamental design and operating pressure. In fact, compressed air was chosen as the interrupting medium because it was found after study of many types of interrupter that this means alone was adequate throughout the range for an oilless breaker.

Paper 42-41, recommended by the AIEE committee on protective devices for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted November 19, 1941; made available for printing December 22, 1941.

L. R. Ludwig is division manager, H. M. Wilcox is in the switchgear engineering department, and B. P. Baker is research engineer, research laboratories, all with Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

The authors are indebted to a number of Westinghouse engineers and laboratory operators for assistance in this development, and particularly to R. C. Cunningham for his contributions.

II. Transverse-Blast Compressed-Air Interrupters

The transverse-air-flow type of interrupter has been shown to be capable of interrupting currents in excess of 60,000 amperes and fundamentally does not appear to have the current limitation inherent in a nozzle type of interrupting element. Consequently, for the 2,500,000-kva breaker this general type of interrupter was chosen. Figure 1A shows a diagrammatic sketch of the form of the interrupting device, and Figure 1B shows a partial assembly of the actual apparatus.

The interrupter is built up of alternate splitter plates and cooler units, disposed substantially parallel to the air blast and perpendicular to the arc. The arc is drawn from back to front across the discharge end of the blast tube and blown into the ends of the slots of the splitter plates. The moving contacts are of the blade type, hinged at the lower end and rotated back and forth by an insulated pull rod. The outer contacts are for carrying current only, and the middle one has the additional function of drawing the arc in the interrupter. The current-carrying contacts are completely isolated from the arcing contact, and, upon opening, they part approximately one inch ahead of arcing contacts. In the closed position, deep engagement into the stationary finger contacts is obtained. In the full open position the moving contacts are all completely withdrawn from the interrupter, so that an isolating air gap is placed in series with the interrupter, and all contacts are accessible for inspection. The assembly as shown is easily removed from the breaker; likewise, the interrupter can be removed as a unit from the contact assembly and supporting structure.

The actual interruption in an arc chamber of this type is accomplished by the air stream driving the arc against and between the lower ends of the splitter plates. When a normal current zero is reached the arc core is in a comparatively highly ionized condition, as indicated by the considerable leakage current and damping effect of the breaker on the recovery voltage, after the current zero.

The rate of deionization in a conducting gas column depends largely on conditions at the boundary where diffusion and recombination are most effective; consequently, it is very important to approach the current zero with a highly turbulent atmosphere surrounding the arc core. In compressed-air circuit breakers these boundary conditions are largely determined by the way in which the air flows with respect to the arc. If an arc is blown into a splitter of refractory material, it will be forced against the edge of the splitter, where it will remain more or less stationary with respect to the splitter. The flow of high-velocity air parallel to the splitter will cause one side of the arc to be highly turbulent, a condition very favorable to deionization. The other side of the arc, however, will be closely pressed to the splitter where the air velocity is substantially zero, and deionization will proceed very slowly. If, however, the splitter is made of some gas-evolving material such as fibre, an entirely different set of conditions will exist adjacent to the splitter.[4]

As the air flow, parallel to the splitter, forces the arc against the splitter edge, the heat from the arc liberates gas from the fibre which projects itself away from the splitter and into the arc stream at high

---

per-unit excitation of 2.91 which, by Figure 4 of the paper is equivalent to $2.91 \times 3.6 = 10.5$ amperes. Table I of the paper shows a test value of 10.7 amperes.

Consideration of Figure 6 in the paper by Robertson, Rogers, and Dalziel[1] shows for an underexcited motor a condition of loading where $V = 1.095$ and $i_a = 0.25$. Here

$$\Delta = \frac{1.095(1.095-0.773-0.06)}{1.906-1.095} = 0.352$$

The excitation voltage from this diagram is found to be 0.835. Whence the total excitation is $0.835 + 0.352 = 1.187$. This is equivalent to $1.187 \times 3.6 = 4.27$ amperes. Table I shows a test value of 4.36 amperes.

Application of the above procedure to other machines has shown that this empirical method will result in values of per-unit excitation under saturated conditions which check fairly closely with actual test results. Besides giving reasonable accuracy it has the further advantages of requiring a minimum of test (or predetermined) data and of being easy to apply.

velocity. This gas bombardment causes the arc stream to be highly turbulent on the side toward the splitter, and the air flow causes the arc to be highly turbulent on the side away from the splitter. Thus, the entire body of the arc lends itself very readily to deionization by diffusion, by reason of its high turbulence.[4] As a result, the space adjacent to a single splitter can be made to recover dielectric strength at a rate equal to the rate of rise of recovery voltage of the fastest powerhouse circuits, providing the ionized gas preceding the current zero is removed as fast as the current decreases toward its zero value. This condition is easily obtained if the rms value of the current being interrupted is small. As the current increases, the amount of gas liberated from the splitters becomes greater, and the air blast may become incapable of removing it fast enough. A 60,000-ampere arc in an arc-chute throat two inches wide will liberate sufficient gas from the splitter to cause the flow of gas to reverse a distance of six inches against a driving pressure of 150 pounds per square inch. If the rate of rise of recovery voltage of the circuit is slow, the stalled flow will have time to recover velocity, and dielectric will be restored. However, if the recovery rate is fast, the space below the splitters will remain clogged too long and reignition will result. Enlarging the throat of the arc chute or increasing the air pressure will obviously improve conditions; however, both result in an increased air consumption for a nominal gain in interrupting ability. Decreasing the volts per splitter by increasing the number of splitters results in some gain, but again as the number of splitters is increased, the gas-evolving surface is also increased, and the gas removal becomes more of a problem.

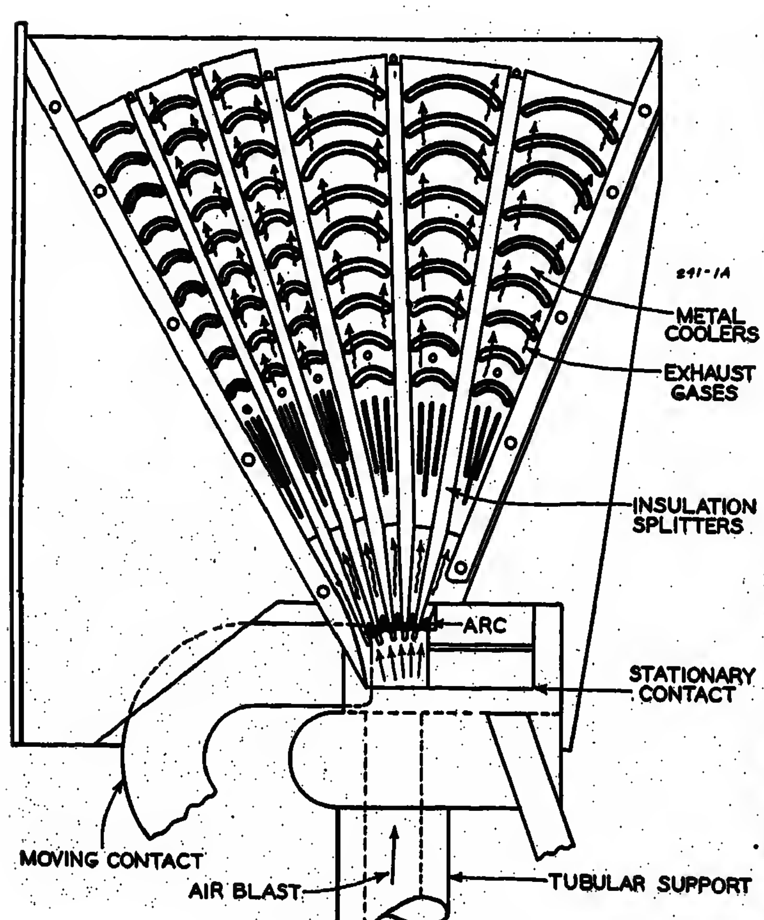

Figure 1A (left). Schematic diagram of a transverse-flow compressed-air circuit breaker

Figure 1B (right). Pole-unit assembly of a 2,500,000-kva 15-kv compressed-air circuit breaker showing the contacts and partially dismantled interrupter, after having interrupted 11 short circuits in excess of 1,500,000 kva

Likewise, spacing the splitters further apart allows more gas to escape, but this allows the arc to loop between the splitters a greater distance which in turn causes more gas to be liberated.

Figure 2 shows the fundamentals of a simple solution to this problem. The arc chute consists of a narrow throat portion and a wide portion. The splitters are full width and terminate at the narrow throat, having a notch cut into them just above the throat. The arc is blown into this notch which is well up into the wide portion of the chute. Since the throat is narrow and the approach to it is streamlined, the air approaches the arc with a high velocity. When the instantaneous value of the current is large, the arc does not block the flow of air, but exerts only enough pressure on it to deflect it to the sides, thus allowing the flow to continue. This diverted flow washes away the extraneous ionized flame as the instantaneous value of current decreases. By providing an escape for a continuous flow of air, the pressure on the arc never exceeds that which is necessary to deflect the air around it, and consequently, it is not pressed too tightly against the splitters which always results in too great evolution of gas and greater clogging. By using the means shown in Figure 2, it has been possible to build the interrupter for 2,500,000 kva in reasonable dimensions and obtain entirely satisfactory operation with a tank pressure of 150 pounds per square inch, even with very high-voltage recovery rates.

III. Breaker Construction and Operation

Figure 3A shows a 4,000-ampere breaker mounted in a steel cell and set up for test at the East Pittsburgh high-power laboratory, for the Consolidated Edison Company. Figure 3B shows a schematic side elevation of the same breaker. It consists essentially of an air-storage tank at the bottom, an air-operating mechanism at one side, suitable connecting levers for operating the contacts, an air-duct between the tank and the vertically situated arc chamber, and a separate mechanically operated blast valve for each pole.

This type of construction naturally places all parts of the breaker which operate at ground potential including the pneumatic and electric control, in the lower compartment of the cubicle. The tank and mechanism which constitute the heaviest parts of the breaker may, therefore, be supported directly on the floor where it is most accessible and completely separated by a horizontal barrier from the high potential compartment just above. This compartment, shown with the doors standing open, houses the contacts, interrupting elements, and all other live parts. The phases are separated from each other by removable vertical barriers extending inwardly from the hinge points of the doors. The contacts are very accessible for inspection; likewise, the barriers and interrupters may be easily withdrawn. Above the interrupter are diffusion chambers and mufflers, one for each phase. Upon interruption, the three mufflers discharge their gas into one common gas receiving chamber, which communicates with the outside through ventilating grilles as shown.

The flow of air for arc interruption is, therefore, as short and direct as possible, with no turns as it passes from the tank, through the blast valves and blast tubes across the arc and through the interrupter into the muffler and gas-receiving chamber at the top.

This is a very important factor in reducing pressure requirements and the quantity of air consumed. Tests have shown that with earlier experimental forms of breakers built with a single blast valve and numerous turns in the blast air-supply piping that the major portion of the energy stored in the air during compression is dissipated before the air stream

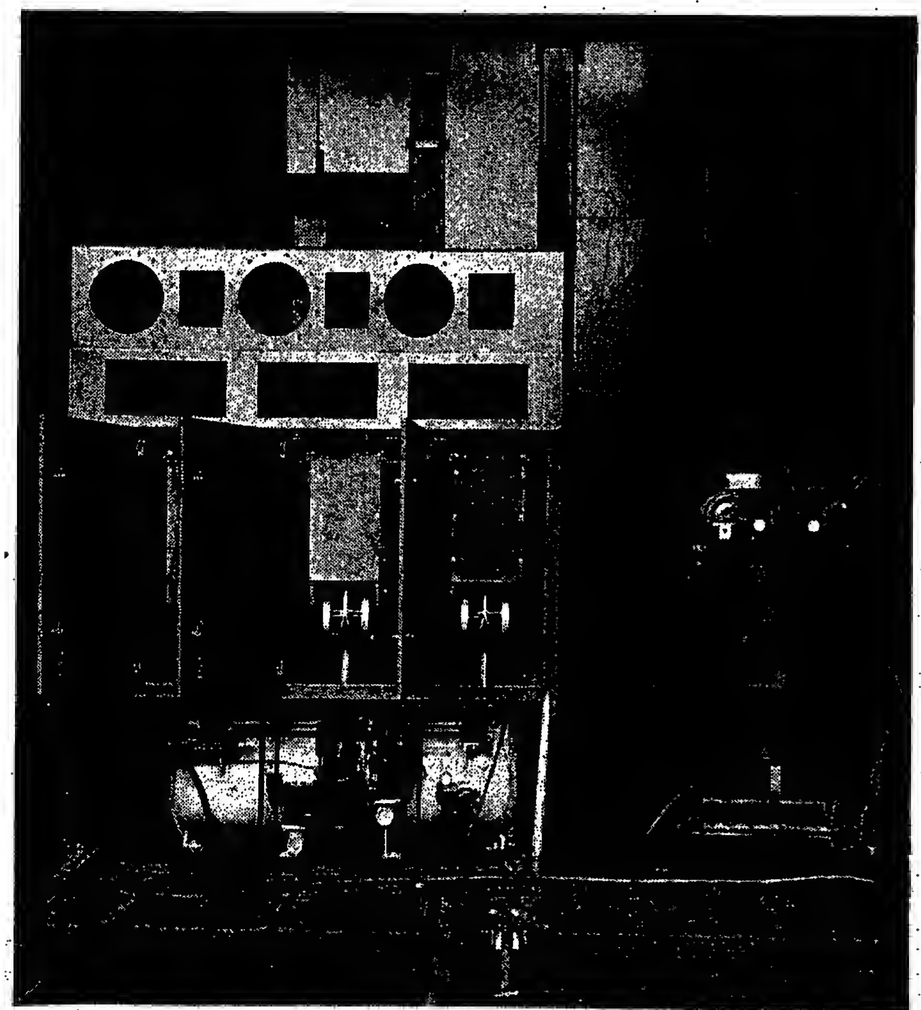

Figure 3A (left). Three-pole 2,500,000-kva 15-kv 4,000-ampere compressed-air circuit breaker in steel cell, set up for test at East Pittsburgh high-power laboratory

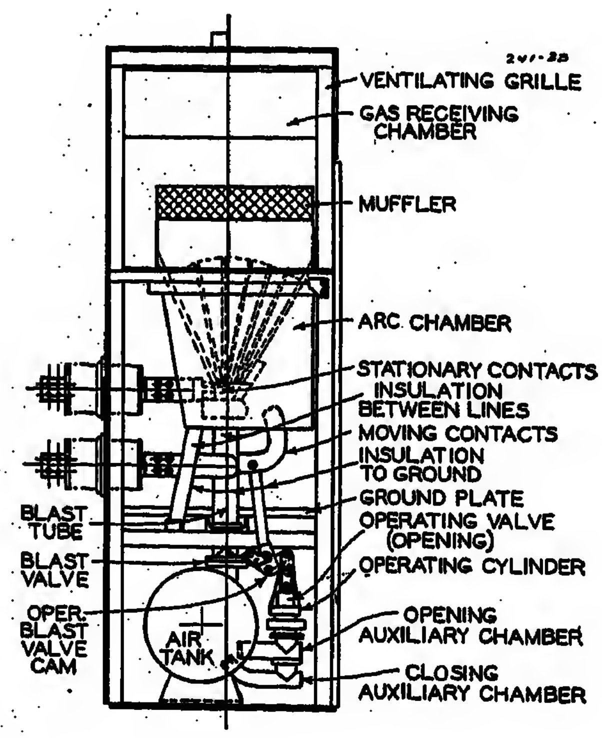

Figure 3B (right). Sectional elevation showing side elevation of the breaker in Figure 3A

reaches the arc chamber. With straight-line air flow these losses are reduced several fold. The three mechanically operated blast valves can be closely timed with respect to contact separation so that an extremely high rate of flow of air through the interrupter occurs during actual interruption, but the over-all air consumption is quite nominal.

The operating mechanism consists of a single air cylinder, in which a piston moves vertically. The piston is connected to a torsion shaft through a lever, piston rod, and a single set of links. The torsion shaft operates three insulating pull rods which in turn are attached to the moving contacts of the three pole units. The blast valves (one for each pole unit) are located at the top of the tank and are operated by rocker arms from cam surfaces which are a part of the torsion shaft. It is, therefore, possible to accurately synchronize the opening of the blast valve with the drawing of the arc in the interrupter. The cams and their co-operating parts are arranged to open the blast valve during the opening motion of the contacts only.

To open the breaker, air is admitted to the upper side of the piston from the opening auxiliary chamber, through a pneumatic relay, in response to a tripping impulse in an electropneumatic pilot valve. To close the breaker, air is admitted below the piston, from the closing auxiliary chamber, through a pneumatic relay in response to a closing impulse in another electropneumatic pilot valve.

The volume of each of the auxiliary chambers is adjusted to some suitable percentage of the volume of the operating cylinder and communicates with the main-pressure storage tank through a small hole of such size that it can charge an auxiliary chamber to full pressure in approximately one second. However, only a small amount of air can flow through this hole during the fraction of a second that it takes the piston to move from one end of the cylinder to the other. Thus, for instance, if the volume of the opening auxiliary chamber is one half of the volume of the operating cylinder, the pressure on the piston at the end of its travel will be approximately one third of the pressure at the beginning of its motion. By this means, it is possible to obtain an accelerating force of several thousand pounds at the beginning of motion and reduce this force to any predetermined value toward the end. This simple force system together with the toggle makes it possible to close the breaker against the heaviest short-circuit current; lock it in the closed position by moving the toggle over center, and upon opening, obtain high-speed contact separation.

If, however, it is necessary to open the breaker immediately after closing, the air below the piston which was used to close the breaker must be exhausted. To take care of this, an exhaust valve is built into the side of the cylinder and actuated by the motion of the piston. This insures that an opening operation is independent of the time the breaker has remained in the closed position; likewise, it can be used to insure that the closing is independent of the time the breaker has remained in the open position. The equivalent of trip-free opening and high-speed reclosing is thus accomplished without latches, springs, or trip-free levers.

IV. Air-Supply System

The mechanical operation and arc interruption of indoor compressed-air circuit breakers has been found to be unaffected by the temperature and moisture content of the air supply. However, moisture removal from the air is desirable to decrease corrosion, protect insulation, and eliminate any tendency from ice formation in the valves or other pneumatic devices. These provisions are met by a system consisting of an intake filter, a two-stage compressor operating to 250 pounds per square inch; a cooling coil, small-storage, and moisture-elimination reservoir; a second cooling coil and large main-storage reservoir. This system is connected to the line through an automatic reducing valve which drops the pressure to 150 pounds per square inch.

Elimination of oil vapors in the air system, essential to prevent explosion, is provided by the use of large slow-running compressors to prevent undue temperature rise and adequate cooling by suitable coils to condense oil vapors. The compressor is also of such a design that it is

difficult for crank-case oil to be carried into the air line.

Auxiliaries in the air-supply system consist of safety valves and two automatic checks to prevent air from either storage reservoir flowing backward to the compressor, necessary gauges, automatic switch to start and stop the compressor, and an automatic alarm valve which provides an indication if the pressure drops due to lack of compressor operation or serious leakage in the system.

Air auxiliaries incorporated as a part of the circuit breakers themselves consist of an additional filter to prevent scale, and so on, from the line entering the breaker tank, an automatic two-way check valve which prevents flow of air from the breaker back into the line and also automatically closes in the event of too large an air flow to the breaker, which could be occasioned by exceptional breaker leakage. An alarm valve and automatic lock-out valve are incorporated as part of the breaker to prevent its operation in case the breaker pressure becomes too low. A safety valve and gauge are also included on each breaker tank.

The breaker tank contains sufficient air for two-breaker operations without obtaining additional supply from the main system.

V. Test Results

The breaker was tested with the high-power laboratory facilities described in the MacNeill–Batten paper,[3] using two parallel generators at 13.2 kv, 60 cycles. Complete tests have been made, both single-phase and three-phase.

Tables I and II show a series of 31 consecutive tests made on an interrupter of this type. The tests were all three-phase, 13.2-kv, both opening and closing–opening, and with current values varying from 6,000 amperes to 105,000 amperes. The test with the highest current of this series, 105,000 amperes, was made with a tank pressure of 125 pounds per square inch and on a circuit with a rate of rise of recovery voltage of 2,080 volts per microsecond.

The maximum current closed was 247,000 amperes crest which had an rms value of 150,000 amperes. In nine of the 31 tests, the power interrupted exceeded 1,500,000 kva. For the 31 tests, the maximum arcing time for any phase did not exceed 0.8 cycle, which due to asymmetry of the current wave means that the breaker never failed to clear the circuit when the contacts were more than a small fraction of an inch apart.

Table III. Single-Phase Tests to Determine Effect of Recovery Voltage

Voltage (Kv)	Current Interrupted (Amperes RMS)	Natural Frequency (Cycles Per Second)	Circuit Voltage-Recovery Rate (Volts Per Microsecond—at Test Voltage)	Arcing Time (Cycles)	Inches Contact Separation at Interruption
13.2	8,000	200,000	13,600	0.8	2.5
13.2	8,000	200,000	13,600	0.7	1.5
13.2	8,000	200,000	13,600	0.8	2.3
13.2	8,000	200,000	13,600	0.5	1.4

12.0	76,000	32,000	2,390	1.2	8.0

Tables I, II, and III are the results of a series of 58 consecutive tests made without any maintenance on the breaker. Toward the end of the series the first two splitters in the arc chute were eroded sufficiently to lose some of their effectiveness, as evidenced by an increased variation in arcing time. The tests included in Table III, although valuable in indicating the life of the chute, are not as typical of the single-phase performance of the breaker in service as an earlier series of nine consecutive tests which was started with a fresh set of splitters and which gave the data presented in Table IV.

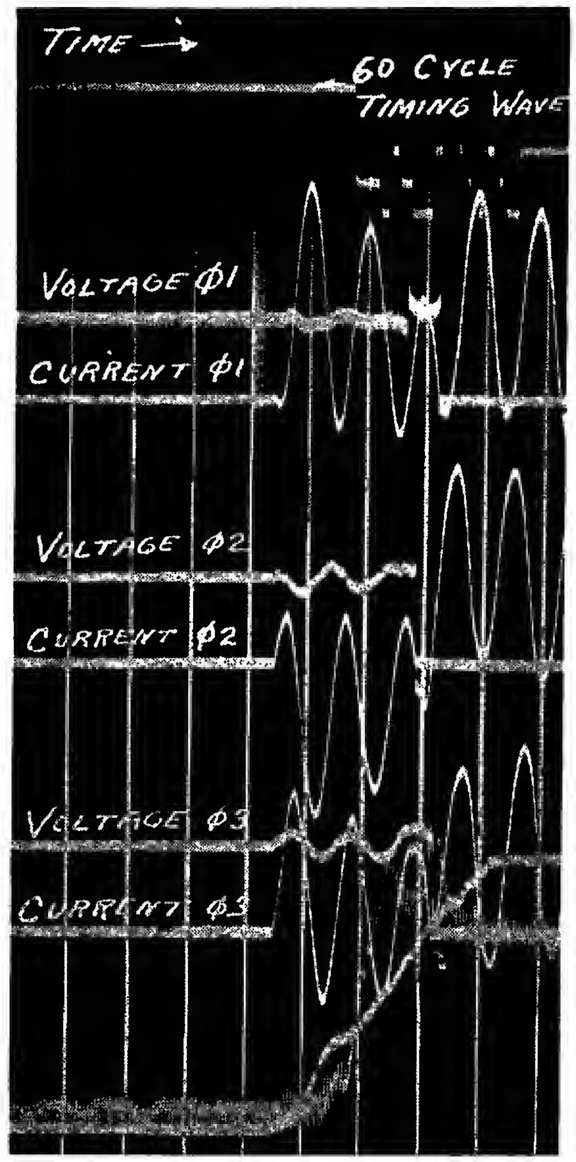

Figure 7. Magnetic oscillogram of an opening operation

Test 22, Table II. 13.2 kv. Current interrupted 105,000, 93,000, and 82,000 amperes

Figure 4 shows the oscillogram for test 7, Table I, which was a closing-opening operation interrupting 48,000, 49,000, and 49,000 amperes for the three phases, and closing in on 150,000, 95,000, and 148,000 amperes crest or 92,000, 59,000, and 86,000 amperes rms respectively.

Figure 5 shows the oscillograms for test 10, Table I, which was an opening operation, interrupting 91,000, 73,000, and 90,000 amperes respectively for the three phases.

Figure 6 shows the oscillogram for test 21, Table II, which was an opening operation, interrupting 102,000, 98,000, and 80,000 amperes for the three phases.

Figure 7 shows the oscillogram for test 22, Table II, also an opening test, with 105,000, 93,000, and 82,000 amperes interrupted for the three phases respectively. For this test the initial pressure in the tank was lowered to 125 pounds per square inch.

The ten tests recorded in Table I were made to demonstrate the breaker to the engineers representing the Consolidated Edison Company. This was the first witness test of an interruption of a three-phase fault approximating 2,500,000 kva.

Figure 1B shows the condition of the splitters, coolers, and contacts following the series of 40 tests as listed in Tables I, II, and III.

The first two splitters showed erosion. The coolers were blackened slightly, and the arcing contacts were pitted; however, the breaker was still capable of carrying current and performing further interrupting duty.

The external demonstration on all of these tests was negligible except for some smoke from the grille in the gas-receiving chamber. The noise was held to acceptable limits by the muffler system previously described.

During the development of the 2,500,000-kva breaker, a total of 140 successful interrupting tests was made which were in excess of 1,500,000 kva. The function of such a large number of tests was to study design variations, various operating pressures, and different types of circuit-recovery transients. It was found that the problem of obtaining satisfactory interruption of 2,500,000 kva was one of considerable magnitude, even when a proven breaker of 1,500,000 kva was already available.

VI. Effect of Circuit-Recovery Rate

In powerhouse service generator short-circuit currents would often exceed the capacity of circuit breakers if reactors were not used to limit these currents. These reactors are often placed near the circuit breaker, and this practice generally leads to calculated circuit voltage-recovery rates which are very high.

In case no reactor is used, the highest circuit voltage-recovery rate will be established by the natural frequency of the generators. Generally a single-frequency transient only is involved and the circuit recovery rate may reach approximately 2,500 volts per microsecond.

When the reactor is introduced, its natural period as well as the natural period of the generator is involved, and double-frequency recovery transients result. A natural frequency of the generator may be approximately 30,000 cycles, but the natural frequency introduced by the reactor

(A) 13.2 kv, 35,000 amperes, 100,000 cycles per second. 4,130 volts per microsecond

(B) 11.0 kv, 53,000 amperes, 240,000 cycles per second. 7,100 volts per microsecond

(C) 12.0 kv, 76,000 amperes, 32,000 cycles per second. 2,390 volts per microsecond

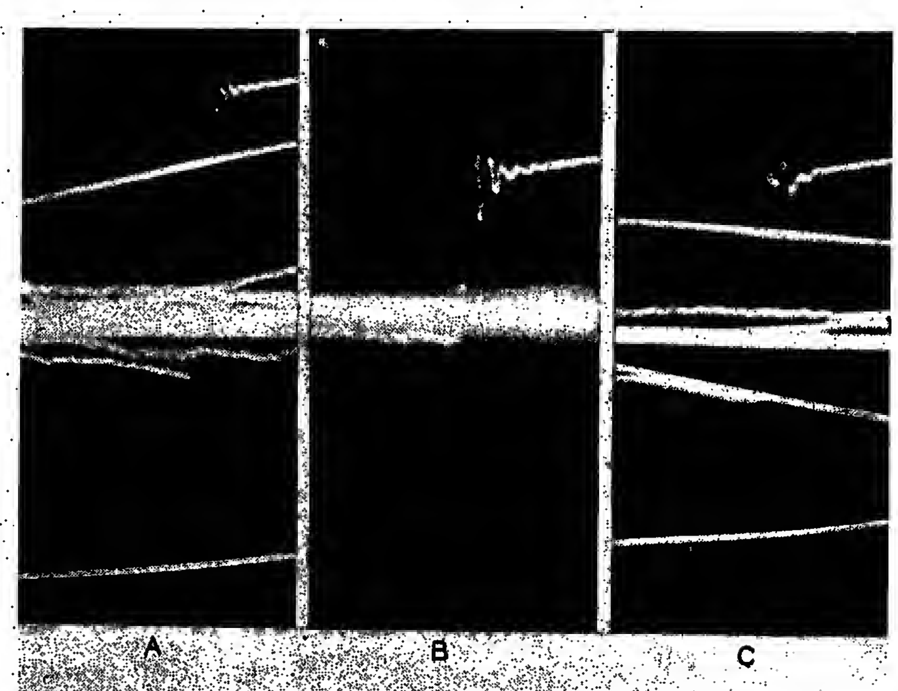

Figure 8. Cathode-ray oscillograms corresponding to three single-phase tests

may reach 200,000 cycles. Circuit recovery rates based on the first crest of the recovery transients may be as high as approximately 12,000 volts per microsecond.

The performance of the 2,500,000 compressed-air breaker has been studied with a wide variety of recovery-voltage conditions. A number of the important tests are summarized in Table III. The first part of the table lists a series of interruptions at 13,200 volts single phase and 8,000 amperes. The circuit-recovery rate was varied from 300 volts per microsecond to 13,600 volts per microsecond. To obtain the high recovery transients, a reactor was placed directly in the test cell with only a few feet of cable between it and the breaker. Interruption was satisfactory in all cases.

The second portion of the table lists tests made at higher currents. To obtain these the laboratory circuit capacitance was reduced, as much as practical, and during several of these tests double-frequency recovery transients were obtained. Three cathode-ray oscillograms of these interruptions are shown in Figure 9. One at 53,000 amperes was obtained with a circuit adjusted for 7,100 volts per microsecond. The second was obtained at 35,000 amperes with the circuit adjusted for 4,130 volts per microsecond, and the third was obtained at 76,000 amperes with the circuit also adjusted for 2,390 volts per microsecond. All three of these circuit conditions represent double-frequency transients, but in the second and third oscillograms the higher frequency is so greatly damped by the conduction current of the breaker following current zero that little trace of the oscillation appears in the recovery-voltage transient recorded by the oscillograph.

These are the highest published voltage-recovery rates measured on circuits on which heavy short-circuit tests have been made.

VII. Conclusions

The complete test results show that the 2,500,000-kva compressed-air breaker, which is the largest air powerhouse breaker ever built, is entirely adequate in interrupting capacity even in the case of extremely high-circuit voltage-recovery rates. The small external demonstration, ease of maintenance, complete freedom from fire hazard, and general mechanical simplicity indicate that there will be a growing tendency to utilize this type of breaker for indoor powerhouse installation.

Synopsis: A scheme of bus protection offering advantages in simplicity, speed, and size uses linear couplers (air-core mutual reactances) in place of current transformers. This solves the troublesome problem of saturation and provides a linear relationship between secondary voltage and primary current. The coupler secondaries for a given bus are connected in a series loop with the relay. When the currents entering and leaving the bus are equal, the net induced voltage in the relay loop is zero. For a fault on the bus, however, the net induced voltage, proportional to the fault current, operates the relay. The problems are:

1. To utilize effectively the smaller available energy.

2. To build couplers of sufficiently equal mutual reactance and unaffected by stray fields.

A toroidal coil solved the latter problem. Thorough tests have shown that the performance is strictly linear with respect to primary current, practically unaffected by the primary d-c transient, and thus can be calculated accurately and simply.

Paper 42-40, recommended by the AIEE committee on protective devices for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 24, 1941; made available for printing December 23, 1941.

The authors acknowledge the assistance of C. A. Woods in connection with the bushing-type couplers, and of other associates who have contributed to the success of this project.

THE linear coupler transformer is a constant mutual reactance connecting the primary circuit to the relay. It introduces a new principle into the protective relaying art, a principle* that is fundamentally sound and that eliminates completely, at its source, the most troublesome problem that has been standing in the way of simple high-speed bus protection. That problem is saturation of the current transformers by the d-c transient current that flows for a number of cycles after the occurrence of a fault. Its solution consists of dispensing with the iron, a solution that appears so obvious on the face of it that it is fair to inquire why it was not adopted years ago. This paper might stop right here were it not for the answer to the last question.

As most frequently occurs, there were a number of obstacles to be hurdled between the quite obvious idea of leaving out the iron, and the completion of a successful bus-protective system using linear coupler transformers. Efficient coupler designs had to be developed, capable of deriving the maximum amount of energy obtainable from the available space without the use of iron. New methods had to be devised to use effectively the lower energy level inherent in the elimination of the iron. This energy is adequate for the operation of an efficient a-c plunger-type element in most cases. Also, the development of the copper oxide rectifier to a highly reliable state during the last several years has made available in a-c circuits the sensitive and reliable action of the d-c polar-type of relay. This has greatly extended the range of sensitivities possible with ironless transformers.

New circuits were necessary, better suited than the conventional bus-differential circuits, for use with the accurately linear mutual reactance. Here a new principle* was applied—a radical departure from the principle of the conventional current transformer.

The influence of external fields and positional effects of the primary conductor on

* The principle of perfect linearity between primary current and secondary induced voltage in couplers as described.

*Rms symmetrical.

**Larger ratios can be covered with proportionately reduced safety factors.

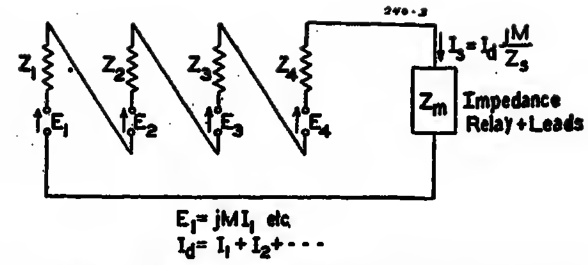

Figure 3. Series-connection equivalent circuit of linear couplers

the response had to be dealt with. This was done not by brute force, but by bringing into play a useful theorem relating to coils wound on nonmagnetic cores of toroidal or ring shape.

Methods had to be devised for winding toroidal coils conforming to the requirements for efficient energy utilization and high accuracy without undue economic limitations.

Thus, it is not simply the elimination of iron in a transformer but rather the technique of using linear couplers in relaying circuits and presentation of the verifying tests which have necessitated this paper.

To more fully understand the place filled by the linear-coupler scheme of bus protection, mention should be made of certain other schemes in current use. Bus-protection schemes that have received the most attention in recent years have revolved about some form of current-differential protection. The relays considered have varied from simple overcurrent relays[1] to various forms of restrained relays. Restrained relays have utilized either the fault current itself,[2] or harmonics in the differential current.[3] Another method of attacking the problem from the standpoint of directional comparison[4] was presented at the 1941 summer convention.

Impedance and reactance schemes,[6] measuring the impedance from the main incoming sources into the feeder reactors have also found considerable application where reactors are used and ratios of fault impedance to reactor impedance are such as to provide discrimination. However, they are necessarily restricted to certain busses which happen to fill these requirements. The fault-bus scheme[1] is also ideal for certain new installations that can be arranged to accommodate it.

In all of the current-differential schemes, the over-all performance necessarily depends upon the performance of the current transformer. For busses near large generating stations, the presence of the d-c component in asymmetrical fault currents has greatly magnified the problem through its saturating effect[7] on the current transformers.

Another related problem is the large ratio of maximum external fault current when the relay should not trip to minimum internal fault current when the relay should trip. A large ratio between these values is encountered in those stations where the neutral is grounded through an impedance, thus materially limiting the minimum phase-to-ground fault current for internal faults without limiting the maximum phase-to-phase and three-phase fault current for external faults.

The very sensitive relay setting required under this condition greatly magnifies the problem created by d-c saturation at high overcurrents. The problem has been solved in some instances by the use of extremely large current transformers designed not to saturate on the d-c component. What is felt to be the most practicable scheme to date utilizing current transformers of standard proportions is the multirestraint variable percentage scheme.[2] In this scheme particular attention is given to providing a sufficient number of restraining elements, actuated by the secondary fault current. Also, the principle of variable percentage characteristics is utilized by which means the relay sensitivity is reduced at the higher currents where current transformer performance is poorest. By this means a range of 100/1 between maximum external fault current and relay setting may be covered without fear of false operation. An operating time of three to six cycles is secured through the use of the high-speed induction-type relay.

Heretofore, the problem has been attacked from the standpoint of either making the current transformers more nearly perfect, which is a costly method, or of designing the relay to meet the limitations of the current transformers. It is immediately obvious that if the current transformers were perfect in their response a simple overcurrent relay differentially connected would be all that would be necessary. One line of attack which has been recently introduced involves the use of a special current transformer with air gaps in the core.[5] This arrangement can be made high speed but cannot cover the 100-to-1 range of the multirestraint variable-percentage scheme. The authors state its range as approximately 10 to 1.

The linear-coupler scheme described herein is essentially a high-speed scheme covering a range at the present state of development of 17 to 1 with a 2-to-1 factor of safety. Tests have shown this rating to be quite conservative.

Summary

Linear couplers are distinguished from current transformers in having a constant mutual impedance even when the entire primary current acts as exciting current, with no current in the secondary. It is the function of a current transformer to produce in its secondary a miniature replica of the current that flows in its primary. It is the function of a linear coupler to produce in its secondary an internal voltage proportional to the current in its primary. To form a differential circuit, these voltages are added in series (Figure

1), as distinguished from current transformers in which the currents are added in parallel. For an external fault the vector sum of all the primary currents is zero. Thus, the vector sum of all induced voltages is zero, and also the relay current is zero. For an internal fault the sum of the primary currents through legitimate circuits is equal to the fault current. Consequently, the vector sum of all induced voltages is proportional to the fault current. The current in the relay is equal to the vector sum of the voltages acting around the relay loop divided by the loop impedance. Thus, this current is also proportional to the fault current.

A one-cycle relaying scheme including couplers and relays has been developed, operating on the principle just outlined, and has been subjected to an exhaustive series of tests. Through type couplers of 0.005 ohm mutual reactance were built in several sizes and shapes to fit in the usual bushing current-transformer compartments or for separate mounting.

Sufficient energy is obtainable from couplers of this proportion to operate an a-c plunger-type relay for fault currents down to 1,500 amperes with a six-circuit bus and 2,000 amperes with a ten-circuit bus. Couplers of reasonable cost can be built to the desired mutual reactance within a tolerance of ±1.5 per cent, thus permitting a maximum false differential of three per cent. Taking a 2-to-1 factor of safety, this results in a minimum allowable setting of six per cent or $^1/_{17}$ of the maximum through fault current. The sensitivities obtained are ample for busses where the setting does not need to be below $^1/_{17}$ of the maximum bus fault.

The tests have demonstrated this simple and straightforward scheme to be thoroughly reliable and practically free from transient effects, so that the performance can be readily calculated. Operation under one cycle was obtained for practically all internal faults and in no cases were operations obtained on external faults within the limits prescribed for proper application.

Tests have verified the feasibility of testing an actual bus installation with low steady-state currents to determine the performance to be expected under fault conditions.

The following paragraphs include an outline of the theory of the linear-coupler scheme, a description of the apparatus employed, and a résumé of the combination tests which have been conducted to verify the theory and prove the equipment designs.

Theory of Linear-Coupler Circuits

Nomenclature

M, m—Mutual reactance and inductance between the primary conductor and secondary winding of a linear coupler

$Z = r + j\omega L$—Secondary self-impedance of a coupler

$Z_s = r_s + j\omega L_s = r_s + jX_s$—Total impedance of coupler-relay loop circuit

E—Induced voltage in coupler

E_s—Vector sum of induced voltages in coupler-relay loop

I, i—Primary current, vector, and instantaneous values. Subscripts 1, 2, 3, and so on designate the various bus circuits

I_s—Secondary current in the relay, vector value

I_f—Fault current, into the bus for an internal fault; into and out of the bus for a through fault

I_d—Vector sum of primary currents; equal to I_f for internal faults, and zero for external faults

Equivalent Circuit

As illustrated in Figure 2b, the equivalent circuit of a linear coupler is simply an internal voltage of value jMI, in series with an impedance of value Z. The equivalent circuit for transient conditions, Figure 2c, is of the same form. However, the internal voltage is then mdi/dt. An alternate form convenient for determining the transient response is also shown in Figure 2d.

As will be shown later, the transient response of the couplers considered is negligible so that the steady-state response can be used for analyzing fault conditions. Thus, for calculations, the series connection shown in Figure 1 may be treated through its equivalent circuit, Figure 3.

Series Connection — Steady-State Conditions

The total voltage acting around the series circuit, Figure 3, is the vector sum of the individual voltages shown. If the mutual reactance, M, is the same for each coupler, the total voltage is equal to this mutual reactance, times I_d, the vector sum of the currents flowing into the bus.

For *internal fault* conditions, the I_d cur-

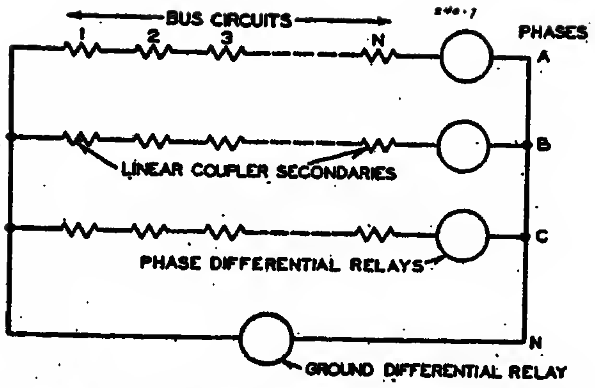

Figure 7. Schematic one-line diagram of connections showing the use of linear couplers and relays for separate phase and ground protection

rent is equal to the fault current I_f, and the voltage induced in the loop is jMI_f. The secondary current flowing in the relay is obtained by dividing this induced voltage by the relay loop impedance. That is, for internal faults,

$$I_s = I_f(jM/Z_s) \qquad (1)$$

For *external fault* conditions since the vector sum of the currents flowing into the bus is zero, the net voltage induced in the loop circuit is zero, and consequently the relay current is zero. If the incoming and outgoing mutual reactances differ by three per cent, a relay current is obtained having a value three per cent of that which flows for an internal fault of the same magnitude. Thus, with couplers built to a standard mutual reactance within ± 1.5 per cent, the mutual reactances of the incoming and outgoing couplers might differ by three per cent under the worst conditions. In order to maintain a 2:1 factor of safety, the relay should not be set below six per cent of the maximum through fault, since current values of three per cent are possible during external fault conditions when the relay should not operate. Table I shows the mutual reactance tolerances required to permit different ratios of maximum through fault to relay setting with a 2:1 safety factor.

Series Connection—Transient Conditions

Internal Faults. An asymmetrical primary current wave contains an a-c component and a d-c transient component, each of which produces a counterpart in the secondary loop circuit, having impedance $Z_s = r_s + j\omega L_s = r_s + jX_s$.

The secondary a-c component amplitude is M/Z_s times that in the primary, as shown for the steady-state analysis.

A primary d-c component of time constant, T, produces a secondary forced d-c component of the same time constant. Referring to Figure 2d, a current of time constant, T, encounters mutual impedance $-m/T$, secondary branch impedance $r_s-(L_s-m)/T$, and sum of branches or secondary loop impedance r_s-L_s/T. Hence, the initial forced d-c component in the secondary relay branch is $-(m/T) \div (r_s - L_s/T)$ times that in the primary.

For a primary current wave initially fully displaced, the initial primary d-c component is equal to the negative amplitude of the primary a-c component, and therefore, the ratio of their secondary components is obtained by dividing their transformation factors, given above. Recognizing that $\omega m = M$, $\omega L_s = X_s$ and that the components have opposite signs in the primary, this division gives:

$$\frac{\text{Forced d-c transient initial magnitude}}{\text{Secondary a-c component amplitude}} = \frac{Z_s/r_s}{\omega T - (X_s/r_s)}$$

A positive value for this ratio signifies that the forced transient is in the same direction as the initial a-c component in the secondary.

In addition to the forced d-c transient, a free d-c transient current flows having an initial amplitude equal and opposite to the sum of initial a-c and forced transient initial amplitudes, thereby preventing a discontinuity. The free transient dies out with the time constant of the secondary loop circuit, $T_s = L_s/r_s$. The ratio X_s/r_s approximates unity for the linear-coupler circuits, resulting in T_s approximately 0.00265 second or one-sixth of a cycle.

The forced and free d-c transients decay and the a-c component reverses, as shown in Figures 5b and 5c until somewhat less than one-half cycle after the fault a positive peak is reached, which may be more or less than the steady-state value, depending on the magnitude and direction of the total d-c transient. Progressing further, the first negative peak is reached, and it can be greater than the steady a-c value if the total transient is negative at this point.

The values of the total d-c transient at the first positive and first negative peak are shown in Figure 5a for the X_s/r_s ratio involved in linear-coupler circuits. The maximum overshoot of the first positive peak occurs for a long primary time constant. It is 5.4 per cent for a time constant of 15.9 cycles as illustrated in Figure 5b. The maximum overshoot of a negative peak occurs for a short time constant of about 0.64 cycle (condition *C*, Figure 5a) and is 11.5 per cent. It is illustrated

(B)

in Figure 5c. Succeeding cycles involve much less overshoot. In the range of time constants usually involved, neither overshoot is much over 5 per cent, as was verified by the tests. Practically this transient is negligible in making relay settings.

For larger ratios of X_s/r_s much larger percentage overshoots occur on the first cycle. Kennedy and Sinks[5] show 60 to 80 per cent overshoot at the first positive peak, with air-gap-type current transformers.

External Faults. The amount of overshoot is of particular importance in connection with high-speed relaying since the false differential through the relay during through faults is increased in direct proportion to it.

Parallel Connection

The current in the relay for the parallel connection has been given.[6] With the nomenclature of Figure 4 it is

$$I_m = I_d \frac{jM}{Z_b + nZ_m}$$

where n is the number of circuits, that is, $n=4$ for the four-circuit bus, Figure 4. This current is zero for external faults and is a definite proportion of the fault current for internal faults. For this connection, it is necessary to have all secondary branch impedances equalized to a common value Z_b. Resistance differentials due to temperature differences must, therefore, be considered. Assuming a relay matched to the parallel impedance of the couplers, a 30-degree centigrade temperature differential between incoming and outgoing circuits would cause approximately eight per cent false differential on through faults.

The parallel connection has the advantage that it would trip correctly for an internal fault even with an inactive coupler open circuited. However, it is subject to the temperature errors mentioned above, and is not as readily supervised as the series loop arrangement. Also, even with equal mutual reactances the parallel connection involves the flow of secondary a-c and transient currents during through faults, whereas the series connection involves none. The simpler series loop arrangement is, therefore, preferred.

Relaying Schemes Using Linear-Coupler Transformers

A schematic one-line diagram of connections utilizing linear couplers and a sensitive relay is shown in Figure 1. The requirements of a suitable relay to be utilized in this scheme are as follows:

1. Since the amount of energy available is small, the relay must be quite sensitive. That is, the volt-amperes consumed by the relay at minimum pickup must be as low as possible.

2. Because of the small amount of energy available, the impedance of the relay should be matched to that of the linear couplers in order that maximum efficiency may be obtained. This involves making the relay impedance equal to the series impedance of all of the couplers with which it is used. There are variations in the self-impedances of the various coupler designs depending principally upon the space available. Also, there are variations in the number of circuits to a bus depending upon the application. For this reason the relay should have taps so that its impedance may be approximately matched to that of the linear couplers to suit the application.

3. Since the relay normally operates with no restraint at all, it should be shockproof.

A schematic internal diagram of the relay wiring is shown in Figure 6. Taps are shown on the primary of a transformer to provide the necessary impedance-matching characteristic. With a given setting on the relay element, the use of a tapped primary winding on the transformer supplying this element will obviously change the minimum tripping current of the relay as expressed in terms of current in the tapped winding. However, this does not change the amount of energy required to operate the relay as expressed in volt-amperes.

The minimum primary current upon which the scheme shown in Figure 1 will operate is determined by the mutual impedance of the linear couplers together with the total impedance of the secondary circuit, and the minimum pickup energy required by the relay. In any given application the minimum value may be determined from the known constants of the circuit by the simple calculations indicated by equation 1.

In determining upon a suitable relay design for this application, requirement 1 as listed above requires the most attention. Providing impedance taps as listed under requirement 2 is a simple matter. In making tests of the over-all scheme, two relay designs were provided which are not necessarily the last word. The first of these involves a simple plunger-type of overcurrent element of medium sensitivity which is inherently shockproof. A second relay was built around a polar-type relay element. This element required the use of a rectifying unit for its operation and operates reliably at very low energy. The sensitivity of the two elements is dealt with more fully under test results, but it is of interest to note here that for each relay the minimum pickup current as expressed in primary amperes was calculated with gratifying accuracy.

Separate Ground Relay. At the present time linear couplers have not been manufactured which would be sufficiently accurate to permit their use in an application where the range of maximum external fault current to minimum internal fault current is as great as 100/1, as sometimes occurs on high-impedance grounded systems. A possible means of expanding the range involves the use of a separate ground relay. The schematic diagram of connections for this is shown in Figure 7. This scheme anticipates the use of a ground relay set sufficiently low to detect the minimum internal ground fault. However, means must be taken to prevent the relay from operating for heavy external interphase faults. In other words, at the current magnitude experienced for heavy interphase faults, the variation in response of linear couplers may be suffi-

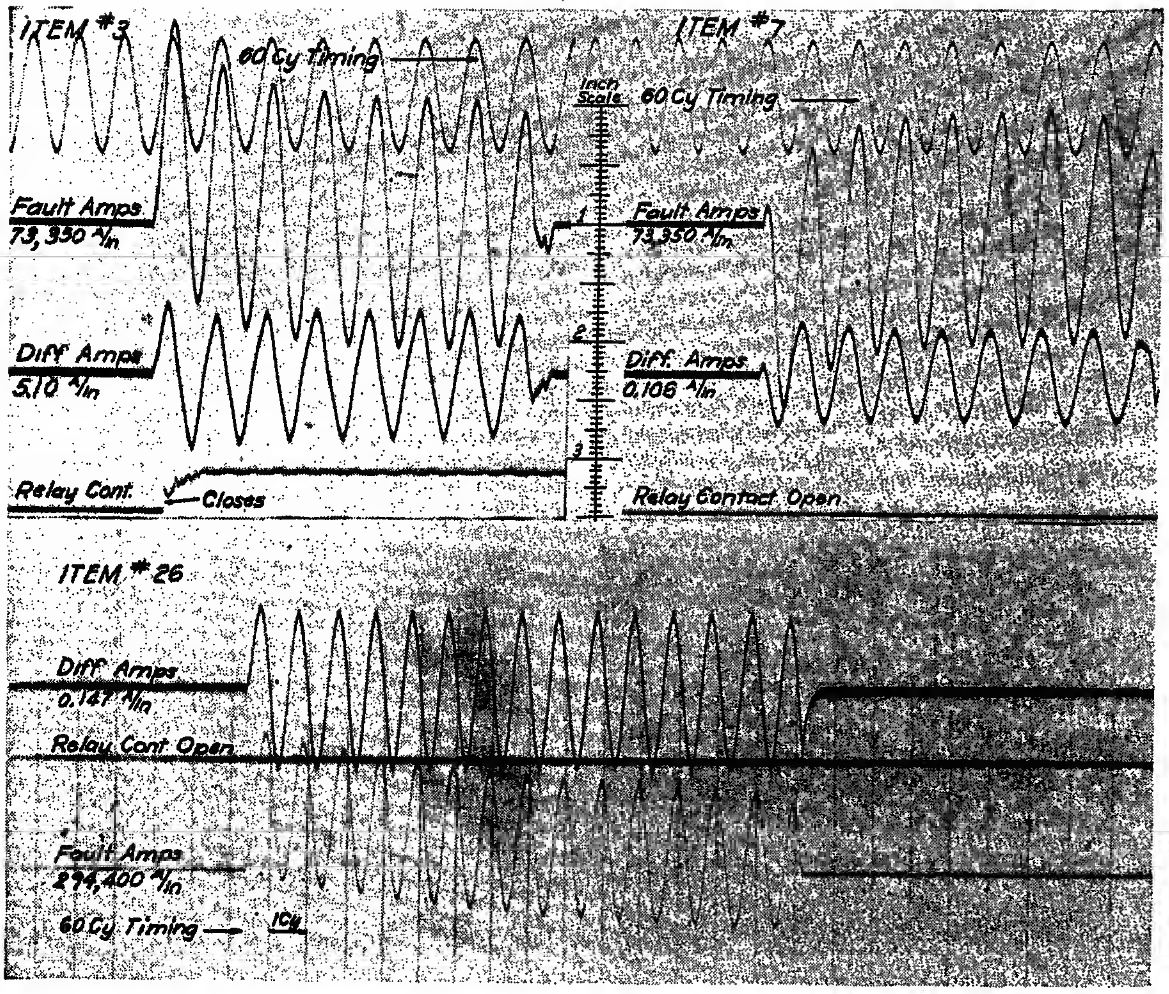

Figure 12. Oscillograms of pertinent fault tests

(*a*) For item 3 test, a 55,200-ampere bus fault showing high-speed one-quarter-cycle operation of plunger-type relay

(*b*) For item 7 test, a 50,800-ampere a-c component through fault with the couplers deliberately adjusted to give maximum error differential. It shows 1.61 per cent differential and no operation of the plunger-type relay (set to respond for a 2,450 ampere bus fault, 4.83 per cent of the 50,800-ampere through fault). While the fault current was initially 95 per cent offset with a short 1.2-cycle d-c time constant, the differential current shows negligible transient effect

(*c*) For item 26 test, a 125,000-ampere a-c component through fault initially 95 per cent offset with a long 8.2 cycle d-c time constant. It shows negligible transient effect in the differential current. The 0.89 per cent false differential did not operate the relay (set to respond for a 1,820-ampere bus fault, 1.45 per cent of the 125,000-ampere through fault)

cient to cause operation of the ground relay because of its sensitive setting.

The separate ground relay will be used only in those stations where there is an impedance in the station neutral connection limiting the phase-to-ground fault current on the bus to a value too low for the phase relays to detect.

The Linear Coupler Design and Construction

The linear coupler is simply an air-core mutual inductance, and as such may be designed and built in any of a large number of ways. The choice of method was selected after study of the required properties of the coupler:

(*a*) Accurate constant mutual inductance with respect to the primary circuit.

(*b*) Negligible mutual inductance to any external or neighboring circuit.

(*c*) A sufficiently high ratio of mutual inductance to internal impedance to obtain the power output required for the relay.

Requirements (*a*) and (*b*) practically demand that the secondary winding be a toroidal or ring winding, as this type of winding is practically without mutual inductance to external circuits and has constant mutual inductance to the primary circuit. Current in a secondary winding, uniformly wound on a nonmagnetic toroidal core approaches a uniform current sheet of finite thickness which produces only circular flux lines confined entirely within the winding and core. All this flux links a conductor passing anywhere through the opening of the core, and none of it links a conductor not passing through no matter how close it may be. The presence of neighboring iron outside of the winding has no influence since there is no magnetomotive force outside of the current sheet. Thus, the secondary winding has a definite mutual reactance with respect to a linking conductor and zero mutual reactance with respect to a conductor that does not pass through the opening.

While the mutual reactances have been visualized in terms of the flux linking the primary for current in the secondary, the relationship is reciprocal. Thus, for the ideal case of a perfectly uniform secondary winding, the voltage induced therein per ampere in the primary is a definite value if the primary conductor links the core, and is zero if it does not.

Practically, a close approach to the uniform sheet winding is realized, the departures therefrom being evaluated by test. The secondary is wound back on itself to avoid any single-turn effect of progressive spiraling around the core.

For bus protection, minimum fault currents which must be detected are usually high enough that economical designs can be made to deliver sufficient energy to the relay when only one primary turn is used. The practical design for bus protection, therefore, usually takes the general form of a through-type current transformer, with an air-core ring winding. Figure 8 shows a type for separate mounting.

The calculation of the mutual inductance and output capacity of the device is very easily worked out according to well-known fundamental formulas. The principal manufacturing problem is to make ring windings which are sufficiently perfect

1. To be free from induction from neighboring conductors.

2. To have a mutual inductance which departs from the exact required values by only a sufficiently small per cent for all possible positions of primary conductor.

These two requirements may each be expressed in terms of the variation from the desired value. The actual coupler will have a definite, though very small mutual inductance with the return conductor, which may be expressed in per cent of the mutual inductance to the primary conductor. This inductance will vary with the spacing and angular position of the return conductor, according to Figure 9, and will usually be zero for two positions and maximum for two other positions.

A final source of variation is error in calibration of the mutual inductance. In order to obtain mutual inductances within the necessary tolerances, adjustments are required after winding the coils. The linear couplers are tested by balancing them against a standard mutual inductance.

Considering all of the sources of variation as mentioned above, it appears quite practical at the present time to control the mutual reactances of couplers within ±1.5 per cent in commercial production.

Combination Tests

Combination tests were made to prove that it was practical and safe to use a simple overcurrent-type high-speed relay

with linear couplers for differential protection, regardless of the number of circuits in the protected zone. This meant demonstrating that the couplers were linear in fact and practically unaffected by any stray fields produced by other circuits.

A bus setup accommodating 10 circuits, was made for test purposes as shown in Figure 10, in which the primary circuits were spaced at 12-inch centers. Four different types of 0.005 ohm, ±1 per cent linear couplers, having different dimensions, were available. One or more of each type were used in various combinations with their secondary windings in series with the relay to form bus differentials of 10, 6, and 2 circuits. Also, the parallel secondary connection of couplers was tested for a six-circuit bus to prove that the parallel connection was feasible, even if not as desirable as the series connection.

An exhaustive series of tests was made to cover the variations in relay type and sensitivity, in coupler size and shape, in fault-current magnitudes and transients, in fault-current distribution, and in the astatic factors. The astatic effects were checked:

1. By interchanging couplers on the primary circuits.
2. By rotating the couplers on their axis.
3. By placing the couplers off center with respect to their primary conductor.
4. By varying the distance from the coupler to the bus.
5. By turning the coupler upside down.
6. By placing magnetic materials between the couplers and in close proximity.

All these astatic effects were found small for spacings involved in practice.

A special setup per Figure 11, using multiple primary turns, was made to get the effect of large current with a smaller source current in order to obtain increased d-c time constant. It should be noted that each primary turn feeds in through one of the smaller outer couplers and returns through the larger center coupler. This arrangement simulates a five-circuit bus with four equal sources feeding to an external fault through the center coupler.

Test Results

Table II gives pertinent information and results of representative tests for 10-, 6-, and 2-circuit busses per Figure 10 and for the special five-circuit bus per Figure 11.

Items 1 to 7 apply for the 10-circuit bus per Figure 10 using the plunger-relay set to pick up at 0.085 ampere in the coupler secondaries. Calculations based on equation 1 give pickup for internal faults at

2,430 amperes. Test item 1 with 10 circuits energized, and item 2 with only one circuit energized, both give pickup at 2,450 amperes when the fault current is proportioned for unity pickup. Based on ±1 per cent tolerance in the couplers this sensitivity should be safe for through-fault currents of 25 times 2,450 or 61,000 amperes. Items 5 to 7 for external faults show that it was safe as the relay current remained below half pickup value. In items 6 and 7 the fault current into the bus was supplied by four circuits and out from the bus through one circuit with the five remaining circuits "idle" representing feeders with no feed back. Item 6 shows normal low (0.25 per cent) differential and item 7 the maximum (1.61 per cent) differential obtainable after deliberately adjusting the coupler positions for maximum astatic effects. The oscillogram, Figure 12b, for item 7, shows a fault current of 50,800 amperes rms a-c component, I_f, plus 68,300 amperes initial d-c component decaying with a short-time constant of 1.2 cycles; and a secondary differential current, practically free of d-c transient, having an a-c component, I_s, of 0.031 ampere which gave no relay operation. These measured data and additional derived data are given in the tabulation. Based on a 0.005-ohm mutual (five volts induced per 1,000 amperes) the 50,800-ampere fault should induce +254 volts total in the incoming-circuit couplers and −254 volts in the outgoing-circuit coupler, which would leave no differential voltage to circulate secondary current. Actually, 0.0310 ampere flowed which multiplied by the loop impedance, Z_s, indicated a differential of 4.09 volts or 1.61 per cent. The relay current, I_s, equals 0.0310 ampere and represents 0.365 times its pickup value of 0.085 ampere. Oscillogram, Figure 12a, for item 3, shows one-fourth cycle operation of the plunger-type relay for a 55,200-ampere high-current internal fault.

Items 8 to 14 also apply for the 10-circuit bus but show the performance of the more sensitive polar-type relay having a sensitivity of 511 amperes. Items 15 to 18 cover a six-circuit bus arrangement. Items 19 to 22 are for a two-circuit arrangement and were included to show the maximum obtainable differential.

The performance of the five-circuit bus arrangement, Figure 11, for long d-c time constant is shown in items 23 to 27. The fault current I_f tabulated is the equivalent value based on a single primary conductor. For item 23, the center-coupler secondary was deliberately reversed to represent an internal fault and the current increased gradually until the relays just operated at 1,820 amperes. The center-coupler secondary connection was then restored to normal, and the induced and differential voltages measured with the secondary circuit open. These induced voltage tests, item 24, showed 0.89 per cent differential over a wide range of steady-state currents, and this percentage differential was substantiated by subsequent transient-fault tests, items 25 to 27. This, therefore, illustrates the possibility of testing an actual bus installation with low steady-state currents to determine the performance to be expected under fault current. Figure 12c shows the oscillogram for item 26, a 125,000-ampere a-c component through fault (representing 69 times relay sensitivity) which was initially 95 per cent offset, involving a 170,000-ampere d-c component decaying slowly with a time constant of 8.2 cycles or 0.137 second. Again the differential current is not offset but quite symmetrical, and the free transient as shown at the end of the fault lasts only a small portion of a cycle. A comparison with Figure 12b for item 7 shows that the d-c component and its time constant have a quite negligible effect on the differential current. Based on the differential current of item 26, showing 0.61 of relay pickup for a 125,000-ampere through fault, relay operation is expected for through faults in excess of 125,000/0.61 = 205,000 amperes; and item 27 shows relay operation at 216,000 amperes with 1.06 times relay pickup, verifying the 205,000 ampere through-fault pickup.

Summarizing, the primary current required to pick up the relay for bus faults was found to be almost precisely as calculated and showed no perceptible transient effect on pickup or speed of operation as a result of d-c component current. The pickup depended only on fault-current magnitude and was independent of its distribution. For external faults the secondary differential was found to average about one fourth of the tolerance band. It did not exceed the tolerance band even when a deliberate attempt was made to get maximum astatic effect. The tests, therefore, verified the fact that the maximum differential for through faults can be calculated with assurance. Above all, the staged fault tests demonstrated that the d-c transients, which are so troublesome with current transformers because of the d-c saturation effects in the iron, have a very negligible effect on the coupler-differential performance, and therefore, it is quite feasible to test an actual bus installation by circulating low-value steady-state current.

Facilities for the Supply of Kilowatts and Kilovars

HOLLIS K. SELS
MEMBER AIEE

THEODORE SEELY
ASSOCIATE AIEE

Synopsis: Increased system kilowatt capacity may be realized by the reduction of generator kilovar requirements and the provision of reactive capacity sources at other points in the system. The factors to be considered in the choice of various reactive sources are discussed. Benefits to be realized from the various reactive sources are described. The paper is based upon system plan studies of a large eastern utility.

IN determining a system's capacity requirements for supplying the electric load—kilowatts and kilovars under all conditions of operation throughout the year—a comprehensive capacity and load study is necessary. This was particularly emphasized by two operating experiences on the system of the Public Service Electric and Gas Company. The first episode was a system voltage disturbance which occurred on October 30, 1938, and the second a system shutdown which occurred as a result of a 132-kv bus fault at Roseland switching station on July 11, 1940. Investigations of these operations introduced the following subjects for consideration:

1. The proper kilowatt and kilovar loading of individual generators, considering their economy, thermal, and stability characteristics.

2. The amount and distribution of various forms of kilovar capacity throughout the system.

3. Certain improvements in system protection, particularly with respect to more rapid fault removal and the maintenance of adequate backup protection.

4. Installation of certain tap-changing-under-load equipment to maintain bus voltages within certain limits and to make all generator kilovar capacity available to the system at all times.

5. And finally a more thorough analysis of the kilowatt and kilovar loads on the system.

Studies have progressed to such a point that a fairly complete report can be made of the conclusions which have been reached. Continuing studies may lead to other equally important conclusions, but, in general, they will probably be only refinements of the conclusions now reached. The application of these conclusions is particularly important at this time with the present scarcity of materials and the necessity for added capacity to meet greatly increased industrial loads.

Paper 42-53, recommended by the AIEE committees on power generation and power transmission and distribution for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted November 27, 1941; made available for printing December 23, 1941.

HOLLIS K. SELS is transmission and substation engineer, and THEODORE SEELY is assistant distribution engineer, both with the electric department of the Public Service Electric and Gas Company, Newark, N. J.

General Description of System

A description of the Public Service Electric and Gas Company system is necessary as some of the results of the studies presented may hold for this system alone; similar studies would have to be conducted on other systems to reach corresponding conclusions. The layout of this system is not unlike many others but the load for the 1941 hourly integrated peak, which was 852,100 kw, is probably more concentrated than most, being spread over an area of approximately 1,400 square miles. This area is roughly rectangular in shape, and about 100 miles long.

Five generating stations supply the territory, three of which, Essex, Kearny, and Marion, are located in the Newark meadows area. Four stations, Essex, Kearny, Marion, and Burlington, are connected together by a 132-kv bulk power system; Perth Amboy, the smallest and least important station, feeds directly into the subtransmission system supplying central New Jersey. Three stations, Essex, Marion, and Burlington, also supply local subtransmission systems.

Other subtransmission areas are supplied by Hudson, Athenia, West Orange, Metuchen, Trenton, and Camden switching stations, which are connected to the bulk power system. In addition, the Roseland switching station connects the Public Service system to the Pennsylvania-New Jersey 220-kv system and the New Jersey Power and Light Company 110-kv system. Several other small interconnections are tied to the various subtransmission networks.

Figure 1 shows diagrammatically the location of the generating stations and switching stations, and the layout of the bulk supply and subtransmission lines.

All generators are normally hand-regulated and controlled under orders of a central load dispatcher. Several large synchronous condensers and frequency changers are located at switching stations and several small synchronous condensers and numerous small motor-generator sets which can be overexcited are located in substations. The larger synchronous condensers provide automatic regulation to some degree. Practically every four-kilovolt distribution circuit is provided with ± ten per cent or ± five per cent induction or tap-changing regulators and many circuits with low power-factor load are equipped with one or more banks of static capacitors. There are 708 four-kilovolt distribution circuits; 143 of these are entirely underground, 28 are more than 50 per cent underground and 87 are less than 50 per cent underground and the remaining 450 circuits are practically all overhead. There are 506 radial distribution circuits, 109 pure multiple-network circuits and 93 combination multiple-network and radial circuits supplying 90 separate networks.

Kilowatt Supply

In purchasing new units, it has been the practice to purchase turbines which have sufficient capacity to deliver full generator kilovolt-amperes output at 100 per cent power factor. Therefore, it has been possible to rerate the kilowatt output of the turbine-generators originally purchased on an 80 per cent or 85 per cent power-factor basis by

1. Increasing the power-factor and kilowatt rating of the generator and in some cases the power output of the turbine.

2. Taking advantage of any increased rating developed on field tests.

3. Using autotransformers to step up the voltage rating of the generator thereby gaining increased kilowatt, kilovolt-ampere, and power-factor ratings.

Table I shows the present turbine-generator capacities as of December 8, 1941, totaling 919,550 kw which is greater than the original kilowatt ratings by 20 per cent primarily due to increases in power-factor ratings. Work is now going forward on the installation of autotransformers on Kearny units 2 and 4 which will increase their kilowatt rating from 47,250 kw at 90 per cent power factor to 54,300 kw at 95 per cent power factor each.

Appreciating that these increased ratings approach the economy, thermal, and stability limitations of the machines, extensive studies and tests have been carried out to determine the values of these limitations. After an analysis of the various

machine limits, Table II was prepared to give the kilowatt and kilovar capacity figures for 1941 under various conditions. The "summer normal" ratings are based on sufficient reduction in kilowatt output to obtain the maximum kilovar output with full kilovolt-ampere output. This is illustrated by the generator-output chart of Figure 2. These charts are not available for all machines so that some of these ratings are subject to some adjustment after further study and tests.

On the generator-output chart, the vertical line at the right represents the nominal output of the turbine in kilowatts. The quarter circle represents the kilovolt-ampere rating of the generator while the almost horizontal line represents the kilovar limit of the generator as determined by the maximum possible field current. The heavy line comprised of the vertical line, possibly a segment of the quarter circle, and the almost horizontal line represent the actual kilowatt- and kilovar-output limits of the generator. The important factor to note is that the full kilovolt-ampere output of the gener-

A—Essex 4, 5, 6 can deliver 37,500 kw each only if Essex 7 is in operation. With the low-pressure boilers only, there is insufficient steam-pipe capacity to these units.

B—Depends on ability of low-pressure units to absorb steam from high-pressure unit 10.

ator is not available at all power factors; Public Service system machines have ratings as synchronous condensers of only about 65 per cent of their kilovolt-ampere rating.

Since stability ratings are relative values, the criterion assumed for the transient-stability studies of individual machines was that the phase-angle displacement for a selected rating should not exceed 50 per cent of the pull-out angle in the time required to clear a fault at the machine terminals. The studies show that the phase-angle displacement is much more dependent on the turbine power output than on the generator power factor. Therefore, generator power-factor limits have been raised to 95 per cent which are shown in Table II.

The kilowatt ratings given are within all limitations on all condensing turbine-generators. In the cases of the noncondensing units (that is, the superposed machines) the ratings given are within all limitations except the stability limit for faults on the 13,200-volt bus to which the particular machine is connected. Therefore, during lightning or sleet storms when system trouble is frequently experienced, it may become desirable to favor the loading of these units by shifting the load from them to less efficient units normally operating in reserve.

So far consideration has been given only to the limitations in the electrical plant, but the use of superposed units and large high-pressure boilers introduces the factor of boiler capacity into the kilowatt supply problem. Low-pressure boilers connected to a main header with one spare boiler installed for a group of ten or so were desirable and economical. However, with high-pressure high-capital-cost boilers which should require cleaning only once in six months, the economy of a spare boiler is questionable. Therefore, a large high-pressure boiler outage generally makes unavailable some high-pressure turbine capacity due to this lack of flexibility in the boiler plant. The tables shown in this paper do not make allowances for both boiler and generator outages in different stations. This problem requires further study and a definite conclusion regarding the relations of the boiler plant to system capacity.

Kilovar Supply

Table III shows the present-system reactive capacity other than in generators as of December 1, 1941. Some of this capacity is considered as either a part of the load or nonfirm; 260,900 kilovars is firm capacity, which is considered the

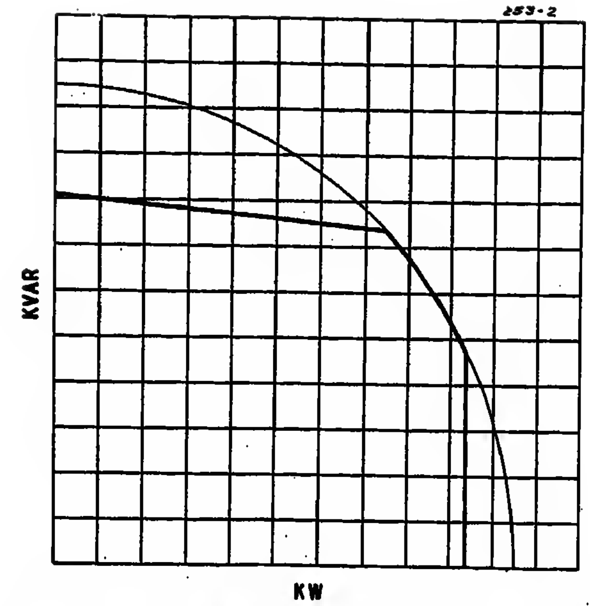

Figure 2. Generator output chart showing typical relative kilowatt and kilovar capacity

same as generator capacity. This has been installed largely to correct power factor and relieve overloaded or low-voltage conditions as they have developed individually. Recently, as the static-capacitor program developed, the broader picture of kilovar supply has been studied so as to co-ordinate the entire program. Prompted by the desire to obtain increased kilowatt generator ratings to meet the recent greatly increased industrial loads, the past conception of carrying the major part of the kilovar load on the generators has had to be abandoned in favor of kilovar capacity installed at the load. The problem has therefore developed into the manner in which this could be accomplished with the greatest speed and lowest cost.

Kilovar capacity can be provided by the use of

Extra copper in the generator stator and field windings

Synchronous condensers

Oversize synchronous motors on motor-generator sets

Static capacitors

Reactive capacity on customers' premises

The use of reactive capacity in one form or another and in appropriate locations, can accomplish the following results in addition to the obvious one of carrying reactive load:

Control voltage (raise only, with static capacitor)

Reduce kilvolt-ampere load between the capacity and the generator

Reduce system investment

Reduce system losses due to kilowatts and kilovars

An analysis has been made of the system costs to determine those elements which are affected by low power factor, starting with the generator as a base and extending to the first load point of the distribution circuit. In the generating station, only the cost of the generator and its switching equipment has been assumed to vary. In switching stations and substations, only transformers and switching equipment have been considered, omitting land, building, masonry compartments, and switchboard. In bulk supply lines, rights of way have been omitted, and in subtransmission and distribution circuits rights of way, poles, and conduits have been neglected. On this basis the incremental investment per kilovolt-ampere which varies with the load power factor has been determined.

The relative net cost of installing kilovar capacity in generators, large synchronous condensers in switching stations, small synchronous condensers in substations and static capacitors on distribution circuits has been determined, evaluating the cost of the equivalent kilovar capacity, the added system investment component effected by kilovar loading, and the incremental losses. These computations show that

1. The static-capacitor installations are the most economical because they are close to the load.

2. The small added cost of providing reactive capacity in generators is next least expensive even with the added system investment and no saving in losses.

3. Adding capacity in the form of synchronous condensers wherever located is the most expensive of all due to their higher initial cost.

Of course, these conclusions apply only to the Public Service system or to those cases where the breakdown of system costs is nearly the same. Other situations would have to be analyzed similarly to arrive at a proper answer.

The limit on the amount of static capacitors which can be installed without switching depends upon the kilovar load at light-load periods, the permissible generator power factor, and the limitations on the distribution system. To determine the maximum amount of static capacitors which can be installed, the annual kilovar load duration curve for the Public Service system was estimated for 1942 based on past records and is shown in Figure 3. This figure shows a minimum net 250,000-kilovar load including the effects of the inherent reactive capacity in the system; however, an investigation of the possible locations showed that the capacitor installations should be limited to 150,000 kilovars effective at their location. At peak loads this would have the effect of reducing the kilovar load on generators by nearly

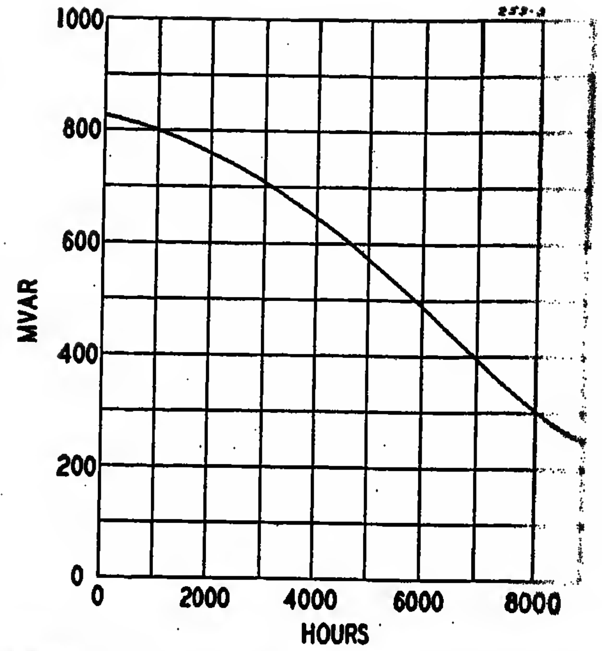

Figure 3. Annual megavar load-duration curve for 1942

200,000 kilovars. It is felt that further experience may show that the distribution plant can absorb more of this capacity without encountering the problem of picking up the system after a major shutdown, and also without experiencing a self-excitation problem on lightly loaded generators. After the limit of static capacitors is reached, if additional reactive capacity cannot be provided economically in new generators or maintained in existing generators, because of the value of their kilowatt output, synchronous condensers offer a quick and economical way in which kilowatt generation can be obtained to meet unexpected demands. The higher over-all cost of large synchronous condensers may be partly offset by the convenience of their operation and their stabilizing effects.

Static Capacitors

Provision of reactive capacity for system purposes in the distribution plant, in the form of static (shunt) capacitors, in addition to improving system conditions with respect to increased kilowatt and kilovar capacities and reduced system losses, affords marked advantages in the distribution plant itself in the form of postponement of facilities, improvement of voltages, and decrease of losses. These features of the shunt capacitor have been so well-publicized that extended comment appears unnecessary. It should be pointed out, however, that when system requirements dictate such installation of shunt capacitors, the location within the associated part of the distribution system may be so selected that optimum concurrent distribution benefits are achieved. Since the major justification of such installation lies with the system requirements, some expansion of the natural field

of the shunt capacitor is warranted in the realization of minor distribution economies. Under present long-delivery schedules for equipment, the capacitor may well be employed as a temporary expedient for overload conditions without extreme penalty, because of its low installation cost and high mobility. Furthermore, long-range economy of the capacitor versus other forms of plant addition may now indicate the capacitor as the proper solution because of the temporary nature of certain loads now being taken on and the high salvage value which is realized in the capacitor.

The experience gained from some 125,000 kva-years of shunt capacitor operation may be of interest to those who are as yet undecided as to the desirable characteristics of capacitors. On the Public Service system bulk capacitors are installed in 180-kva, three-phase banks, using 12 individual 15-kva units for each installation. The banks are wye-connected, with mid-point solidly connected to circuit neutral. Indicating-type cutouts are used on phase connections, phase and neutral lightning arresters are usually employed, and capacitor cases are grounded.

No case of harmonic resonance has as yet been encountered with shunt capacitors. Some instances of telephone inductive interference on common-neutral circuits equipped with capacitors have required use of neutral reactor on the capacitor bank; but the cost of such corrective equipment is not regarded as sufficient to prove out the capacitor for its peculiar purposes.

The operating record of all capacitor units on the Public Service system is regarded as highly satisfactory. Of a total of some 5,600 15-kva units, 25 units have been removed from the lines for various reasons. Of this number, 17 units failed electrically after service periods of from one month to two years. The remaining eight units developed mechanical difficulties, such as bulged tank, leaking bushing, or open tank seam, requiring removal of the unit for repairs.

Improvements in System Protection

Recognizing that markedly increasing the kilowatt rating of generators has decreased their original margin of stability, it has become necessary to adopt several measures for improving the system protection. Many stability studies have shown that the best means of increasing the stability of a system, aside from eliminating faults or restricting them to a single phase, is rapid fault removal. Reference has already been made to the slight improvement in stability with higher generator field strengths or lower power-factor operation of high-speed low-inertia superposed generator units. A careful review of the system has been made which has produced the following recommendations:

1. Rebuilding of overstressed circuit breakers for higher speeds and greater capacities.
2. Reinsulating of certain station busses and lines with post-type insulators.
3. Reconstruction of a major part of the open-wire subtransmission system to a protected phase design.
4. Installation of automatic-generator field control to insure the proper maintenance of adequate field strengths at all times.
5. Installation of high-speed carrier and pilot-wire relays in the bulk supply lines and more important subtransmission lines.
6. Installation of voltage-controlled system-segregating relays to act as backup protection on prolonged system disturbances.
7. Splitting of 132-kv system into separate or higher impedance systems by operating with sectionalized busses at certain locations.
8. Continuance of bus differential protection on all principal busses under all conditions of operation.

Tap-Changing Equipment

Following the normal practice of hand field regulation on generators and carrying as much of the kilovar load on the generators as is possible or economical may lead to excessive voltage gradients in the transmission and distribution system. Also faced with the necessity of maintaining certain voltage limits on switching station, substation, and high-voltage customer busses and holding within a ±3 per cent voltage variation on regulated primary and secondary customers' services, it becomes necessary to install either synchronous condensers in substations or tap-changing-under-load equipment on certain step-up and step-down transformers even though the generator busses are regulated higher

during heavy-load periods and lower at light loads. In some cases tap-changing equipment is cheaper, if sufficient kilovar capacity is available, and the kilovar load can be transmitted without incurring too much loss.

In fact, tap-changing equipment is necessary to some extent to avoid building up excess reserves of kilovar capacity. Network-analyzer load-flow studies have demonstrated that unavailable kilovar capacity may be as much as ten per cent of the installed capacity, and the installation of tap changers in transformers between generating stations can frequently make much of this capacity available and still meet given bus-voltage limitations. Therefore this type of equipment may avoid the installation of kilovar capacity by keeping the unavailable kilovar capacity to a minimum and maintaining customers' service voltages within given limits when sufficient kilovar capacity is available in generators or condensers at other locations. It is, therefore, possible to install kilovar capacity at the most advantageous location which will release other capacity for the benefit of other locations. The installation of a ±5 per cent tap-changing transformer at Essex generating station will release approximately 25,000 kilovars of excess station capacity to the system and at the same time will improve the 132-kv system voltage conditions.

Analysis of Loads and Comparison With Capacity

There must be sufficient power and reactive capacity (kilowatts and kilovars) in service to handle the system loads under all reasonable conditions. It is already obvious that the power capacity is provided by turbine generators. In the Public Service system there is a slight amount available in interconnection diversity entitlements and load curtailment obtainable by operating all-service busses on their gasoline engines. The maximum power capacity is a relatively definite figure, being fixed by the outputs of the various turbines as shown in Table II.

The reactive capacity consists of the excess capacity in generator stator and field windings and the capacities of synchronous condensers and motors and static capacitors, plus a proportionate share of the capacitance in the 220-kv system. The maximum reactive capacity is a relatively indefinite figure since the excess capacity in generators is highly variable depending on the kilowatt load carried as shown in Figure 2. According to the power output of the generators and their power factors, their reactive outputs may vary through an overall range of 0 per cent up to 65 per cent of their kilovolt-ampere ratings.

As with kilowatts the installed kilovar capacity on the system must be greater than the arithmetic sum of the kilovar loads and the assumed reserves except that

1. Generator kilowatt outputs and bus-voltage limitations make it impossible to distribute the kilovar load among the sources exactly.

2. When kilowatts are being taken from an interconnection during an emergency, it must be possible to supply kilovars to that interconnection in order to maintain a reasonable voltage.

Therefore, a greater percentage of kilovar reserves is required than for kilowatt reserves.

Kilowatt and kilovar loads are determined by the reading and summation of all sources of this capacity considering the losses in the transmission and distribution system as a part of the load. The kilovar losses in the system are partially offset by the inherent reactive capacity in the system considered as a part of the load. Kilowatt and kilovar quantities are metered directly because power-factor meters and kilovolt-ampere readings do not permit a sufficiently accurate determination of these quantities. System load data for Public Service Company are estimated for 1941 and 1942 as shown in Table A.

Table A

Condition	1941 Megawatts	1941 Megavars	1942 Megawatts	1942 Megavars
Annual peak, December (5–6 p.m. hourly integrated)	878	627	965	692
Winter day	742	709	817	777
Summer day	734	739	818	825

Every additional kilowatt of industrial load (day load) has associated with it approximately one kilovar of reactive load; this reactive load must be carried just as surely as the power load. Therefore, every kilowatt of turbine capacity added to the system must have added with it one kilovar of reactive capacity for industrial load and about one-half kilovar for residential load. Since reactive loads cannot be economically transmitted as far as power loads, this means that reactive capacity needs to be selected and located more carefully than power capacity, generally closer to the load.

It is evident from the system load data that the lower day load power factor requires a portion of the kilowatt capacity over the December peak to handle the succeeding heavy summer kilovar load. Also the December peak kilowatt load does not greatly exceed the following summer kilowatt load. Therefore in any given calendar year when the load is steadily growing the required installed capacity is determined when maintenance schedules are the heaviest and failures and system disturbances are most likely to occur, that is during the summer period.

Consideration has been given to kilowatt- and kilovar-load reduction by reducing system voltage, but since system- and customer-voltage regulation is obtained by feeder regulators installed in substations, the system voltage reduction would not take effect until the regulators had locked out. Since system stability is also rapidly decreased with system voltage, and tests have shown that a reduction in voltage reduces the load almost proportionately, this scheme of load reduction is not considered feasible or desirable. Hence the problem reduces to one of providing adequate facilities. If, for any reason these facilities are not sufficient, load must be dropped or customers must be called upon for load reduction.

A comparison of 1942 summer load and summer normal capacity is shown in Table IV for the Public Service system with one and two units out of service. Based on such a study, the 1942 program for 150,000 kilovars of additional reactive capacity was authorized. This is made up of 50,000 kva of static capacitors installed on distribution circuits which reaches the established limit of 150,000 kilovars of capacitor installations and 77,500 kva of synchronous condensers in 7,500-kva and 5,000-kva units installed on four-kilovolt busses in substations. This 127,500 kva of installed capacity together with the calculated reduction in system losses makes up the 150,000 kilovars shown in the tabulation. Some of this capacity may be used to permit higher power-factor operation of the generators during the summer. Maintenance schedules for 1942 have been arranged so that no more than one unit is expected to be unavailable for any cause during the summer, and the spinning reserves on the Pennsylvania-New Jersey interconnection are sufficient to meet all requirements.

A similar tabulation for 1943 shows that an additional 30,000 kilovars of capacity is required, and this is to be

provided by the installation of a 30,000-kva outdoor hydrogen-cooled synchronous condenser at Roseland switching station. This will continue the maintenance of generator kilowatt ratings for high industrial loads.

Conclusions

It is not the intention of the authors to summarize or restate the many conclusions which have been tabulated throughout the article but to close their case by focusing attention on three things:

1. The data which form the basis of the studies apply only to the Public Service system and should not form the basis of a generalization but may be accepted as a method of analysis.

2. Reactive capacity in one form or another, particularly static capacitors, can quickly make available additional kilowatt capacity and, by proper location, postpone the installation of additional transmission and distribution facilities.

3. The conception of a separate kilowatt and kilovar load and supply should offer a practical means of presenting to administrative officers the highly technical problem of providing adequate electrical-supply facilities.

It is hoped that a method of analyzing facilities for the supply of kilowatt and kilovar loads has been presented so that utility engineers may at this time of shortages in materials approach the problem objectively with the intention of getting the utmost capacity out of existing equipment without decreasing the services which are so urgently needed by industry and the nation.

A Study of the Modified Kramer or Asynchronous–Synchronous Cascade Variable-Speed Drive

M. M. LIWSCHITZ
MEMBER AIEE

L. A. KILGORE
MEMBER AIEE

Synopsis: Several large wind-tunnel drives recently built have involved a system of speed control which has seldom been used commercially, and a number of new problems had to be solved. The system consists of a wound-rotor induction motor whose slip rings are connected to a synchronous motor driving a variable-speed d-c generator which feeds a constant-speed d-c–a-c set putting the major part of the secondary power back into the line.

This drive is found to be very efficient and particularly suited to very large fan or pump drives where a wide range of speed is required. The problems of steady-state and dynamic stability are discussed and some novel methods of analysis given.

LARGE wind tunnels require a wide range of speed and accurate speed control and if their use factor is high, a high efficiency over the working range is desirable. Also minimum disturbance to the power system is important in many cases. To meet these requirements a speed-control system has been adopted which, while not new in principle, involved the solution of a number of interesting problems. The system as shown in Figure 1 consists of a wound-rotor driving motor (A) whose secondary winding feeds a synchronous motor (S_1) driving a variable-speed d-c generator (DC_1) which in turn drives a d-c–a-c set (DC_2 and S_2) to return most of the secondary power back to the line. The name "modified Kramer set" is suggested by the authors since the scheme involves conversion of the secondary power to d-c and field control for the speed changes as in the well-known Kramer set. The term "modified" was used because the Kramer set used a rotary converter and the d-c power was usually fed into a d-c motor on the same shaft as the main motor. Another descriptive name would be asynchronous-synchronous cascade.

Speed Control and Design Features

Speed control is accomplished in this system by controlling the speed of the variable-speed set, and as long as the synchronous machine remains in synchronism with the induced secondary voltage, the motor must run at a speed corresponding to the difference in frequencies. The speed of the variable-speed set can be adjusted by changing field of either the d-c motor or the d-c generator, just as in a wide-range variable-voltage d-c system. The inherent speed regulation is determined by the regulation of the d-c machines. The application of an accurate speed regulator to such a system is a subject in itself, too lengthy for this paper. It is apparent that automatic control of the speed can be had by controlling the d-c fields.

The constant-speed set is started first since it is smaller and requires relatively little starting current. The variable-speed set may then be brought to speed and the synchronous motor field energized. In this manner it is possible to excite the main motor from the secondary while it is stationary and disconnected from the line. After careful adjustment of frequency and voltage, the primary winding may be synchronized just as an oncoming generator may be. This control also can be made fully automatic.

In order to understand the design problem involved, one must consider the power distribution as shown in Figure 2 for a typical fan curve. It will be seen that the maximum secondary power to be handled occurs at two thirds of synchronous speed, but the maximum torque on the variable-speed set will be at full speed. Hence it is desirable to work at full flux throughout the upper range of speed, obtaining speed control by changing the field of the constant-speed d-c motor. However, in order to limit the size of this d-c motor it is found desirable to obtain the lower part of the speed range by field control of the generator holding nearly constant d-c voltage. The exact point of changing from control of motor to generator field is determined by the economics of the design.

Steady-State Stability

Some interesting problems arise in connection with the stability of such a combination, and the methods developed for handling these may be of value in other similar problems.

Since the synchronous motor must stay in synchronism, the machines must be designed so that their combined characteris-

Paper 42-64, recommended by the AIEE committees on electrical machinery, industrial power applications, and air transportation for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 12, 1941; made available for printing December 19, 1941. Publication of this paper approved by War Department and by National Research Council.

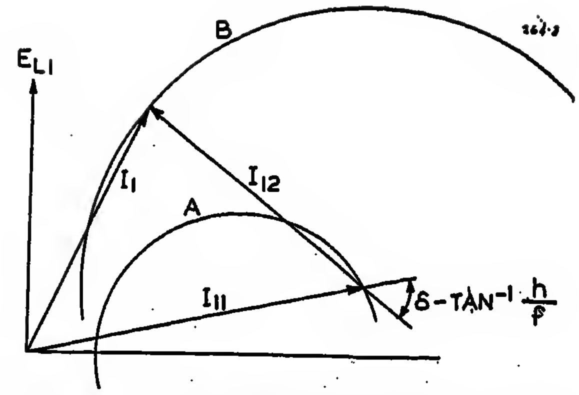

Figure 3. Circle diagram of the doubly fed machine

tics result in stability. For the steady-state synchronizing-torque calculation, the induction motor may be treated approximately as a transformer with high magnetizing current just as in the conventional induction-motor theory. However, the secondary circuit now includes the impedances and the internal voltage of the synchronous machine. Hence the stability calculation resolves itself into a simple two-machine problem.

Another exact method was given in a previous paper on the doubly fed machine.[1] This consisted in resolving the torque into components:

$$T = [e_1^2 r_2 s - e_2^2 r_1 + e_1 e_2 \sqrt{l_1^2 + m_1^2} \times \sin(\delta + \alpha)] \frac{1}{l^2 + m^2}$$

where l_1, m_1, l and m are functions of the slip s. The first component is the well-known induction-motor torque (but, of course, including the total secondary-circuit impedance). The second component is due to the primary resistance and secondary excitation and is negative. The third component is a function of the angle $(\delta+\alpha)$ and when smaller than 90 degrees results in positive torque increasing with the angle.

The components of the stator current of the induction motor are due to primary voltage and the synchronous-machine excitation.

$$I_{11} = E_{L1} \frac{f + jh}{l + jm}$$

$$I_{12} = -E_{L2} \frac{\cos \delta - j \sin \delta}{l + jm}$$

Thus the angle between I_{11} and $-I_{12}$ will be

$$\beta = \delta - \tan^{-1} \frac{h}{f}$$

The primary current I_1 is determined by the output and power factor desired at a given speed. For the same speed (slip) the current component I_{11} can be easily found by solving the equivalent circuit for $E_{L2}=0$ or by using adequate formulas or from the circle diagram of the induction machine for $E_{L2}=0$. Thus the current component I_{12} can be found as the geometrical difference between I_1 and I_{11}. In Figure 3, the primary current I_1 is fixed. The current component I_1 is found from the circle diagram A as the current corresponding to the slip on which I_1 is based. Assuming constant slip and variable angle δ between E_{L1} and E_{L2} the vector I_{11} will not change its position, the vector I_{12} will describe a circle (B in Figure 3) with the end point of I_{11} as center and I_{12} as radius. This circle is the circle diagram of the primary current I_1 for constant slip and variable angle δ. From this it is possible to judge the approximate overload capacity of the machine for the conditions given by the current I_1.

Dynamic Stability

The load, the driving motor, and the connected sets constitute a system of masses connected by springs or by electrical ties which act like spring connections. These masses can oscillate at a number of different natural frequencies corresponding to different modes of vibration. These modes of vibration could theoretically be excited by pulsating torques or could be set in sustained oscillation if there was sufficient energy fed into the oscillating system by the negative damping characteristics of some machine.

Before analyzing the rest of the system it is well to consider the nature of negative damping in such machines. A method of analysis for negative damping in both the doubly fed machine and the synchronous machines has been discussed in previous papers[1,2] and is being discussed in another current paper.[3]

However, it is possible to get a very clear picture of the physical problems and fair quantitative results for large machines by making some simplifying assumptions. These are:

The per-unit primary resistance of the large induction motor is small.

The rotor impedances of the synchronous motor at the oscillation frequency are equal on the two axes.

This gives a revolving field of flux linking the stator winding of the induction motor which is determined only by the fixed primary voltage and frequency. Any small angular oscillations of the rotor induce additional voltages in the secondary at slip frequency plus the oscillation frequency and slip frequency minus oscillation frequency. These voltages are superimposed on the steady-state quantities and act through the reactance of the induction machine (as viewed from the secondary) and the equivalent impedances of the synchronous machine. Both of these extra components induce oscillation frequency currents in the rotor of the synchronous machine, and its impedance must be evaluated on this basis. This would form a basis for calculation as indicated in appendix A, in which the damping coefficient is determined from the speed-torque curve of the induction motor with its rotor short circuited through the impedance of the synchronous machine. The negative-damping coefficient (ratio of change in torque to change in velocity) in per unit is shown to be the slope of a line drawn between two points at $(s+\Delta)$ and $(s-\Delta)$ slip values. To further simplify the approximate solution, let us assume that the resistance of the rotor circuit of the synchronous machine is negligible while considering the effects of primary resistance, and that the primary resistance is negligible while considering the effects of secondary resistance. This is approximately true because the reactance predominates in determining the currents and amplitudes, so that the losses and in-phase components of currents may be approximated by calculating the effect of the resistances one at a time.

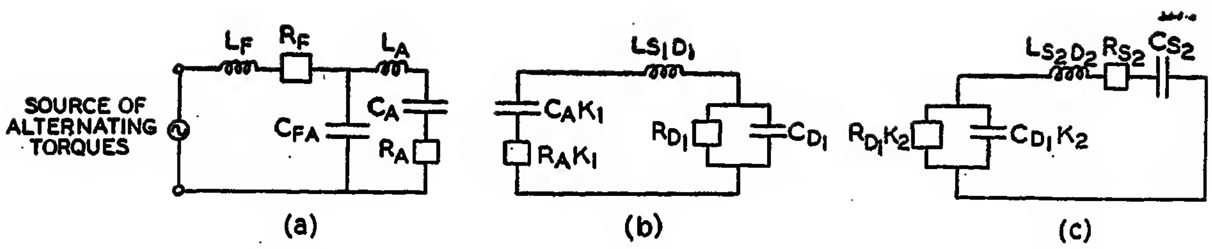

Figure 4. Electrical analogy for the parts of a mechanical system

This results in the approximate solution that the resistance of the secondary circuit acts to cause a negative damping whose value depends on the slope of the speed-torque curve of the induction motor short-circuited through the impedance of the synchronous machine, neglecting rotor resistances. Again since the actual rotor currents involved are at slip frequency plus and minus the oscillation frequency, this slope is to be determined between two points at slip values $(s+\Delta)$ and $(s-\Delta)$. This can readily be seen to be true for the case where the oscillation frequency becomes very low, and one may think of the oscillation as moving from point to point on the speed-torque curve.

The effect of the resistance of the synchronous-motor rotor circuits is to produce positive damping of any angular oscillations between the machines. Again the same concept of taking the slope of the speed-torque curve may be used, except that the slip is zero. One can make an approximate allowance for the difference on the two axes by taking the direct-axis equivalent circuit and a voltage proportional to the flux in the quadrature axis, and a voltage for the quadrature-axis flux proportional to the direct-axis flux. This relation is due to the fact that it is the flux on one axis that induces voltage in the rotor circuit of the other axis due to small angular oscillations.

Electrical Equivalent of Mechanical Systems

According to well-known methods one can analyze torsional vibration problems by representing the parts by their electrical equivalents, as shown in Table I. Thus the equivalent circuit for the fan load and the induction machines will be represented by Figure 4A. L_F and R_F correspond to the moment of inertia and the damping of the fan; C_{FA} represents the spring of the shaft between the fan and the rotor of the induction machine; L_A corresponds to the moment of inertia of the rotor of the induction machine. C_A and R_A correspond to the change of power of the induction machine due to the synchronizing torque, and the damping between the synchronous machine (S_1) and the induction machine. The resistance R_A can be negative for negative damping.

Table I

Mechanical Quantities	Electrical Equivalent
Angular velocity	Current (I)
Torque	Voltage (E)
Moment of inertia	Inductance (L)
Torsional flexibility (reciprocal of stiffness)	Capacity (C)
Damping (loss proportional to oscillation velocity squared)	Resistance (R)

The moments of inertia (L) will be expressed in pound-feet-seconds² per mechanical radian, the synchronizing torques and torsional stiffness ($1/C$) in pound-feet per mechanical radian, and the damping torques (R) in pound-feet-seconds per mechanical radian.

Since the synchronous machine (S_1) has a different number of poles and a different angular velocity (speed) than the induction machine, the capacitance and the resistance that correspond to its synchronizing torque and its damping will have other values than those of the induction machine (C_A and R_A) namely

$$C_{S1}=C_A\left(\frac{P_{S_1}}{P_A}\right)^2=C_AK_1$$

$$R_{S1}=R_A\left(\frac{P_{S_1}}{P_A}\right)^2=R_AK_1$$

This is in accordance with the fact that the power which corresponds to the synchronizing torque and the damping is the same for both machines.

Any oscillations of the synchronous machine (S_1) will be transmitted to the DC_1 and an alternating electromotive force will be induced in the armature of this machine of the value

$$e=\frac{N}{2\pi}\frac{P}{a}\phi 10^{-8}\frac{dw}{dt}\text{ volts}$$

This electromotive force will produce a current that depends on the ohmic resistances and the inductances of the armature circuits of both d-c machines, and, as a consequence, power will be transmitted from the DC_1 to the DC_2. This power transmission will damp the oscillations, that is, it will act as a damping force. The inductance causes a lagging of the current and the resultant torque. This gives a component of torque 180 degrees out of phase with the displacement, hence it is analogous to a spring. Thus the d-c machines are connected by spring and damping torques. The corresponding capacitance and resistance can be assumed connected in parallel or in series. The paralleling has the advantage that the formulas obtained are more general, independent of the frequency of the oscillation.

For this case the damping torque of the DC_1 will be

$$I=\frac{e}{\Sigma R}\qquad T_d=IE_L\frac{0.739}{\Omega}\text{ lb ft sec}$$

and the synchronizing torque

$$T_s=\frac{\Sigma R}{\Sigma L}T_d\text{ lb ft}$$

E_L is the armature voltage of the d-c machine, ΣR and ΣL are the sums of the resistances and inductances of the circuit of both d-c machines, Ω is the angular velocity of the DC_1.

The equivalent circuit for the synchronous machine (S_1) and the d-c machine (DC_1) is shown in Figure 4B. L_{S1D1} represents the moment of inertia of the variable-speed set (S_1+DC_1), R_{D1} represents the damping and C_{D1} the synchronizing torque of the DC_1.

Both the d-c machines are coupled by spring and damping in the same manner as the synchronous machines (S_1) and the induction machine (A). For similar reasons the constants R_{D2} and C_{D2} that represent the DC_2 are different from R_{D_1} and C_{D1}: both d-c machines have different speed and different coil fluxes. The ratio of the torques produced by the current I in both machines is

$$\frac{T_{D2}}{T_{D1}}=\frac{n_{D1}}{n_{D2}}\frac{(N\phi)_{D2}}{(N\phi)_{D1}}$$

Thus the constants for the DC_2 will be

$$K_{D2}=R_{D1}K_2\qquad C_{D2}=C_{D1}K_2$$

$$K_2=\frac{n_{D1}}{n_{D2}}\frac{(N\phi)_{D2}}{(N\phi)_{D1}}$$

The equivalent circuit for the constant-speed set (DC_2+S_2) will be therefore represented by the Figure 4C. $L_{S_2D_2}$ represents the moment of inertia of the constant-speed set (DC_2+S_2), R_{S_2} represents the damping, C_{S_2} the synchronizing torque of the synchronous machine (S_2).

Using the equivalent circuit Figure 4 it is possible to set up the differential equation for the whole set. By solving this equation the resonant frequencies can be found, and the damping factors of the oscillations can be determined. However, it is more convenient to connect the three separate circuits of Figure 4 to one circuit and to set up the differential equation for this circuit. Dividing all constants of

Figure 4B by the factor $(P_{S1}/P_A)^2$ and all constants of Figure 4C by the factor $(P_{S1}/P_A)^2 \times K_2$ the equivalent circuit Figure 5 will be obtained.

Solution of Equivalent Circuits for the Electrical Analogy

An electrical system such as shown in Figure 5 can readily be solved for a given frequency, however, the determination of the natural frequencies is quite difficult. In the practical problem described in reference 4 a set of simultaneous equations was set up for the branches of the network, and a numerical solution obtained by matrix methods. This involves four complex roots or eight distinct roots and is too laborious for general use. A more practical semigraphical solution with the usual complex number representation of the impedances was obtained by plotting the current for a given applied voltage at different frequencies. Two frequencies between which the phase of the current reversed were taken as an indication that resonance lay between them, and more points were tried near the peak currents to determine the exact resonance. The circuit was set up approximately on the a-c calculating board. Although negative resistance or even the very low positive resistance of some branches could not be represented, the solution did indicate the points of resonance which could then be calculated accurately.

The circuits were checked at the natural frequencies for any net negative damping assuming a small impressed force in the branch containing the negative resistance. Also, the amplitudes for any impressed forces at the propeller at the natural frequencies were checked by these methods.

Conclusion

Methods have been indicated for determining the stability limits of this system, and the dynamic stability or hunting characteristics have been analyzed. The results of the application of this type of analysis indicate that the machines can readily be designed to be stable. Also providing the motor is operated well below synchronous speed, 8 or 12 per cent below for large machines, it is possible to avoid any tendency to hunt.

List of Symbols

This does not include certain symbols defined as used, or the symbols indicating the machines as shown in Figure 1.

a—Number of parallels
e_1, e_2—Impressed voltage of primary and secondary

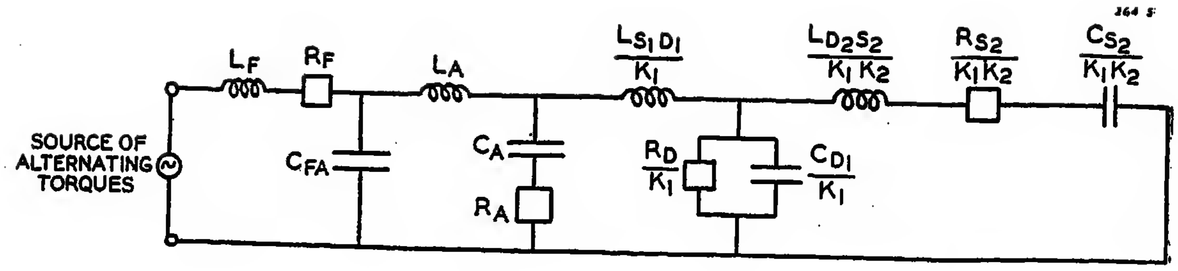

Figure 5. Electrical analogy for the combined mechanical system

E_{L1}, E_{L2}—Induced voltages in primary and secondary
$f=(1+\tau_2)$
f_1, f_2—Frequency of primary and secondary impressed voltage
$h=-r_2/sx_m$
I—Current
I_m—Magnetizing current
$l=[(1+\tau_2)r_1+(1+\tau_1)r_2/s]xs$
l, L—Inductance
$m=\left[x_1+(1+\tau_1)x_2-\frac{r_2}{\tau_1}\frac{r_1}{x_m}\right]xs$
n—Rpm
N—Total number of conductors
r_1, r_2—Stator and rotor resistances
r_{Dd}—Resistance of damper winding on the direct axis
r_{Dq}—Resistance of damper winding on the quadrature axis
r_f—Field resistance
s—Per-unit slip
T—Torque
T_d—Damping torque per radian per second
T_s—Synchronizing torque per radian
x_1, x_2—Stator and rotor leakage reactance
x_{ad}—Reactance of armature reaction on direct axis
x_{aq}—Reactance of armature reaction on quadrature axis
x_{Dd}—Leakage reactance of direct-axis damper winding
x_{Dq}—Leakage reactance of quadrature-axis damper winding
x_f—Leakage reactance of the field
x_m—Magnetizing reactance
Z—Impedance
α—Power-factor angle
β—Angle between machines
δ—Angle between voltages of machines
Δ—Per-unit torsional oscillation frequency
$\tau_2=x_2/x_m$—Leakage coefficient
ϕ—Flux per pole
Ω—Angular velocity

Appendix A. Simplified Solution of Negative Damping for a Doubly Fed Polyphase Machine

In the analysis, the following assumptions are made:

1. The primary resistance is negligible in comparison with primary reactance at the frequencies considered.

2. The three-phase winding of the machine can be replaced by an equivalent two-phase winding.

3. The coefficients of self-inductance of primary and secondary (L_1 and L_2) and of mutual inductance (M) are independent of the relative position of rotor and stator.

4. The primary flux is sinusoidally distributed, and its amplitude is the same at all times.

5. The angular motion of the rotor with respect to that of the stator flux is represented by

$$\theta=\omega_s t+f(t) \qquad (1)$$

where ω_s is equal to 2π times the frequency of the a-c voltage applied to the rotor.

6. The amplitude of the angular oscillations represented by $f(t)$ is small, so that $\cos f(t)$ can be taken as unity, and $\sin f(t)$ can be taken as $f(t)$. This is a good approximation up to about 15 electrical degrees. On this basis

$$\cos\theta=\cos\omega_s t-f(t)\sin\omega_s t \qquad (2)$$

$$\sin\theta=\sin\omega_s t+f(t)\cos\omega_s t \qquad (3)$$

7. The systems providing excitation for stator and rotor are very large, so that they are unaffected by any change in the motor.

The flux linkages in phase a of the secondary due to primary flux are equal to

$$\psi_{a_2}{}'=-\frac{M\psi_1}{L_1}\cos\theta \qquad (4)$$

where ψ_1 represents the primary-flux linkages. Similarly, the flux linkages in secondary phase b are

$$\psi_{b_2}{}'=-\frac{M\psi_1}{L_1}\sin\theta \qquad (5)$$

The voltage in phase a of the secondary is

$$e_{a2}=p\psi_{a_2}{}'-E_2\sin(\omega_s t-\phi) \qquad (6)$$

where E_2 is the amplitude of the voltage applied to the secondary, and ϕ is the phase angle between this voltage and the voltage $p\psi_{a2}{}'$. The voltage in phase b is

$$e_{b_2}=p\psi_{b_2}{}'+E_2\cos(\omega_s t-\phi) \qquad (7)$$

In the operational form the currents in phases a and b of the secondary are

$$i_a=\frac{p\psi_{a_2}{}'-E_2\sin(\omega_s t-\phi)}{r+pL} \qquad (8)$$

$$i_b=\frac{p\psi_{b_2}{}'+E_2\cos(\omega_s t-\phi)}{r+pL} \qquad (9)$$

The total flux linkages of the secondary phases are

$$\psi_{a_2}=-M\frac{\psi_1}{L_1}-i_aL \qquad (10)$$

$$\psi_{b_2}=-M\frac{\psi_1}{L_1}-i_bL \qquad (11)$$

In equations 7 to 11, r is the resistance and L is the equivalent coefficient of self-inductance of the secondary, which is equal to

$$L=L_2-\frac{M^2}{L_1} \qquad (12)$$

From the two-reaction theory of torque the torque in the machine is

$$T = i_a\psi_{b_2} - i_b\psi_{a_2}$$

$$= M\frac{\psi_1}{L_1}\sin\theta \times \left[\frac{M\dfrac{\psi_1}{L_1}p\cos\theta + E_2\sin(\omega_s t-\phi)}{r+pL}\right] + M\frac{\psi_1}{L_1}\cos\theta \times \left[\frac{-M\dfrac{\psi_1}{L_1}p\sin\theta + E_2\cos(\omega_s t-\phi)}{r+pL}\right] \tag{13}$$

This torque equation can be expanded and simplified to equation 14.

$$T = M\frac{\psi_1}{L_1}\left[M\frac{\psi_1}{L_1}\left(\frac{-r\omega_s + f(t)\omega_s^2 L}{r^2+\omega_s^2L^2} - \sin\theta\,\frac{f(t)\omega_s\cos\omega_s t + pf(t)\sin\omega_s t}{r+pL} + \cos\theta\,\frac{f(t)\omega_s\sin\omega_s t - pf(t)\cos\omega_s t}{r+pL}\right) + E_2\left(\frac{1}{r^2+\omega_s^2L^2}\right)(r\cos\phi - \omega_s L\sin\phi - f(t)\omega_s L\cos\phi - f(t)r\sin\phi)\right] \tag{14}$$

If the angular oscillation represented by $f(t)$ is set equal to $\theta_\Delta \sin\omega_\Delta t$, where θ_Δ is the amplitude of the fundamental frequency of variation and ω_Δ is 2π times this frequency, the torque is represented by equation 15, in which $\omega_+ = (\omega_s+\omega_\Delta)$, $\omega_- = (\omega_s - \omega_\Delta)$, and the secondary resistance is r_+ at ω_+, r_- at ω_-, and r_s at ω_s.

$$T = \left(M\frac{\psi_1}{L_1}\right)^2\left(\frac{-r_s\omega_s}{r_s^2+\omega_s^2L^2}\right) + M\frac{\psi_1}{L_1}E_2\left(\frac{1}{r_s^2+\omega_s^2L^2}\right)(r_s\cos\phi - \omega_s L\sin\phi) - \left(M\frac{\psi_1}{L_1}\right)^2\left(\frac{\theta_\Delta}{2}\right)\left(\frac{\omega_+ r_+}{r_+^2+\omega_+^2L^2} - \frac{\omega_- r_-}{r_-^2+\omega_-^2L^2}\right)\cos\omega_\Delta t - \left(M\frac{\psi_1}{L_1}\right)\times\left[M\frac{\psi_1}{L_1}\left(\frac{\theta_\Delta}{2}\right)\left(\frac{\omega_+^2}{r_+^2+\omega_+^2L^2} + \frac{\omega_-^2}{r_-^2+\omega_-^2L^2} - \frac{2\omega_s^2}{r_s^2+\omega_s^2L^2}\right)L + E_2\theta_\Delta\frac{\omega_s L\cos\phi + r\sin\phi}{r_s^2+\omega_s^2L^2}\right]\times \sin\omega_\Delta t \tag{15}$$

The sin $\omega_\Delta t$ term of equation 15 represents a torque in phase with and opposed to the alternating displacement, and is therefore the synchronizing torque.

The cos $\omega_\Delta t$ term represents a torque in phase with and aiding the velocity. The nature of this torque is such that it tends to increase any small variation in the motion of the rotor, and thus it provides negative damping in the machine.

This equation indicates that the damping factor at any speed can be determined from the speed-torque curve obtained with the rotor short-circuited. The slope of a line between two points on this curve is the value of the damping coefficient at the speed halfway between those points. Thus if vibration is forced at the frequency corresponding to ω_Δ, and the speed of the machine is $(\omega-\omega_s)$, the damping factor will be the slope of the line connecting points on the curve at the speeds $(\omega-\omega_s)+\omega_\Delta$ and $(\omega-\omega_s)-\omega_\Delta$.

In the practical case the secondary is not connected to a system of infinite capacity, so the secondary voltages induced by the pulsations act through a circuit which includes the impedance of the machine connected in the secondary. Since the pulsations induce oscillation frequency currents in the rotor of the connected synchronous machine, the rotor-circuit resistances must be divided by the per-unit oscillation frequency when this impedance is added into the equivalent circuit.

Appendix B. Tests on Model System

In order to study the stability of the system under consideration, a model has been set up as shown in Figure 6. The induction machine A was loaded by a d-c generator for want of a fan, but a flywheel has been put on the shaft of this d-c machine as a substitute for the high WR^2 of the fan. A variable ohmic resistance and a variable inductance have been put in the armature circuit of both d-c machines DC_1 and DC_2 in order to vary the damping torque as well as the synchronizing torque of these machines. The constant-speed set (DC_2+S_2) consisted of duplicates of the machines of the variable-speed set (DC_1+S_1) with the sole exception that the synchronous machine (S_1) had a damper winding of copper while the synchronous machine (S_2) had a damper winding of material with high resistivity.

The rating and the constants of the different machines were as follows:

Induction motor:

100 horsepower—2,200/440 volts—60 cycles—3 phases—6 poles

$r_1 = 1.2 \quad r_2 = 1.19$
$x_1 = 4.5 \quad x_2 = 4.0$
$x_m = 147 \quad WR^2 = 172$ pound-feet^2
Flywheel $WR^2 = 164$ pound-feet^2

Synchronous machines:

100 kva—2,300 volts—60 cycles—3 phases—6 poles

$r_1 = 1.27 \quad x_{ad} = 57.0 \quad r_f = 0.161$
$x_1 = 5.0 \quad x_{aq} = 54.3 \quad x_f = 6.2$
$r_{Dd} = 2.76 \quad r_{Dq} = 1.27$
$x_{Dd} = 8.3 \quad x_{Dq} = 4.36$
$WR^2 = 195$ pound-feet^2

Transformer between A and S_1:

3×33 kva—2,300/440 volts—60 cycles

$r_1 = 0.32 \quad x_1 + x_2 = 1.5$
$r_2 = 0.0734$ (including brushes)

The constants given above are expressed in ohms per phase for 60 cycles; they are reduced to the primary of each machine.

D-c machines:

150 horsepower—230 volts—525 amperes—1,100 rpm—$WR^2 = 305$ pound-feet^2—6 poles—6 parallels —$N = 450$

Armatere resistance $r_a = 0.0073$
Armature reactance $x_a = 0.11$ at 25 cycles

As could be expected, the tests have shown that the system is statically stable and that the speed control takes the same course as in the conventional Kramer set, where the machine that absorbs the slip power of the induction machine is a rotary converter. A continuous variation of the speed is possible without any disturbances.

In order to study the dynamic stability, the damping of the system has been artificially weakened by overexcitation of the synchronous motor (S_1) or by putting an inductance in the armature circuit of both d-c machines. Two kinds of conditions under which sustained oscillations have been observed are given in the following:

Condition *A*

Machine	Volts	Amperes	Cos ϕ	Slip
A	2,310	25.5	0.736 leading	26.6%
S_1	626	31.5	0.57 leading	
DC_1	58	75		
S_2	2,310	0		

The frequency of the oscillation was $f_o = 2.5$ cycles per second. The machine (S_1) was overexcited. Between both d-c machines was placed an additional resistance $= 0.024$ ohm.

For these conditions the following damping and synchronizing torques were determined:

Machine	Td (Pound-Feet-Seconds)	Ts (Pound-Feet)
S_1	−58	3,100
DC_1	62.7	1,590
S_2	9.6	885

The factor K_1 (Figure 4) is here equal to 1, the factor K_2 is equal to $\dfrac{1{,}200}{320}\times\dfrac{2.41}{0.512} = 17.6$, thus the equivalent circuit and its constants are as shown in Figure 7.

Substituting the impedances of Figure 7 in the equations, the characteristic differential equation of the system can be found, and by solving this equation the tested frequency of the oscillations can be checked. The substitution leads to a differential equation of seventh degree. For the solution of such an equation Graeffe's method or the matrix method, both of which are rather laborious, has to be used. An examination of Figure 7 shows that this is not necessary in our case, where the machine (S_2) has a much higher rating than it has in the real induction synchronous cascade.

$f_o = 2.5$ cycles per second corresponds to $p = 15.7$. The impedance of the machine (S_2) is so large for this value of p that it has practically no influence on the impedance that represents the two d-c machines. Thus we can omit the tail of Figure 7, and the differential equation will be only of the fifth degree. A further reduction by 1 is possible, if we limit our considerations to a natural frequency around 2.5 cycles per second. It is then possible to replace both impedances in parallel that represent the two d-c machines by one impedance. With this as-

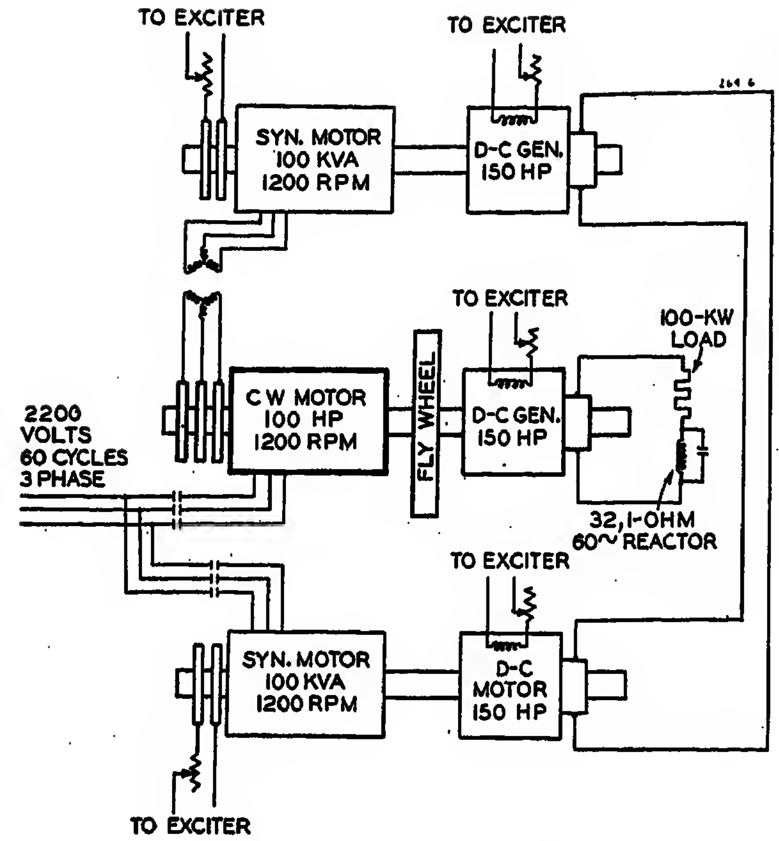

Figure 6 (left). Variable-speed synchronous Kramer-set laboratory-model test of large wind-tunnel drive

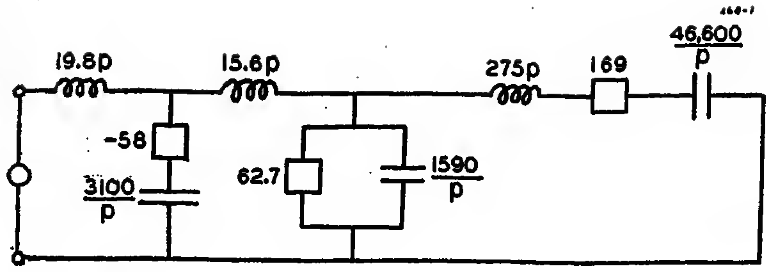

Figure 7 (upper right). Electrical analogy with numerical values corresponding to model test

sumption the following impedances will determine the oscillations:

$$Z_1=19.8 \qquad Z_2=-58+\frac{3,100}{p}$$

$$Z_3=43+15.6p+\frac{490}{p}$$

The characteristic differential equation is with these constants

$$p^4-3.89p^3+379p^2+338p+4,910=0$$

The roots of this equation are

$$p_{1,2}=2.4\pm j19$$
$$p_{3,4}=0.54\pm j3.6$$

To the angular velocity 19 corresponds $f_0=3.02$ cycles per second. Since the real part of this pair of roots is positive, the damping is negative, and the oscillations are sustained.

To the other pair of roots corresponds a slow oscillation with 0.57 cycles per second. A slower oscillation than this has been observed during the tests. It must be noticed that the damping and synchronizing torques depend on the frequency of the oscillations. The values of these torques as given above were determined for $f_0=2.7$ and are not correct for the low oscillations. Thus the second pair of roots is only approximate.

Condition *B*

Machine	Volts	Amperes	Cos ϕ	Slip
A	2,460	17.7	0.71 leading	35.4%
S_1	920	26.7	0.50 leading	
DC_1	80	90		

The frequency of the oscillations was $f_0=2.9$ cycles per second. The second d-c machine had been cut out, and the DC_1 was loaded into a resistor. A large reactance between both d-c machines had given under the same conditions the same frequency of oscillations. The machine (S_1) was overexcited ($e_d=1.95$).

For these conditions the damping and synchronizing torque of the synchronous motor (S_1) are

$T_d=8.8$ pound-feet-seconds
$T_s=3,330$ pound-feet

The differential equation of the oscillation is

$$p^2+1.0+382=0$$

and the roots are

$$p=-0.5\pm j19.5$$

To the angular velocity 19.5 corresponds $f_0=3.1$ cycles per second. The calculation gives a small positive damping, while the test has shown sustained oscillations, that is negative damping. The discrepancy is caused by the difficulty of exact determination of the input (and output) current, and so on, at the starting of the oscillations. The figures under conditions *A* and *B* are only approximate.

Synopsis: The features of a new protective relay scheme are described. The scheme is designed to remove underexcited a-c generators from the system, upon occurrence of undervoltage, before loss of synchronism occurs. The relay development and its operating characteristics are described. Calculations required to determine generator behavior after loss of field are also presented to make the application of this scheme easily applied to generators on any system.

The Problem

THOUGH electrical circuits from generator armature windings outward to utilization apparatus have received much attention from a protective viewpoint in the past 20 years, relatively little attention has been given to generator field-winding protection. Calculations show that loss of field in a large generator may cause serious voltage disturbance to the system. A need for some suitable protection method that will initiate disconnection of the troubled machine is indicated.

When loss of field occurs on a loaded generator, the magnetic coupling between the rotor and the stator becomes so weakened that the rotor advances and, after a short period, pulls out of synchronism with the system. The unit continues to carry load of varying magnitude but draws a high component of wattless current from the system.

Continued operation without excitation has harmful effects to both the generator and to the system. The generator, now an asynchronous machine, will be subject to high circulating currents in the face of the field rotor or in the amortisseur winding, and these may cause injurious heating, at least in local areas. Also induced current or voltage will appear in the field winding depending upon whether it is short circuited or open circuited.

The effects of field failure may be much more important on the system, particularly if the generator is a large unit in relation to other operating capacity. For complete loss of field, calculations have indicated that, on most power systems not equipped with automatic-generator voltage regulators, seriously low-system voltages may be reached in not more than 10 to 15 seconds and in some cases in as short a time as one second.

System loads affect the degree of voltage disturbance after loss of field. If a large percentage of the load is induction motors equipped to be disconnected only after the voltage has reached 25 to 50 per cent of normal, many of these will stall as the voltage is reduced to approximately 75 per cent of normal at the bus. This condition becoming cumulative, may cause voltage instability until the voltage has been reduced to a value where most of the motor load does become disconnected.

Since 1927 there have been five serious machine-excitation failures on the system with which the authors are connected. In addition to these, three other cases of field trouble have developed in large machines which might easily have caused loss of field, had the conditions not been discovered and corrected. One of these failures reached the stage of voltage instability, as referred to above, because of motor loads, and the station bus voltage was reduced to 37 per cent of normal before a sufficient number of motors was disconnected to permit recovery to approximately 80 per cent of normal voltage.

It became evident some years ago that this system in New York required adequate means for main-generator field protection. The results of the development which followed, and a description of the means for applying it, are outlined in sufficient detail to permit practical use of the information by others.

Field protective relays should be sensitive to any reduction of excitation that will, at any generator load, become unsatisfactory for continued operation of the machine. Relays which operate at a specific value of field current or voltage do not give full coverage, since they must be set to operate at values well below no-load excitation conditions and yet be required to function for excitation disturbances under full-load conditions that are within safe operating range so far as the relays can determine. The new relay scheme described herein provides the degree of sensitivity desired and equally satisfies the requirements for field protection at any level of generator loading.

Generator Behavior After Loss of Field

Field loss in a generator may be partial or complete. Types of partial field failure are:

(*a*) Field rheostat trouble.

(*b*) Reductions in excitation voltage.

(*c*) Internal short circuit in a section of the field winding.

(*d*) Operating error.

Complete field failure would include:

(*a*) Winding open circuit.

(*b*) Slip ring or equivalent short circuit.

(*c*) Loss of field to main exciter.

(*d*) Accidental opening of field supply breaker.

(*e*) Operating error.

To show the behavior of generators when complete loss of field occurs, two machines on the system with which the authors are connected, were selected. One of these shows conditions for the case of "accidental tripping of field supply breaker," and the other, "loss of field to main exciter." The machine used to show effects of the first condition is one of the largest units on the system and operates at 1,800 rpm. The curves showing the various behaviors are given in Figure 1. The generator used in the second case is a unit of medium size which operates at 3,600 rpm. Its characteristic curves are given in Figure 2.

In both cases the system was considered to be operating with normal capacity for off-peak conditions. No generator automatic voltage regulators were considered to be in service.

In calculating the effects shown in Figures 1 and 2 many varying effects must be taken into consideration. The more important of these may be itemized as:

1. The effects of turbine-governor action are not likely to be great before loss of synchronism. However, after loss of synchronism, violent governor action may occur,[1,2] thereby causing wide fluctuations in generator power output. There may be small power oscillations before loss of synchronism due to the effects of inertia in the rotating parts of the affected generator.

2. Generator and system impedances must be carefully considered since their relative values determine, in large part, the degree of voltage disturbances after loss of field. Obviously the effect on system voltage will be greater as the relative size of the machine increases.

3. The time constant of the generator field circuit determines the rate of decay in bus voltage after loss of field. The field-winding open-circuit time constant as modified by any field circuit external resistance determines, in approximately inverse porportion, the rate of decay in internal generated voltage and bus voltage.

4. Initial power output of the affected generator has an effect on the elapsed time from loss of field to loss of synchronism. Obviously the time will be shorter as the load on the generator becomes larger.

5. Initial reactive loading on the affected generator must be taken into account, since the loss of that output has its effects on the reactive output required of the other system machines. Higher reactive loading tends toward greater reduction of bus voltage after loss of field.

6. Generator voltage regulators were not considered in these calculations, since they are not used generally on the system with which the authors are concerned. If regulators are used on sufficient generating capacity, they will help materially in maintaining bus voltage when one generator has lost its field.

The methods used in calculating the changes occurring after loss of field are given in appendixes I, II, III, which are a part of this paper.

Development of Protective Equipment

The results of Figure 1 show that a relay designed to measure "input" megavars might readily be used to detect generator field excitation disturbances to the degree desired. However, as is shown here, the rate of decay of voltage is so fast for some machines that the rate of increase in "input" megavars is greatly reduced before loss of synchronism occurs. Hence, the torque and operating speed of such a relay is reduced where fast performance is desired. The rate of change in reactive current is not affected. Consequently a relay designed to measure reactive current and be sensitive to its direction would be a better instrument for this purpose. This reactive current relay must have high operating speed if it is to clear the machine before the bus voltage is reduced below the minimum permissible value.

Calculations have indicated that such a relay applied as single-phase elements would be subject to incorrect operations on unbalanced system short circuits. Hence, a polyphase relay with three elements (one per phase) was indicated.

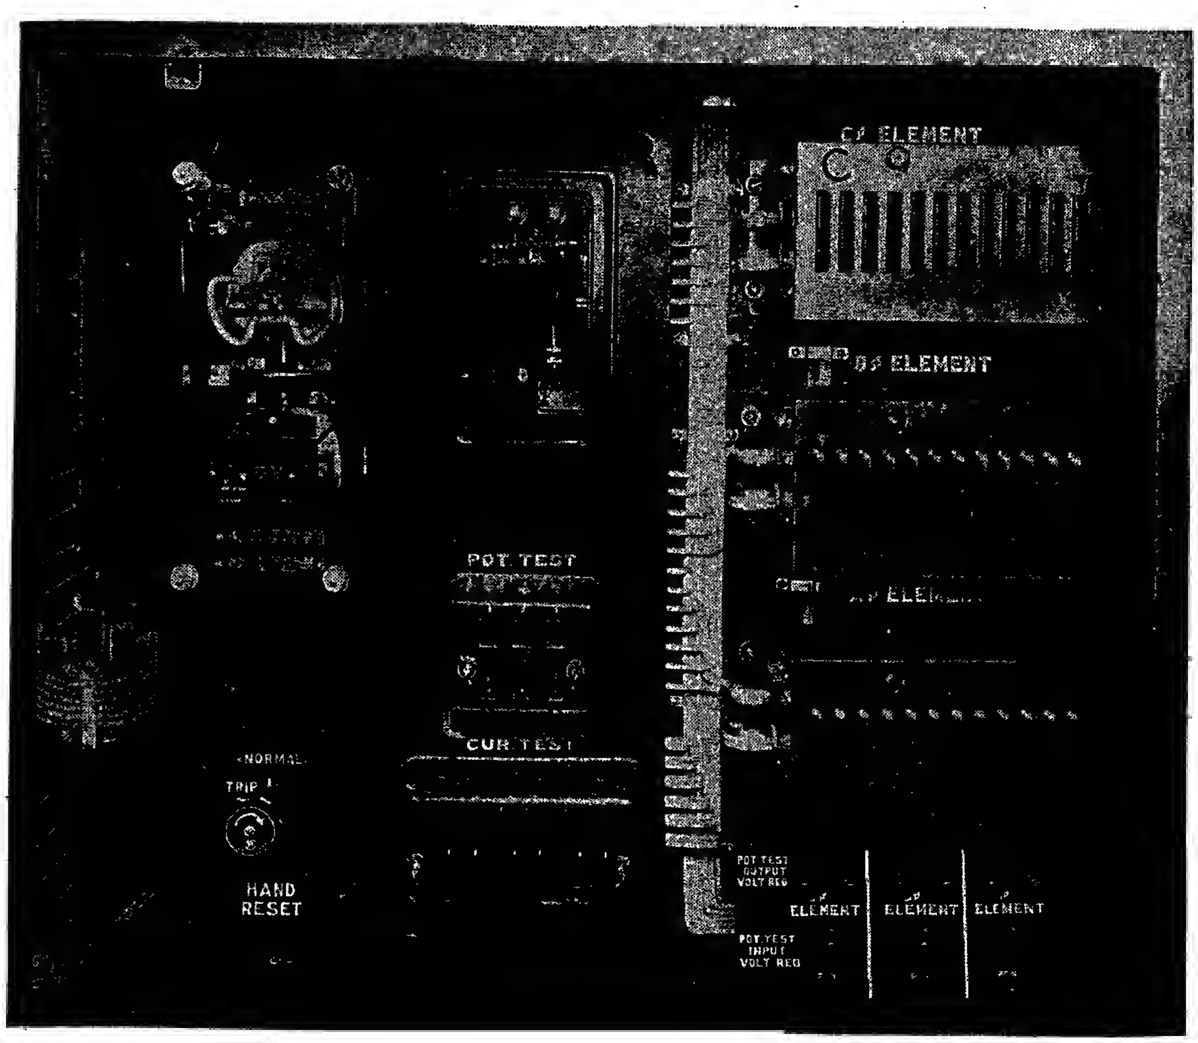

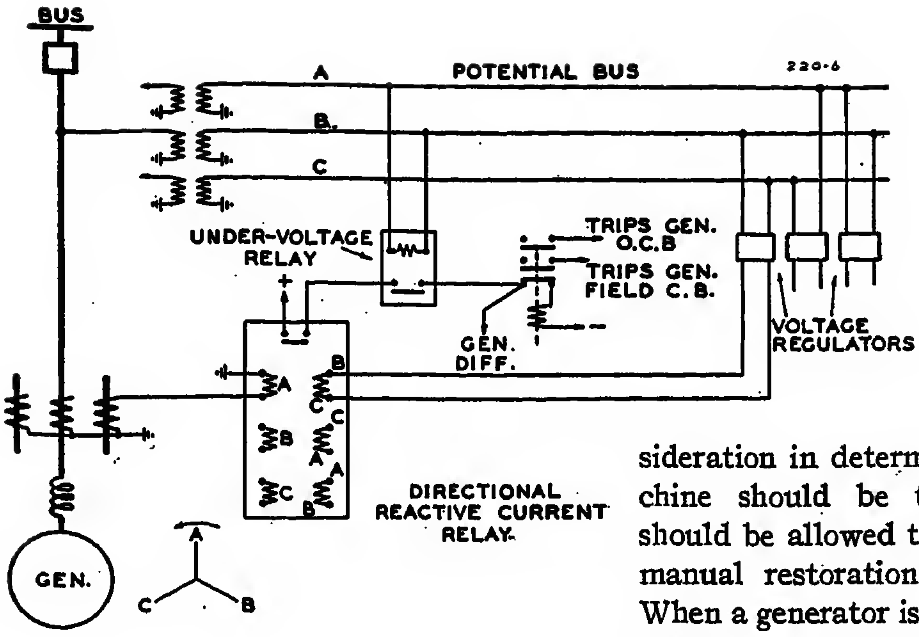

Figure 6. Schematic diagram of relay connections

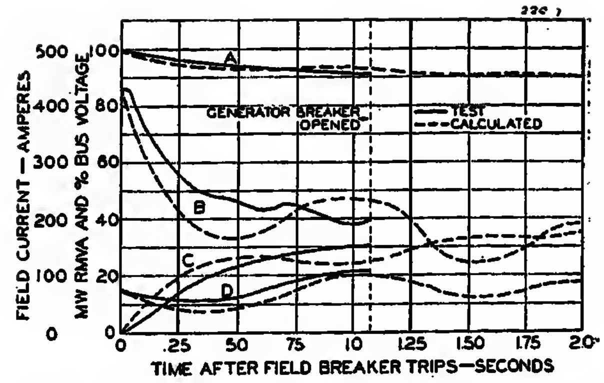

Figure 7. Loss-of-field test on a 50,000-kw generator—field breaker tripped

A—Bus voltage
B—Field current
C—Generator reactive kilovolt-amperes into generator
D—Generator output kilowatts

The relay is a polyphase induction disk, three-element self-reset watt-type device with provisions for time and wattage adjustments. Seven wattage taps varying from 50 to approximately 500 watts permit use of the same relay on any size generator.

To permit measurement of reactive current a magnetic-type voltage regulator was chosen to maintain constant voltage at the relay when variations occur in the bus voltage. The magnetic voltage regulator holds ±1 per cent of normal voltage on the relay coil and permits not more than ±5 degree phase shift while the input voltage varies from 60 per cent to 110 per cent of normal.

Care was required to assure satisfactory performance from zero to 60 cycles and over a corresponding range in voltage on the potential supply to the magnetic regulators and to the relay. Since the generator potential transformers are used for the relays, these may be energized during the generator starting period, thereby producing this wide range of frequency and voltage.

Figure 3 shows the phase-angle characteristics of the relay supplied through the magnetic voltage regulators with input voltage at 120 and at 70 volts. It will be noted that the relay maximum torque appears at about 90 degrees leading current. To obtain this characteristic the relay voltage leads the normal in-phase current by 90 degrees, as would be necessary in applying a watt element for reactive current measurements.

Figure 4 shows the time-reactive current curve of the relay when supplied at 120 and 70 volts through the magnetic voltage regulators.

It will be noted in both Figures 3 and 4 that the relay torque does not change appreciably over this wide voltage range and that the phase shift of the tripping characteristic is not great.

Bus-voltage magnitude is a major consideration in determining whether a machine should be tripped instantly or should be allowed to operate and permit manual restoration of field excitation. When a generator is small compared with the system-connected generation and is linked to the other system generators through relatively low impedance, loss of field in that machine may not cause a serious voltage disturbance. Field-current interruptions may occur or serious field-current reductions may be experienced where quick correction of the trouble is possible and the generator need not be lost from the system.

An undervoltage relay has, therefore, been made a part of the present scheme. It is a standard voltage-regulator type element adjustable to operate at the particular voltage value dictated by the characteristics of an individual machine. Its contacts are connected in series with those of the reactive current relay to prevent tripping unless the bus voltage approaches a value beyond which continued operation of the generator would be unsafe.

Figure 5 shows a typical installation of the relay equipment.

Figure 6 shows a simplified connection diagram of the relays and their associated equipment. Tripping of the generator circuit breaker is first initiated and the field supply is then disconnected by an auxiliary switch on the generator circuit breaker.

System Tests

The reactive current relay was set up for tests on a 50,000-kw machine. The unit was loaded to 14,000 kw at unity power factor. The main-field breaker was then opened, thereby connecting the field winding to its discharge resistor through the main-field rheostat. Oscillographic records were obtained of field current, megawatts and megavars. Bus voltage was obtained with a recording voltmeter. Some of the results of this test, test 1, are shown in Figure 7. In the same illustration, curves are given showing the calculated values for the same conditions. Agreement was close enough to assure that behavior after loss of field can be determined with sufficient accuracy for applying field protective relays.

Altogether four similar tests were made on two machines of the same design and rating. All initial and final behaviors observed on tests 1 and 2 are given in Table I. Complete data were not taken on the last two tests, which were made at higher initial loads.

Calculations show, for this system, that the dividing line in machine rating is about 50 to 60 megawatts beyond which loss of field may produce unstable voltage conditions for the most unfavorable operating and load conditions. Agreement has been reached to apply the protection to all machines on the system of 50-megawatts and larger except for two 60-megawatts, 25-cycle units whose characteristics are such that they could be made the "exceptions."

Conclusions

The relay equipment described makes practicable protective measures which will cover virtually all cases and types of loss of field in generators. It is believed that

Table I. Results of Loss-of-Field Tests on 50,000-Kw Generator

Test	Condition	Generator Armature Current	Generator Armature Volts	Generator Armature Mw	Generator Armature Mvar	Field Current	Field Volts	Time to Trip (Sec.)

All values are per-unit on machine rating, 137,500 kva, and 13,500 volts except where indicated otherwise.

this further improves the reliability of electric service since a thoroughly reliable relay device has been developed which does not of itself create a hazard.

The scheme provides a relay combination which is sensitive to serious excitation reductions, regardless of initial machine load and excitation values.

This new type of field protection has now been applied to all 60-cycle generators rated 50 megawatts and above, excepting two units already provided with undercurrent-undervoltage relays, and to one large 25-cycle machine on the system with which the authors are connected. Though the first installations have been in service over a year no operating experience is yet available.

Appendix I. Calculation Method for Complete Loss of Field

Basis of Calculations

The method used is a step-by-step process and takes into account the decrement of system generator internal voltages as the unexcited machine draws magnetizing current. Although less labor in calculations would result if this decrement were neglected, the authors' calculations for some 15 generators indicate that this decrement is usually about 5 per cent at the relay operating point, and may be as much as 10 to 15 per cent at "pull-out." Consequently, it is felt that the additional labor is justified.

To simplify and reduce this work as far as possible, consistent with reasonable accuracy, several simplifying assumptions have been made. The first of these is neglecting the effects of changes in system load during loss-of-field conditions. Actually some reduction will take place and will cause the bus voltage to be slightly higher than calculated at the relay operating point.

Secondly, oscillations between system generators have been neglected, and these generators have been lumped into one equivalent machine. Since changes in system load have been neglected, this machine is considered to act as motor, absorbing the power output of the unexcited generator. While the actual system generators are in no sense motors, their effects upon the unexcited generator and its bus voltage are much the same. This assumption is often used in transient-stability calculations.[8]

Third, saturation of the magnetic circuits in the unexcited generator and in the system generators has been neglected. While such saturation in the unexcited unit acts to hasten the decay of bus voltage, the saturation in the system generators acts oppositely. Furthermore, the authors' calculations indicate that the unexcited machine flux is usually in the unsaturated region at the relay operating points.

Fourth, constant prime-mover input to the unexcited generator is assumed, since the average output is constant up to "pull-out."

Fifth, to determine the relative swinging of the unexcited generator rotor against the system, system swings are neglected and an equivalent inertia is used for the unexcited machine. This inertia may be calculated by formula 4 of appendix II.

Sixth, effects of system generator voltage regulators have been neglected.

The formulas and symbols which have been used by the authors are for steam driven turbogenerators and are given in appendix II.

Where system conditions will not permit the use of the above assumptions, determination of loss-of-field conditions becomes more complicated. However, practically all cases should be capable of solution quite readily if an a-c calculating board is used.

Determination of System Equivalent-Motor Constants

The first step is to determine which system generators are likely to be appreciably affected by loss of excitation on the unit under consideration.

The system equivalent-motor synchronous reactance, x_{ds}, defined in appendix II, is the reactance from the unexcited machine terminals to the synchronous internal voltages of the selected system generators, such voltages being considered equal and in phase. The transient reactance x_{ds}', is determined in the same way.

The system equivalent motor inertia, H_s, is the sum of the corresponding inertias of the system generators.

The field time constant of the system equivalent motor, T_{sf}', is a weighted average of the system-generator field time constants, with greater weight being given to the units expected to supply the greater portions of the unexcited generator magnetizing current.

Step-by-Step Calculations

After the initial values of all quantities have been determined, the size of the time interval, Δt, should be selected to cause relatively small changes in angle and direct axis flux during this period. For purposes of clarity in the following explanations, it will be assumed that a 0.1-second interval has been selected.

During the first time interval, that is, from time zero to time 0.1 second, the angle δ is held constant, and only the generator direct axis flux, e_g, is changed. The value of this flux at time zero, that is, $e_{g(0)}$, is reduced by the amount $\Delta e_{g(0)}$, the change from time zero to time 0.1 second, determined from either formula 8 or 9, depending upon whether the excitation supply voltage decays gradually or whether it drops to zero instantly, as in a solid short circuit. The value of E_g to be used in this formula will, of course, be that for time zero, that is, $E_{g(0)}$. No change in e_s will occur as may be seen from formula 10.

With $e_{g(0\cdot1)}$, $e_{s(0\cdot1)}$ and $\delta_{(0\cdot1)}$ thus determined for time 0.1 second, corresponding synchronous voltages $E_{g(0\cdot1)}$ and $E_{s(0\cdot1)}$, generator output, $P_{g(0\cdot1)}$, and other required quantities may be determined from the formulas in appendix II.

During the next time interval, that is, from time 0.1 second to time 0.2 second, e_g, e_s, and δ will change. The change $\Delta e_{g(0\cdot1)}$ will be determined as before, using $E_{g(0\cdot1)}$, and will be added to $e_{g(0\cdot1)}$ to obtain e_g at time 0.2 second, that is, $e_{g(0\cdot2)}$. Flux $e_{s(0\cdot2)}$ will be obtained similarly.

To obtain the new angle at time 0.2 second, $\delta_{(0\cdot2)}$, several intermediate steps must be taken. The difference between the assumed constant input to the machine, that is, the initial output P_{gi} neglecting losses, and the output at time 0.1 second, $P_{g(0\cdot1)}$, constitutes an accelerating or decelerating force, depending upon whether this difference is positive or negative. This force is considered as acting from time 0.05 second to time 0.15 second, and during this period will produce a change in the velocity of the generator rotor above system speed. This velocity change is designated by the symbol $\Delta\omega_{(0\cdot1)}$ and is obtained from formula 6. The velocity at time 0.15 second is considered as an average velocity for the time interval 0.1 second to 0.2 second, and is designated by the symbol $\omega_{(0\cdot15)}$. This velocity is equal to the algebraic sum of the above change in speed, $\Delta\omega_{(0\cdot1)}$, and the corresponding average speed at time 0.05 second, designated by the symbol $\omega_{(0\cdot05)}$. Since the angle δ was held constant from time zero to time 0.1 second, $\omega_{(0\cdot05)}$ is zero, and therefore $\omega_{(0\cdot15)}$, is equal to $\Delta\omega_{(0\cdot1)}$.

The average velocity $\omega_{(0\cdot15)}$ for the time interval, 0.1 second to 0.2 second, is meas-

ured in the electrical degrees per time interval, that is, degrees per 0.1 second. Consequently, $\omega_{(0.15)}$ is numerically equal to the change in the angle δ during this period. Therefore, δ at time 0.2 second, $\delta_{(0.2)}$, is equal to the angle δ at time 0.1 second, $\delta_{(0.1)}$ plus $\omega_{(0.15)}$.

The angle at time 0.3 second is obtained similarly. Velocity $\omega_{(0.25)}$ is equal to $\omega_{(0.15)}$ plus $\Delta\omega_{(0.2)}$, and $\delta_{(0.3)}$ is equal to $\delta_{(0.2)}$ plus $\omega_{(0.25)}$.

All subsequent step-by-step calculations are made by a continuation of this method. These steps are shown in detail by the sample calculations of appendix III for the generator of Figure 1.

Other quantities, such as generator terminal voltage and magnetizing current, may easily be obtained for each time interval by the usual vector calculations.

Inasmuch as each step of calculations depends upon the previous step, the accuracy at each step should be checked as far as possible.

Simplifications When T_{gf}' Is Large and H_{gt}' Is Small

When the ratio of the generator-field time constant, T_{gf}', to the generator equivalent inertia, H_g', is around 2.0 or greater, the generator-output power oscillations are small and may be neglected without appreciable error. Consequently, as the flux decays, the machine advances by just enough to hold constant output.

Therefore, the procedure here consists in determining e_g and e_s for each step as before, and then determining by trial-and-error process the angle δ which will produce the constant output. Although two or three trials may be necessary for each step, the number of steps to be calculated will be considerably less than required by the previously outlined method of step increments of velocity and velocity change, because much larger time intervals may be used.

Appendix II. Calculation Nomenclature and Formulas

Nomenclature

E_g = Generator voltage behind synchronous reactance x_{dg} (per-unit field current—saturation neglected).

e_g = Generator voltage corresponding to direct-axis flux (per-unit generator direct-axis flux).

x_{dg} = Generator direct-axis synchronous reactance.

x_{dg}' = Generator direct-axis transient reactance.

I = Generator output current.

δ = Angle between generator and system equivalent motor—electrical degrees.

P_g = Generator power output to system.

Q_g = Generator reactive kilovolt-amperes supplied to system and corresponding to voltage E_g and current I.

E_s = System equivalent-motor voltage behind synchronous reactance x_{ds} (per-unit field current—saturation neglected).

e_s = System equivalent-motor voltage corresponding to direct-axis flux (per-unit motor direct-axis flux).

x_{ds} = Direct-axis synchronous reactance of system equivalent motor plus system impedance between this motor and the generator.

x_{ds}' = Direct-axis transient reactance of system equivalent motor plus system impedance between this motor and the generator.

$x_{gs} = x_{dg} + x_{ds}$.

T_{gdo}' = Open-circuit time constant of generator—seconds.

T_{gf}' = Field-circuit time constant of generator during loss-of-field conditions—seconds.

T_{sf}' = Field-circuit time constant of system equivalent motor during loss-of-field conditions—seconds.

t = Time in seconds.

Δt = Time interval selected for step-by-step calculations—seconds.

H_g = Inertia of generator and turbine rotors—kilowatt seconds of generator and turbine rotors divided by the kilovolt-ampere base used in calculations.

H_s = Inertia of system equivalent motor—kilowatt-seconds of system equivalent motor divided by kilovolt-ampere base used in calculations.

H_g' = Equivalent inertia of generator and turbine rotors relative to an infinite system inertia—kilowatt-seconds divided by kilovolt-ampere base used in calculations.

K_g' = Generator acceleration constant corresponding to H_g'.

E_{si} = Initial value of E_s before generator loss of excitation.

P_{gi} = Initial value of P_g before loss of excitation.

f = System frequency—cycles per second.

$\delta_{(t)} = \delta$ at time t.

$E_{g(t)} = E_g$ at time t.

$E_{s(t)} = E_s$ at time t.

$e_{g(t)} = e_g$ at time t.

$e_{s(t)} = e_s$ at time t.

$\Delta e_{g(t)}$ = Change in e_g during time interval Δt between time t and time $(t+\Delta t)$.

$\Delta e_{s(t)}$ = Change in e_s during time interval Δt between time t and time $(t+\Delta t)$.

$P_{g(t)}$ = Generator power output at time t.

$Q_{g(t)} = Q_g$ at time t.

$\omega_{(t+1/2\Delta t)}$ = Average velocity of generator rotor above system speed during time interval Δt between time t and time $(t+\Delta t)$—electrical degrees per time interval Δt.

$\omega_{(t-1/2\Delta t)}$ = Average velocity of generator rotor above system speed during the time interval Δt between time $(t-\Delta t)$ and time t—electrical degrees per time interval Δt.

$\Delta\omega_{(t)}$ = Change in velocity of generator rotor from the average velocity $\omega_{(t-1/2\Delta t)}$ to the average velocity $\omega_{(t+1/2\Delta t)}$—electrical degrees per (time interval $\Delta t)^2$.

$E_{gf(t)}$ = Average generator per-unit field current corresponding to average exciter output voltage during time interval between time t and time $(t+\Delta t)$, divided by the generator field circuit resistance.

All quantities are per-unit quantities on the selected system kilovolt-ampere base unless otherwise indicated.

Field Investigation of the Characteristics of Lightning Currents Discharged by Arresters

I. W. GROSS
MEMBER AIEE

G. D. McCANN
ASSOCIATE AIEE

EDWARD BECK
MEMBER AIEE

Synopsis: Data have been obtained during the past three years on the magnitude and wave shape of lightning currents discharged by arresters in service on several solidly grounded neutral circuits of the American Gas and Electric Company system. Correlated measurements have been obtained with the cathode-ray oscillograph, the fulchronograph, and the surge-front recorder. The maximum arrester-phase leg current recorded in this investigation was 9,600 amperes with 70 per cent of the currents less than 1,000 amperes. The wave fronts of the low-magnitude currents were, in general, abrupt. For crest magnitudes of over 1,000 amperes they ranged from two to over 25 microseconds to crest. The maximum rate of rise recorded was 2,500 amperes per microsecond.

The components in all discharges were of relatively short duration, with times to half value averaging 25 microseconds and with no measurable durations in excess of 500 microseconds.

Of the 18 arrester-phase legs studied, all but one discharged at least once during the investigation. Nineteen of the 21 separate records of discharges in three-phase arrester banks had currents which, if arresters had not been installed, would have produced voltages in excess of the standard basic impulse level for the voltage class of the apparatus involved, so that failure of unprotected equipment might have occurred.

Purpose and Scope

THIS investigation was undertaken in 1939 to determine the lightning duty imposed on arresters in service. Factors that affect this are frequency of occurrence, magnitude, wave shape, and multiple character of the discharges. Five measuring stations were set up at different three-phase arrester locations, two in substations of The Ohio Power Company in Ohio, and three in substations of the Appalachian Electric Power Company in Virginia. One of the latter locations was moved during the course of the investigation so that in all, a total of six arrester banks was studied.

Description of System and Recording Installations

A summary of the pertinent characteristics of the substations at which the recording installations were made is given in Table I. They are located in regions where lightning was known to be frequent and at arrester banks where past experiences had indicated that a higher than average number of discharges was to be expected. The power sources feeding the circuits on which the study was made are solidly grounded.

The two recording stations on The Ohio Power Company system are at 33-kv delta-connected transformers. The installations on the Appalachian Electric Power company system are made in one similar 33-kv station; in two 12-kv stations, one with grounded-neutral and the other with delta-connected transformers; and in one 132-kv station with delta-connected transformers. The station grounds and earth resistivity are low at all of these locations.

Pictures and a schematic diagram of the recording equipment are shown in Figures 1 and 2. Each installation consists of a high-speed fulchronograph, and surge-crest ammeter links in each arrester phase lead together with a slow-speed fulchronograph, crest ammeter links, and a magnetic surge-front recorder in the common ground lead of the three arrester phases. In two cases (Twin City and Stone Creek), a cathode-ray oscillograph is also connected in the common lead. The cathode-ray oscillograph equipment was designed and built especially for the purpose of automatically recording lightning transients. It consists essentially of a glass-envelope hot-cathode oscillograph tube, the necessary electrical circuits, a special camera to photograph the trace produced by the transient on the fluorescent screen, and a current shunt. These recording instruments have been described in the literature.[1,2]

The field installations were serviced on an average of once a week during the lightning season, and usually after each lightning storm.

Paper 42-17, recommended by the AIEE committees on power transmission and distribution, and protective devices for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 12, 1941; made available for printing December 11, 1941.

I. W. GROSS is electrical research engineer with American Gas and Electric Service Corporation, New York, N. Y. G. D. MCCANN is transmission engineer, industry engineering department, and EDWARD BECK is section engineer, switchgear engineering department, both with Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

This investigation has been made possible by the co-operative efforts of the two companies with which the authors are associated, as well as a number of individuals. The authors acknowledge the contributions of the field organizations of The Ohio Power Company and the Appalachian Electric Power Company in installing and servicing the field installations, and of O. Ackermann of the Westinghouse Electric and Manufacturing Company for his assistance in the design and supervision of the cathode-ray oscillographs.

GENERATOR AND SYSTEM CONSTANTS

$x_{dg}=0.940$	$T_{gdo}'=6.26$ seconds
$x_{dg}'=0.241$	$T_{gf}'=0.975$ second (corresponding to field resistance of 0.138 ohm and external resistance of 0.747 ohm)
$x_{ds}=0.511$	$T_{sf}'=9\ 0$ seconds
$x_{ds}'=0.264$	$H_s=53.4$ seconds
$x_{gs}=1.451$	$H_g=7.7$ seconds
$\Delta t=0.1$ second	$H_g'=6.73$ seconds

Reactance—generator bus to generator terminals $=0.048$

All values are on machine rating 137,500 kva and 13,500 volts. Reactances are per unit.

Formulas

$$E_g=\frac{e_g-0.582e_s\cos\delta}{0.518-0.099(\cos\delta)^2}$$

$$E_s=\frac{e_s-0\ 329e_g\cos\delta}{0.830-0.159(\cos\delta)^2}$$

$$P_g+jQ_g=0.689E_gE_s\sin\delta+j(0.689E_g^2-0.689E_gE_s\cos\delta)$$

$$\Delta\omega_{(t)}=16.0(0.436-P_{g(t)})\text{ since }P_{gi}=0.436$$

$$\Delta e_{g(t)}=-0.103E_{g(t)}$$

$$\Delta e_{s(t)}=\frac{0.836-E_{s(t)}}{90}\text{ since }E_{si}=0.836$$

The values calculated with the preceding formulas are listed in Table II.

General Discussion of Records

Twenty-one separate sets of records have been obtained involving 49 single-phase arrester-discharge currents with a total of 88 individual components. Records were obtained at all six stations and their distribution is shown in the lower part of Table I and in the top curve of Figure 3. As shown in Figure 3, more discharges per arrester year were obtained than in other previously reported investigations. This is because the locations were chosen from past experience which indicated that they would yield more than the average number of records. The curves in this figure show considerable variation from each other. This is probably due to a number of factors including variance in lightning frequency, the number of arresters in multiple, and the type of line construction.

Of the 21 separate records, ten involved discharges in three phases, eight in two phases, and three in only one phase. Sixteen of the records showed only single-component discharges in each of the individual arrester phases. In the remaining five, which had multiple components in one or more phases, the number of components varied from two to 12. Of the 21 records, all but three had maximum crest magnitudes in the common lead which were substantially equal to the sum of the maximum crests in the individual phases.

In 12 of the records all of the components were entirely negative. Four records were entirely positive. For two records the components in two of the phases were entirely negative, while the components in the third phase were entirely positive. One record had nonoscillatory components of both polarities in the same phase. Two of the records had oscillatory components. Twenty-three of the 88 individual components, or 26 per cent, were initially positive.

Detailed Discussion of Particular Records

A few of the records which have been obtained are discussed in detail because of their special interest. In considering the fulchronograms, the limit of sensitivity of the fulchronograph should be borne in mind. Its lower range of current sensitivity is about 50 amperes. In addition, the wave shape of arrester-discharge currents with times to half value of less than about 20 microseconds will not be recorded. Therefore, in the case of currents of short time to half value or of short duration, the instrument will indicate that they were short but will not supply accurate information on the times involved. Attention is called to this because most of the components of discharge currents recorded in this investigation were of short duration.

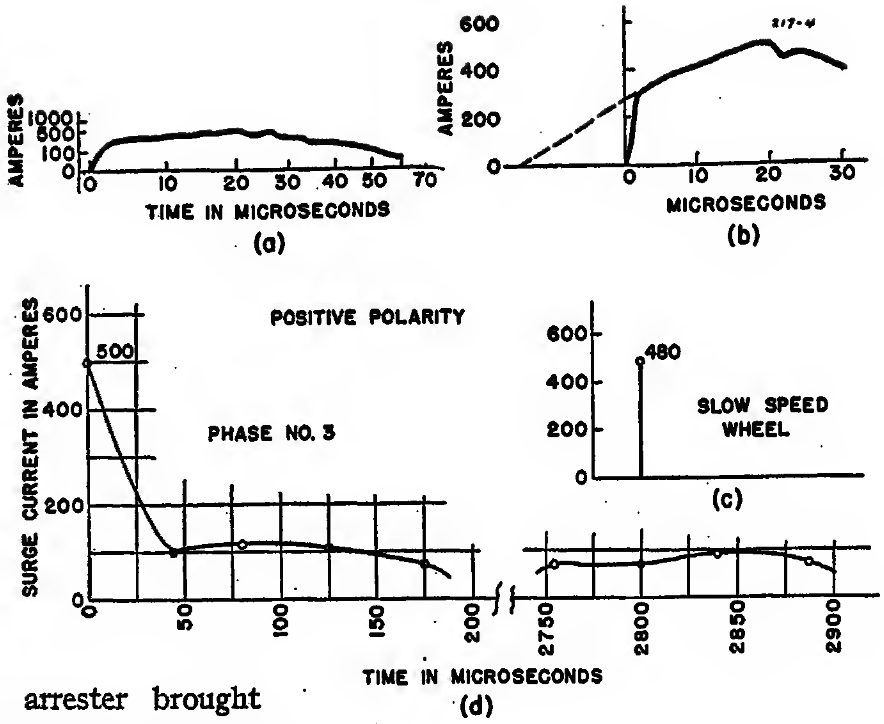

Figure 4. Record 71 obtained at the Twin City substation, May 8, 1941

(a) Cathode-ray oscillogram of current in common ground of lightning arrester

(b) Replot of oscillogram to a linear scale

(c) Slow-speed fulchronogram of current in common ground

(d) High-speed fulchronogram of current in phase 3

Record 71, Figure 4. This record represents the first case in which directly comparable simultaneous field records of current were obtained with the fulchronographs and the cathode-ray oscillograph. Since only one arrester phase discharged, the same current passed through one high-speed fulchronograph, the low-speed fulchronograph, and the cathode-ray oscillograph, permitting a direct comparison of their records.

The current rose abruptly in 2.5 microseconds to 250 amperes and reached its crest of 500 amperes in 20 microseconds. It decayed to half value in 33 microseconds. After decaying to 100 amperes in 45 microseconds, it persisted at about this value until it decayed below the recording range of the fulchronograph in 175 microseconds. In 2,750 microseconds it again rose to about 100 amperes and lasted to 2,900 microseconds. This second portion might either be power follow or lightning current.

The cathode-ray oscillogram of this record illustrates the effect of the arrester breakdown on the wave shape of the front of the discharge current. After the gap breaks down, there is a rapid rise of current through the arrester brought about by the change in the surge circuit. This rate of change, measured in the arrester circuit during the period of readjustment, is greater than that which would exist in the line surge if no arrester discharge had occurred. Thus, the wave front of the original surge is more nearly as shown by the broken line of Figure 4b.

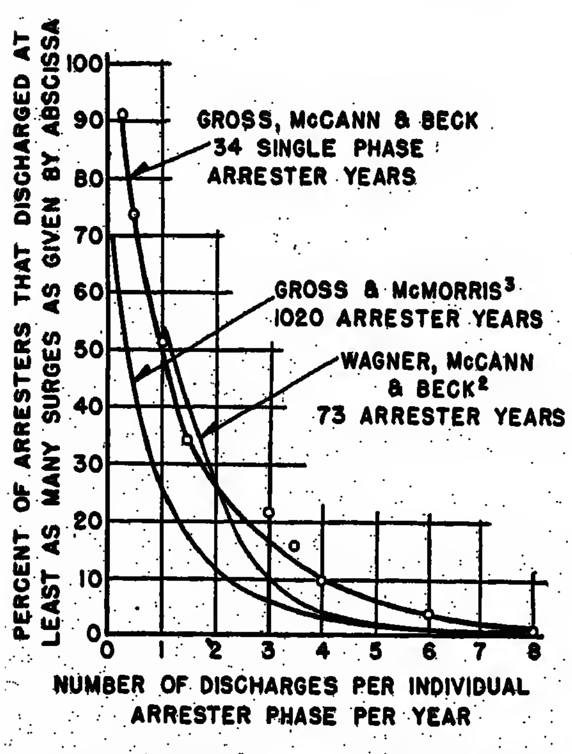

Figure 3. Weighted distribution of lightning discharges through individual arresters

Record 72, Figure 5. Only the cathode-ray oscillogram is shown for this record, since the duration is so short that only one link of each of the high-speed fulchronographs was magnetized. For this record, the surge-crest ammeter links, the slow-speed fulchronograph, and the cathode-ray oscillograph records indicate a crest magnitude of 1,000 amperes in the common ground lead. Surge-crest ammeter links and high-speed fulchronographs in the individual phase legs indicate currents totalling 550 amperes which is considerably less than the recorded neutral current. The reason for this is unknown and as pointed out previously, such a discrepancy has occurred in only a very few cases.

The neutral current has an abrupt front of less than one quarter of a microsecond and a time to half value of 8 microseconds. It decayed to zero in 32 microseconds and then rose to about 30 amperes after 66 microseconds.

Record 77, Figure 6. This record is of particular interest. It gives the first cathode-ray oscillograph record of a lightning-arrester discharge current of considerable magnitude. It shows in detail the entire duration of the discharge. In addition, it is substantiated by fulchronograph records in each of the three poles and the neutral of the arrester. It was obtained during the failure of a defective bushing in the station.

Because of its importance, the original oscillogram shown in Figure 6a has been replotted to linear co-ordinates in Figure 6b. The fulchronograms are plotted in Figure 6c.

An analysis of the record shows that

Table II. Tabulation of Data on Surge Fronts*

Phases Discharged	Record Number	Nominal System Kv	Crest Magnitude in Amperes Average of Instruments	Time to Crest in Microseconds: Cathode-Ray Oscillograph	Time to Crest in Microseconds: Surge-Front Recorder	Average Rate of Rise in Amperes Per Microsecond: Cathode-Ray Oscillograph	Average Rate of Rise in Amperes Per Microsecond: Surge-Front Recorder
3	92	33	−9,600		3.7		2,500
3	77	33	−6,500	3.5	4.4	1,850	1,480
2	87	33	−5,150		8.8		585
3	73	33	−3,650		6.6		555
2	91	132	−3,150		Over 25		Less 125
3	66	33	−2,000		8.3		240
3	55	33	−1,600		2		800

Of 11 additional records of surges with crest magnitudes less than 1,000 amperes, all had surge fronts of less than one microsecond as indicated by seven cathode-ray oscillograms and six surge-front recorded records, except the surge of record 71, Figure 4, which had an effective front of 2.5 microseconds.

* These measurements were made in the common ground lead of three-phase arrester banks.

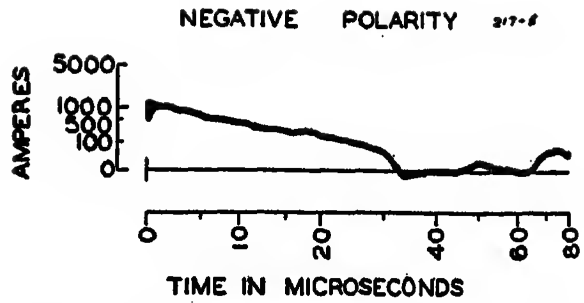

Figure 5. Cathode-ray oscillogram of record 72 obtained in common lead of arrester bank at the Twin City substation, May 22, 1941

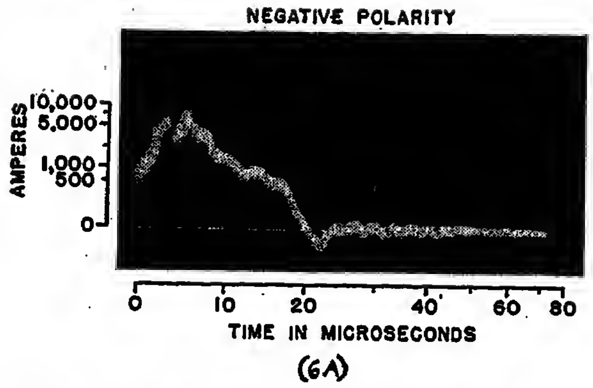
The fulchronographs and surge-crest ammeter links both recorded single negative crest magnitudes of zero amperes in phase 1, 50 amperes in phase 2, 500 amperes in phase 3, and 1,000 amperes in the common ground. The high-speed fulchronographs showed no measurable duration



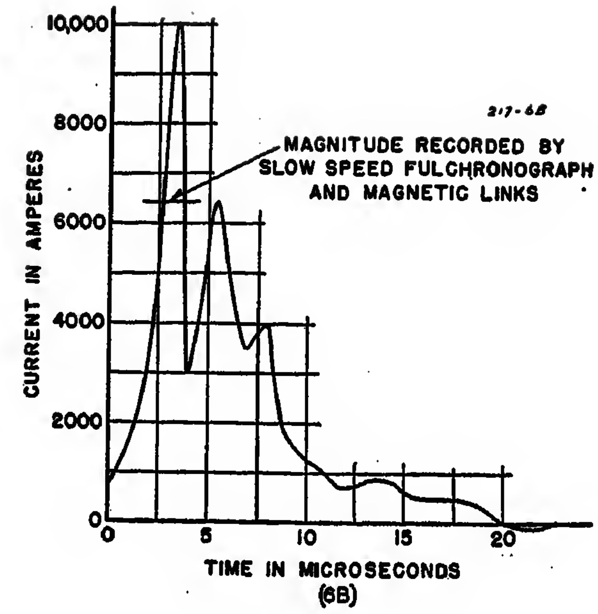


Figure 6. Record 77 obtained at the Stone Creek substation, June 12, 1941

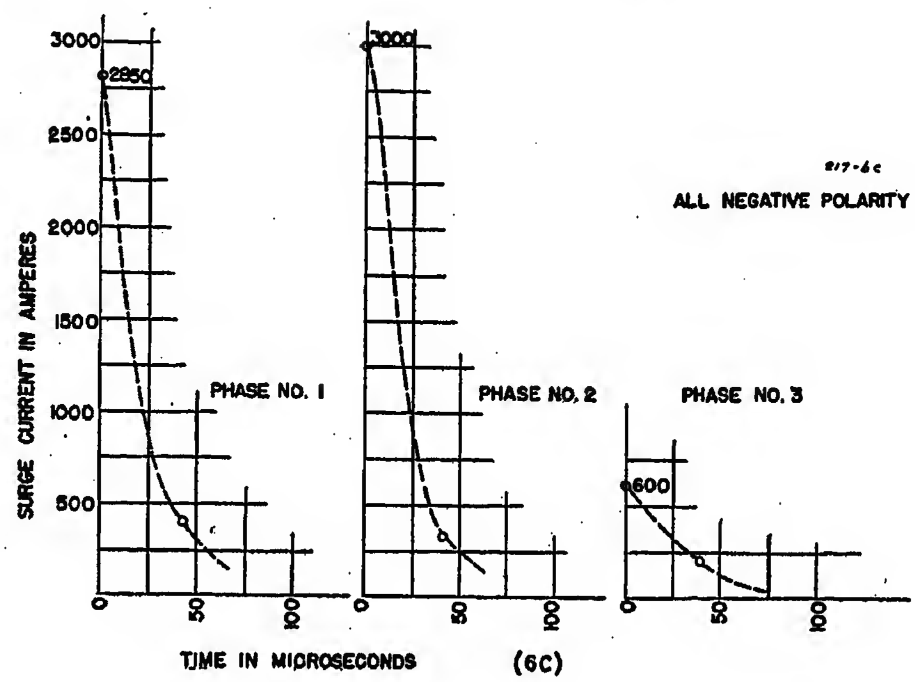
6A Cathode-ray oscillogram of current in common ground lead of arrester bank

6B Replot of oscillogram to a linear scale

6C High-speed fulchronograms of current in each arrester phase

Slow-speed fulchronograph recorded a negative crest of 6,500 amperes and the same crest magnitudes as recorded by the fulchronographs were recorded by the surge-crest ammeter links

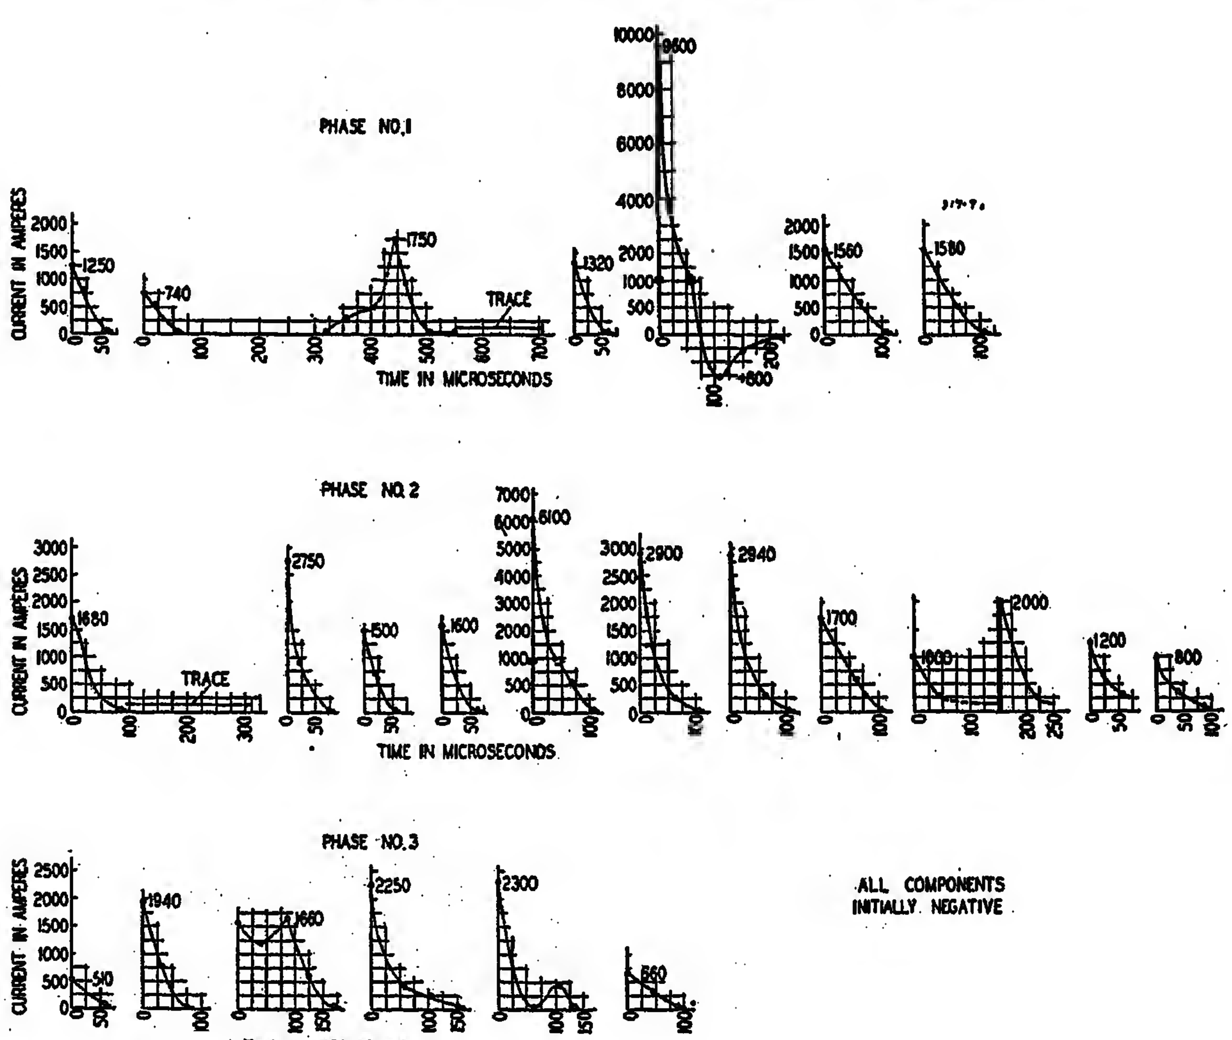


the three-phase legs of the arrester discharged simultaneously for the sum of the crest currents recorded by the fulchronographs and the surge-crest ammeter links in each phase equals the crest magnitude of 6,500 amperes recorded by the fulchronograph and surge-crest ammeter links in the common ground lead. The cathode-ray oscillogram showed a peak current of 10,000 amperes with a high oscillation believed to have been caused by the bushing failure. Its mean value of 6,500 amperes is in complete agreement with the records of the fulchronographs and magnetic links. The shape of the tail of the wave was probably affected by the bushing failure and, therefore, should not be taken as indicative of the normal arrester discharge.

Record 94, Figure 7. This record consists only of the high-speed fulchronograms in the individual phase legs of the arrester, as the slow-speed fulchronograph and the oscillograph in the common ground lead were not in operation. The record is of interest, because of the considerable number of components in all phases, 7 in phase 1, 12 in phase 2, and 6 or 7 in phase 3. The third component in phase 3 may actually be two superimposed on each other. The crest currents ranged from a maximum of 9,600 amperes, the highest recorded in this investigation, to a minimum of 510 amperes. The maximum measurable duration of any component was 400 microseconds. All of the components were totally negative, with the exception of the 9,600 ampere component which was initially negative followed by a positive portion with a crest of 800 amperes.

Record 96, Figure 8. This figure shows cathode-ray oscillograms of current in the common ground lead. The duration as measurable on the fulchronograms was too short to warrant plotting,

Figure 7 (below). High-speed fulchronograms of the current in each lightning arrester phase for record 94 obtained July 18, 1941 at the Twin City substation



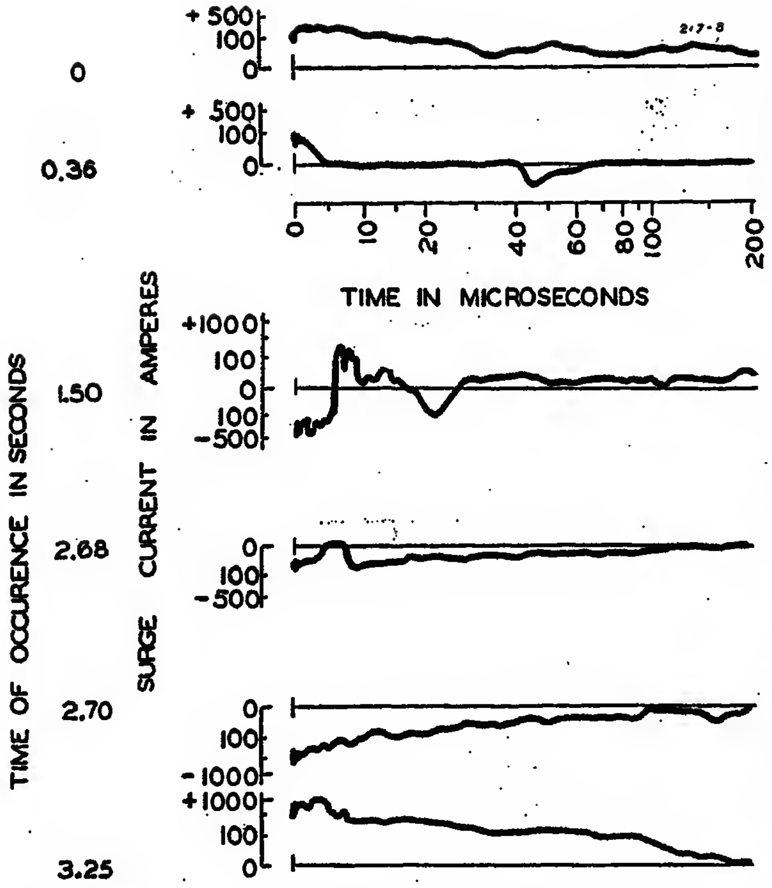


Figure 8 (left). Cathode-ray oscillograms of record 96 obtained in common ground lead of arrester bank at the Stone Creek substation, July 28, 1941

The fulchronographs recorded components of no measurable duration and the following crest magnitudes:

Phase 1	+150	+trace	
	−100	−200	+600
Phase 2	No current		
Phase 3	+150	+trace	
	−100	−300	+450
Neutral	+300	+trace	
	−100	−500	+1000

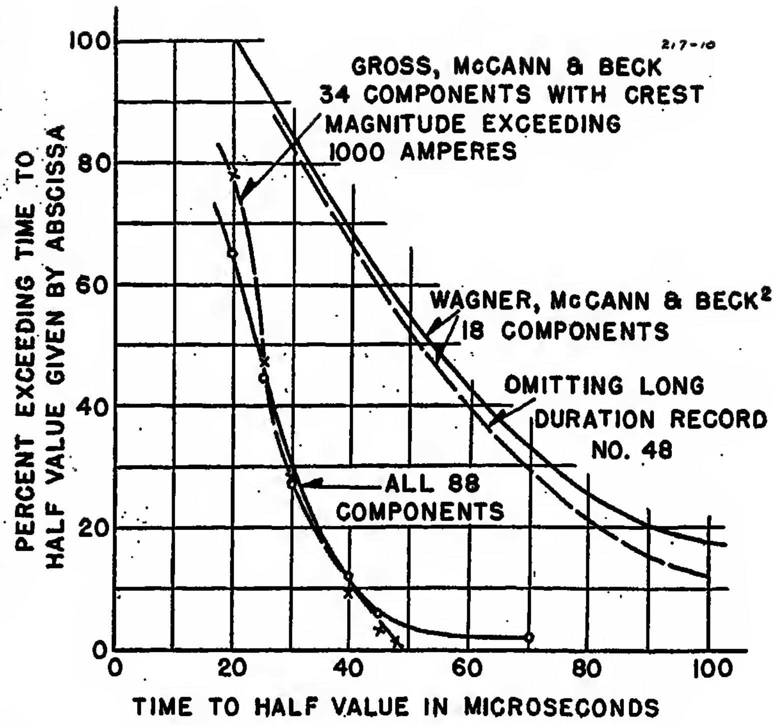

Figure 10. Percentage distribution-curves of times to half value of individual components of lightning currents discharged by arresters

but the recorded crest currents are tabulated in the caption of the figure. The arrester phase leg currents were of low magnitude and short duration, as indicated by the fulchronograph records and the oscillograms. The fronts of all components are abrupt.

Analysis and Discussion of Data

The records obtained have yielded considerable information on the magnitudes and wave shapes of currents discharged by arresters in service. Data on wave fronts are given in Table II and Figures 9, 10, and 11 show the distribution of crest currents, times to half value, and measurable durations of individual components. Comparisons are made with similar data published previously, since, as more and more data accumulate and are integrated, existing curves may be modified by the added data.

Crest Currents. Figure 9 shows the distribution of the crest magnitudes of all 88 components recorded in this investigation. For comparison with data secured in other investigations made with the surge-crest ammeter link only, a curve for the crests of the maximum components in each of the 49 arrester discharges is also shown. There is substantial agreement between this curve and the curve published by Gross and McMorris.[3] The deviations between the curves in the region of the low currents are probably the result of differences in instrument sensitivity. It is of interest that the percentage distribution of the crest magnitudes of the individual components differs only slightly from that of the maximum crest current of each discharge.

The maximum current so far recorded in this investigation is 9,600 amperes, obtained in record 94, Figure 7. Currents considerably higher than this value do occur infrequently in service as reported by other investigators; therefore, the upper limit of current in Figure 9 must be considered with reservations for the time being.

Wave Fronts. Table II lists the data obtained on wave fronts by means of the magnetic surge-front recorder and the cathode-ray oscillograph. They indicate that the low current discharges have abrupt fronts, usually less than a microsecond. This is to be expected, since for a short period following the sudden breakdown of the arrester gap, the current rises quickly as discussed for record 71, Figure 4. The low current discharges thus give little information on the fronts of the surges occurring on the line. For currents in excess of 1,000 amperes the fronts vary between 2 and 25 microseconds with average rates of rise of from less than 125 to 2,500 amperes per microsecond. The highest rate of rise reported by Wagner, McCann, and Beck[2] is 3,200 amperes per microsecond. Considering the number of measurements (29) of wave front reported in these two papers, the percentage of arrester discharges hav-

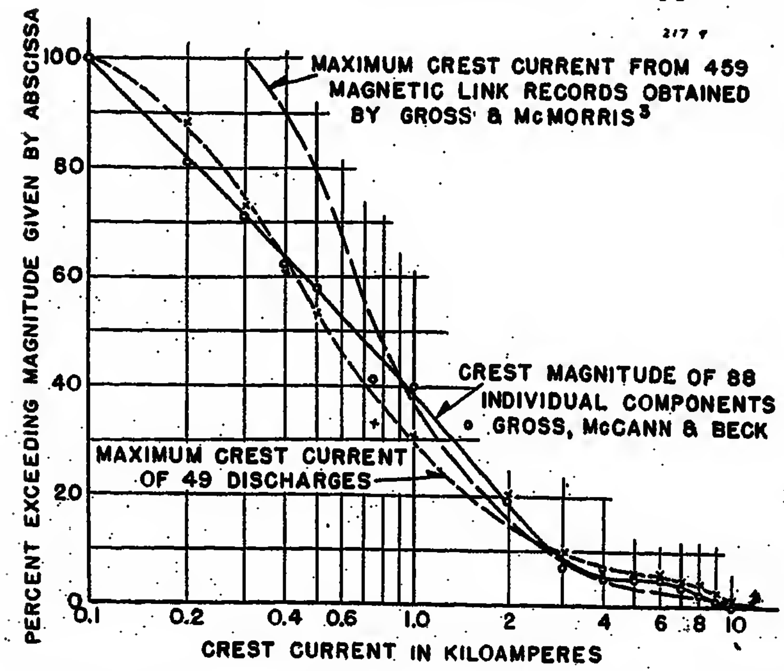

Figure 9 (left). Percentage distribution curves of the crest magnitudes of lightning currents discharged by arresters

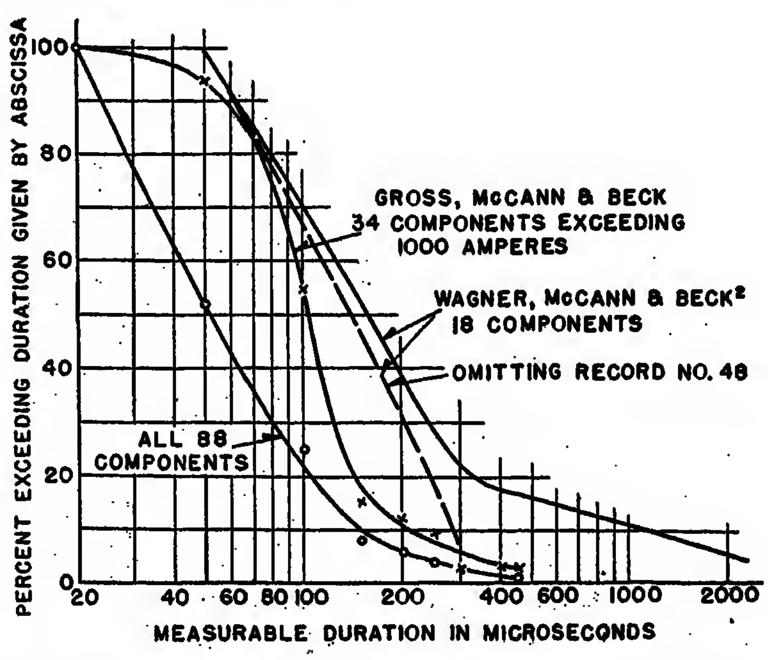

Figure 11 (right). Percentage distribution curves of the measurable duration of individual components of arrester discharges

ing rates of rise greater than 3,200 amperes per microsecond will be small.

Times to Half Value. Figure 10 shows the percentage distribution of times to half value plotted on two bases:

1. Considering all 88 components.
2. Considering only the 34 components that exceeded 1,000 amperes.

This was done because the time to half value of the small magnitude components might be influenced by the fulchronograph's lower limit of sensitivity. However, both curves are in good agreement but indicate considerably shorter times to half value than the curves published by Wagner, McCann, and Beck covering measurements on a number of systems prior to 1941. It should be noted that the Wagner, McCann, and Beck curves include only the few records secured on the American Gas and Electric Company system before 1941.

Measurable Duration. Percentage distribution curves of the measurable duration of arrester-discharge currents are given in Figure 11. This duration is the time required for the current in a component to decay below about 50 amperes. Since the measurable duration should be greatly influenced by the crest magnitude of the surge, the data have been plotted both for all 88 components and for the 34 exceeding 1,000 amperes. As would be expected, longer durations are recorded for the higher magnitude discharges. The longest duration obtained in this investigation is below 500 microseconds. This corresponds to the results reported by Wagner, McCann, and Beck if the long-duration surge obtained by them on an ungrounded system is omitted. This was expected since the present study has been conducted entirely on solidly grounded neutral systems. As has been previously pointed out,[2,4] the windings of grounded-neutral transformer banks providing a path to ground in parallel with the arrester, are more likely to absorb the low-magnitude, long-duration portions of a surge than are the arresters.

Arrester Protection. The number of arrester discharges which were associated with surges that would have produced dangerous potentials in the absence of the arresters have been estimated and listed in Table I. If one or more arrester current components in one or more phases of any discharge had a crest magnitude which indicated that the incoming surge on the line would have produced a voltage at the station in excess of the standard basic impulse level, with no arresters present, it was counted as one possible failure. Nineteen of the total of 21 records had currents above the critical value. At Twin City, Stone Creek, and Rocky Mount, all discharges were in the danger zone. At every station, at least one surge appeared that might have caused damage.

Synopsis: The intensive manufacturing activity accompanying the present defense program has stimulated interest in industrial electric power distribution. The ultimate objective is one of effectively satisfying electric power requirements with reasonable first cost consistent with a fair standard of safety and service reliability.

This paper presents the fundamental aspects of industrial power distribution, with particular reference to low-voltage power supply to distributed electrical machinery, and compares various basic system designs, including large concentrated substations and distributed load-center substations with radial and secondary network modifications, as to safety, service reliability, simplicity, and so on, relative to estimated installed cost. The comparative analysis comprehends the complete electrical system between high-voltage supply bus and utilization terminal of low-voltage feeders. The ideal size of unit substation as influenced by operating voltage and load density is covered.

Principles of system design here disclosed are applicable not only to new plant construction but to expansion or modernization of existing plants as well.

THE intent of this paper is to present the comparative merits of the several typical forms of industrial plant electrical distribution systems presented with a view to the general adoption of that system which will, in the majority of cases, meet the overall requirements most effectively.

General Considerations

The characteristic features on which the evaluation of merit depend are:

First cost.
Safety.
Service reliability.
Simplicity of operation.
Voltage regulation.
Efficiency.
Maintenance cost.
Flexibility in meeting load changes.

Paper 42-21, recommended by the AIEE committee on industrial power applications for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 14, 1941; made available for printing December 8, 1941.

D. L. Beeman and R. H. Kaufmann are both of the industrial engineering department, General Electric Company, Schenectady, N. Y.

Only the *over-all* system performance is significant. This requires simultaneous recognition of all elements between the primary power source and the ultimate utilization machines. These elements are: primary feeder switching and transmission circuits, step-down transformers together with their associated high-voltage and low-voltage switching equipment, low-voltage circuits to secondary distribution centers, secondary distribution panels and branch circuits to individual loads.

Primary Operating Voltage

The primary operating voltage will, in general, be fixed by considerations outside the general factory requirements. The presence of a considerable number of large motors may favor the use of 2,400 or 4,160-volt primary systems. It will otherwise be generally preferable to adopt the incoming utility-system voltage so long as it is not in excess of 15 kv. Common system voltages are 4,160 and 13,200 volts.

Secondary Operating Voltage

The great majority of manufacturing plants with which we are concerned incorporate machine tools powered by relatively small motors, usually not in excess of 25 horsepower. Except for very small fractional horsepower units, the adoption of a nominal 440-volt level is to be preferred to lower voltages. Advantage can thus be taken of substantial reductions in secondary switching cost and size together with corresponding reductions in secondary cable cost.

The use of four-wire system suitable for 440-volt motors offers a promising means of supplying both power and fluorescent lighting from a common system retaining the advantages of 440-volt operation.

Incandescent lighting, while of ever lessening importance for factory lighting, may be encountered, and is suited to 120-volt operation. This operating voltage may be derived from 440-volt system by transformers, or by separate lighting transformers independent of the power system.

A load composed largely of incandescent lights and small motors unsuited to 440-volt service would favor the use of a 208Y/120-volt system.

Load Density

The load densities commonly encountered, including both power and lighting, are in the range of about 8 to 25 volt-amperes per square foot.

Lighting load levels for up-to-date illumination intensity may be expected to be 4 to 6 volt-amperes per square foot for incandescent lamps and 2 to 3 volt-amperes per square foot for high power-factor fluorescent lamps.

Power-load densities will be subject to greater variation ranging between about 6 and 20 volt-amperes per square foot. Areas devoted largely to assembly will show the lower load levels while intensive manufacturing areas will show the higher levels.

Accumulated records indicate a fairly limited load-density range in the order of 8 to 15 volt-amperes per square foot for existing manufacturing plants, and the higher contemplated values apply to proposed new plants. Plants of higher load density are known, but this fact does not affect the following discussion.

Specific System Comparison

To avoid abstract comparisons, a representative distributed load block has been selected totaling 3,600 to 3,750 kva with a load density of 10 volt-amperes per square foot and suited to 440-volt utilization. Individual control of low-voltage radial feeders, averaging 150 kva each, is to be provided in all cases. The primary service is considered to be 4,160-volt, three-phase, 60-cycle, with a short-circuit interrupting requirement of 150,000 kva.

Evaluations of comparative installed cost includes all electrical equipment between the main high-voltage power supply bus and the terminals of the 150 kva low-voltage feeders.

The typical forms of distribution systems have been classified as follows:

A. Single large substation—radial low-voltage feeders.

B. Distributed load-center system.

1. Simple radial (Figure 4).
2. Primary selective (Figure 5).
3. Secondary selective (Figure 7).
4. Secondary network (Figure 8).

Variations and combinations of these systems are used, but this does not alter the basic data presented here.

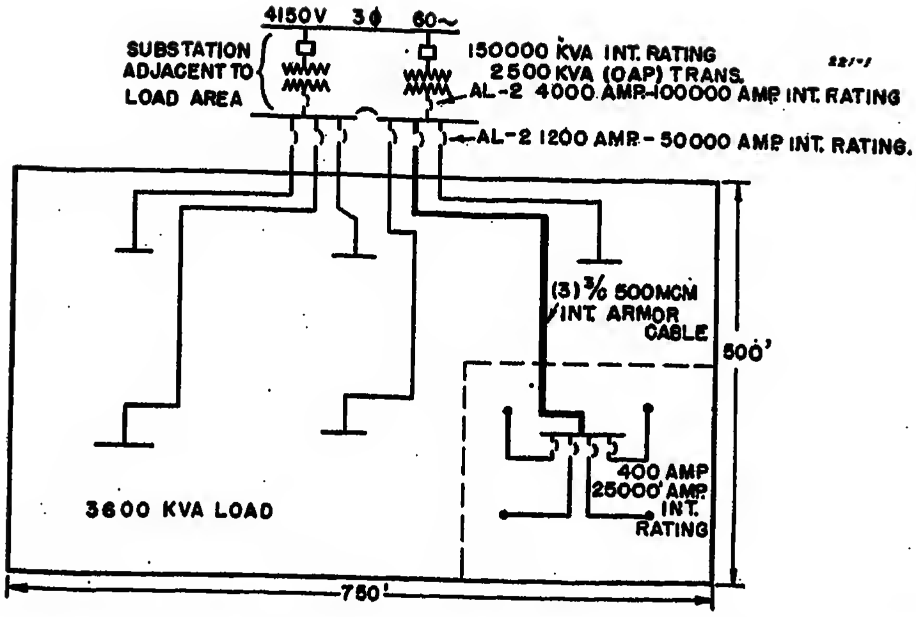

Figure 1. Schematic diagram of conventional distribution system

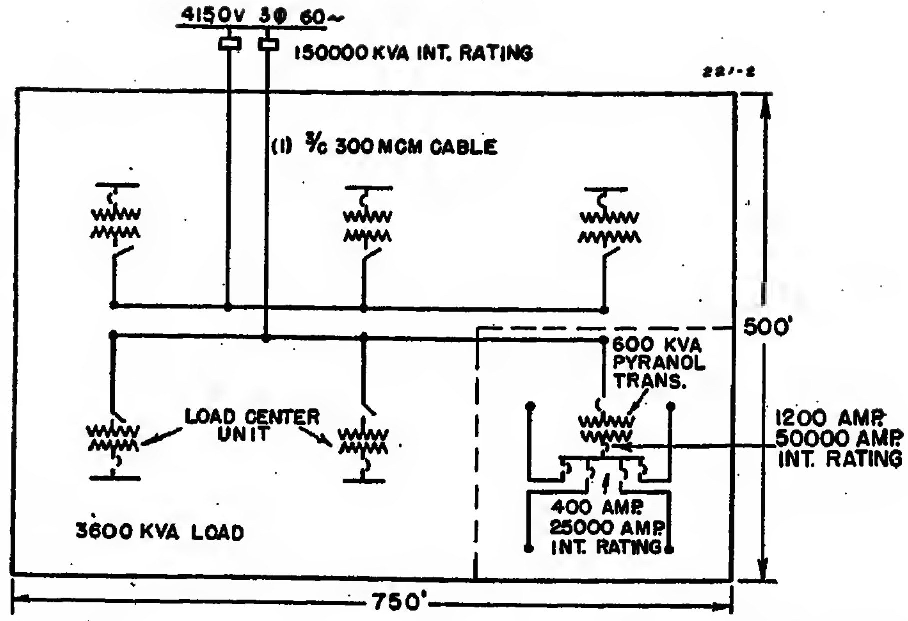

Figure 2. Schematic diagram of load-center distribution system

To simplify the text and aid in clarifying the interpretation of results, the system comparative study has been presented in two sections:

1. A comparison of the single large substation versus the distributed load-center system.

2. Comparison of the several forms of load-center distribution.

I. Single Large Substation Versus Distributed Load-Center System

In the past it has been common practice to distribute power to a relatively large factory area at utilization voltage from a single step-down substation accommodating several thousand kilovolt-amperes. This will be referred to as the conventional method, a typical circuit diagram of which is illustrated in Figure 1.

The modern load-center distribution method incorporates distributed step-down stations of small capacity (600–1,000 kva for 440-volt operation and 300–600 kva for 208Y/120- or 220-volt operation) from which low-voltage power is distributed to the immediately surrounding area as shown in Figure 2. A *load-center unit* is defined as an integrated step-down station consolidating step-down transformer, high-voltage switching unit, and low-voltage switching equipment, as typified by the illustration in Figure 3.

Application of the distributed load-center system not only allows a substantial reduction in total system investment cost, but also provides numerous other advantages.

Cost

The distributed load-center system shows a lower installed cost than the conventional system because:

1. Power is transmitted directly to the utilization area at high voltage. This materially reduces cable investment cost and total I^2R losses.

2. The cost of low-voltage switching equipment is materially less than for the conventional method because of lower short-circuit currents associated with the smaller substations.

Although transformer cost per kilovolt-ampere diminishes with increasing rating, this influence is far overshadowed by the cost reductions enumerated under 1 and 2 for ratings of 600–1,000 kva at 440 volts and 300–600 kva at 220 volts.

For example, the installed cost of these two systems, based on the reference load block of 3,750 kva, would be about $71,000 for the distributed load-center system, Figure 2, compared with about $103,000 for the large single substation type Figure 1.

Reductions in secondary cable and secondary switching-equipment costs for the distributed load-center system overshadow the increase in transformer cost. The necessity of simultaneous recognition of all system parts for determining the lowest *over-all* first cost is evident.

System Planning and Financing

The use of small load-center substations permits electrical capacity to be added in small increments when and where needed; thus large capital layouts are not required, making it easier to finance plant extension. This eliminates the necessity for involved planning; hence, reduces engineering costs and errors. On the other hand, large substations require involved forecasting of location and magnitude of loads and high initial investment, which is not completely put to work until the anticipated load is reached. If future developments do not permit utilizing the capacity of the large substation as planned, then the initial investment is not utilized efficiently or effectively.

A spare transformer for the small load-center unit represents less idle capital than the larger spare unit for the large station.

Installation Considerations

The small substations compared with large ones offer many advantages from the standpoint of handling and installation. For example:

1. No expensive enclosures or foundations are required.

2. The small self-contained metal-enclosed load-center unit can be located within the working area close to the center of the particular load area being served, while the large substation must generally be located at one side of the working area because of size and weight of component parts to be handled.

3. They can be moved more easily from one location to another to cope with changes in electrical demands accompanying changes in manufacturing technique.

4. In the event of a failure, service can be restored more quickly because less time and equipment is required to move the small units. The change can usually be made with equipment and personnel normally available around the average factory.

These advantages are only fully realized with completely metal-enclosed unit-type substations as shown in Figure 2.

Voltage Regulation

Because of the shorter secondary runs in load-center distribution, voltage drop and light flicker are less. This improves the performance of motors and lamps, and hence facilitates more and better production.

System Flexibility

Load-center distribution is ideally adapted to industrial plants, because it may be used in various circuit arrangements to meet varying degrees of service continuity required by manufacturing processes, and because small units are

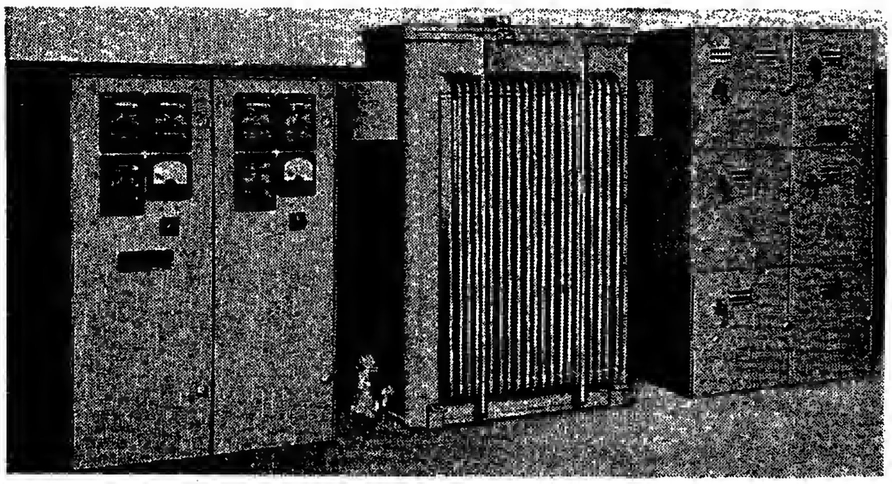

Figure 3. Typical form of load-center unit substation

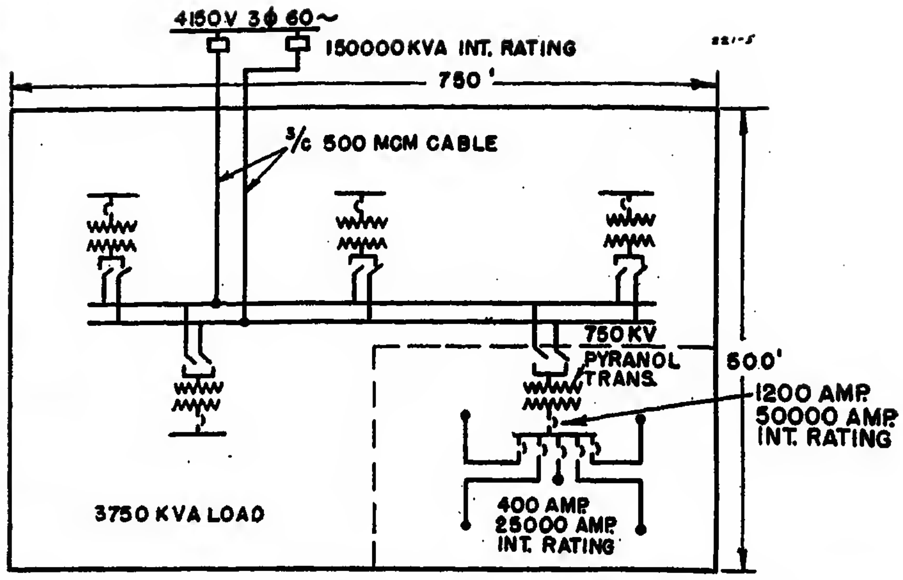

Figure 5. Schematic diagram of primary-selective-circuit arrangement

used, variation may be adapted within small factories.

This comparison indicates the load-center distribution system as being the most desirable for the average industrial plants. The single large substation design is not only more costly, but is deficient in other important respects, such as electrical operating efficiency, voltage regulation, greater initial engineering and planning, higher financing cost, and less flexibility as to future expansion or extensions.

Subsequent analysis of variations in system arrangement will, therefore, be limited to the distributed load-center design.

II. Load-Center-System Circuit Arrangements

The principal reason for considering variations in circuit arrangements is that of service reliability. The various arrangements may be classified into four groups typified by forms 1, 2, 3 and 4, which provide progressively increased service reliability and may be individually characterized as follows:

(All percentage cost figures are based on the typical example previously defined.)

Type 1—Simple Radial (*See Figure 4*)

This arrangement represents the simplest form of load-center distribution and provides a single direct electrical channel extending to each low-voltage load area. All system elements are considered to be operated at rated capacity.

The lowest possible *installed cost* is obtained due to simplicity of the arrangement and complete absence of secondary power-supply duplication, together with selection of the optimum size of load-center unit. (See appendix for further discussion.)

For cost comparison, this arrangement will be arbitrarily assigned a value of 100 per cent.

The inherent simplicity together with circuit breakers of adequate interrupting capacity results in a high order of safety. The load-center unit-substation primary disconnecting switches are for isolating a load-center unit only when completely deenergized.

All load to a particular area is always delivered by way of a single well-defined route which makes for simplicity in operation.

Voltage regulation is only slightly inferior to the best circuit arrangement considered, the difference being due to normally operating all transformers and cable at full rated capacity.

Service reliability of this arrangement is not the best, for a failure of the primary cable or its associated junctions interrupts power flow to the entire load block pending repair or installation of a temporary high-voltage circuit in place of the faulty section. A failure of a load-center transformer or its associated connections results in an interruption of power to that local area pending repair or replacement of the faulty unit. To deenergize one element for inspection or maintenance (that is, primary feeder breaker, load-center transformer or high-voltage disconnect switch) likewise demands interruption of power flow.

In the great majority of applications, a higher degree of service reliability will be desired and warranted.

Type 2—Primary Selective (*See Figure 5*)

As will be observed from the figure, this circuit arrangement is distinguished by the use of duplicate primary high-voltage feeders, either of which is capable of handling the entire load block in combination with a high-voltage transfer means at each load center.

Under normal operating conditions, approximately equal numbers of load-center unit substations are fed from each primary cable. While operating normally in this condition, operating characteristics are practically the same as the type 1.

The presence of the primary transfer means makes it possible to reestablish service to all load centers with one primary feeder deenergized.

A failure of one primary cable would interrupt service to those load centers which were being fed from this circuit. Service can be restored by changing the position of the transfer means at the respective load-center unit substations. The duration of the outage will depend on the time required to locate the system operator who is authorized to operate the transfer means and the time consumed in visiting those stations at which power interruption occurred.

For maintenance or inspection of pri-

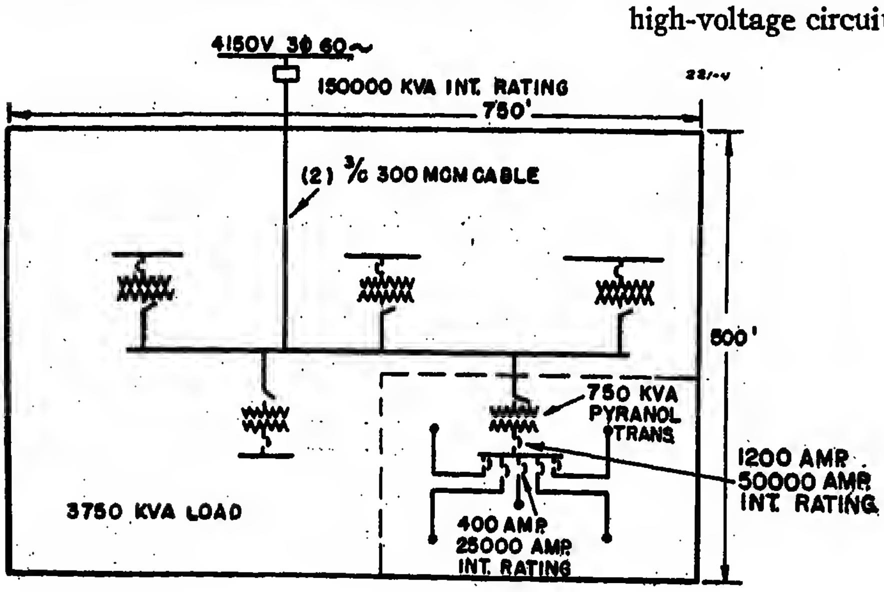

Figure 4. Schematic diagram of simple radial-circuit arrangement

mary circuit equipment, only a short interruption is occasioned since load centers are individually transferred before deenergizing the primary feeder.

It is important to note that, following reestablishment of voltage on a primary feeder, load-center units should again be returned to their normal feeder, which will account for another service interruption of short duration.

The use of a *primary loop circuit* as illustrated in Figure 6 constitutes a variation of the primary selective circuit arrangements. Unless automatic sectionalizing circuit breakers are incorporated, a primary circuit fault results in an extended interruption to the entire load, no part of which can be reenergized until the circuit has been sectionalized to exclude the faulty section. The chief advantages of the loop circuit are:

1. The ability to combine feeder and tie-circuit functions when primary power-supply stations are located on opposite sides of the plant.

2. The ability to isolate a particular load center in the event that fire or explosion should damage both primary cables at one location.

3. Primary circuit loading is inherently equalized with both primary switches at each load center closed as they normally would be.

The *installed cost* is increased due to additional primary switching equipment, high-voltage cable, and the use of primary transfer means on all load-center unit substations. The cost of this arrangement, relative to the cost of the simple radial becomes about 130 per cent.

For a primary circuit-interrupting requirement not exceeding 50,000 kva at circuit voltages below five kilovolts, metal-clad circuit-breaker transfer means, including a two-position structure with one circuit breaker, can be used without increasing the over-all cost level by more than approximately five per cent, as compared with disconnecting switches as the transfer means.

Safety is impaired when the primary transfer means is disconnect switches. Although interlocked to prevent operation except when low-voltage breakers are open, hazards nevertheless exist. The presence of a transformer turn-to-turn coil failures may allow the flow of substantial primary current irrespective of low-voltage breaker position. A major electrical fault at a transformer or its associated primary connections, which produces a primary circuit trip-out, may lead to serious consequences since normal routine procedure provides for transferring all deenergized load-center units to

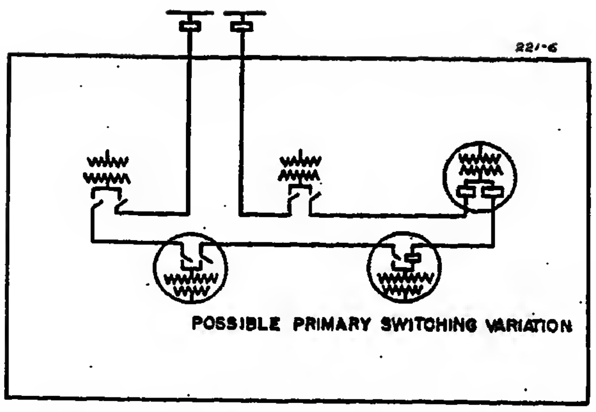

Figure 6. Schematic diagram of primary-selective-circuit arrangements with loop primary feeder

healthy feeders. When the faulty transformer is so transferred, the faulty circuit is *closed* on the healthy feeder by means of the transfer disconnect switch. Of lesser importance but nevertheless disturbing is the fact that a complete shutdown of both primary feeders results, and much confusion may easily exist before service is reestablished.

Circuit breakers adequate for high-voltage system short-circuit duty should be considered in all cases, as they eliminate the shortcomings of disconnect switches.

Service reliability is much better than that provided by this circuit arrangement except under unusual circumstances as covered under the topic of safety. It is to be expected that primary circuit failures will be far more numerous than transformer failures, many of which will be accounted for by imperfect cable tap connections or termination.

The service interruption of more or less indeterminate duration following a primary circuit outage is of course objectionable but may, in many instances, be tolerated.

The fact that both primary circuits are usually brought into close proximity at every unit substation represents a distinct hazard to service continuity.

The presence of the transfer means which must be manipulated on a number of load centers for every transfer from normal to emergency operation and again in restoring normal conditions, makes this circuit arrangement slightly more complicated to operate than the simple radial circuit arrangement.

Type 3—Secondary Selective *(See Figure 7)*

The secondary selective circuit arrangement differs from those previously described in that the load center incorporates complementary branches, each permanently associated with a particular high-voltage feeder. Transfer from normal to emergency operation is accomplished by means of a low-voltage tie breaker between the two complementary sections. This extends the duplication of supply to the load-center low-voltage bus and thus provides for continued service with either a transformer or a primary feeder out of service.

Under normal conditions the tie breaker is open and both transformer breakers are closed, in which state the system exhibits all the elements of simplicity to be found in the simple radial system.

For emergency operation, the transformer low-voltage breaker associated with the channel which has been or is to be deenergized is opened and the low-voltage tie breaker closed. Loading levels have been selected such that a transformer is subjected to not more than 125 percent rating during emergency operation.

The *installed cost* is increased over that of the primary selective arrangement largely because of reduced normal loading level on transformers. The relative cost level is between 145 and 150 per cent of the cost of the simple radial circuit. However, the reduced normal transformer loading provides additional benefits, aside from service reliability in the form of lower losses, lower transformer temperature and consequent increased life, and better voltage regulation. The cost per kva can be reduced by normally operating the transformers at a load more nearly equal to rating, depending on load curtailment to avoid excessive transformer load during emergency operation.

The same order of *safety* as associated with the simple radial circuits is retained. All transfer switching from normal to emergency conditions and vice versa is performed on full interrupting-capacity low-voltage air circuit breakers. The possibility of producing a complete primary system shutdown by transferring a fault to the healthy feeder is eliminated. The individual transformer primary disconnect switch is used only for isolating purposes and on this basis may be considered to represent only a slight hazard.

In respect to *service reliability*, this circuit arrangement excels the primary-selective circuit. Continued operation is insured with a transformer as well as a primary cable out of service. For very little increased cost, provision can be made for automatic transfer to emergency operation through electrical operation of the tie breaker, by which means restoration of voltage may be accomplished within an interval of about one to two seconds. The normal operation of transformers at considerably less than rating allows an unusual temporary load demand in any area to be met without distress.

Simplicity of operation comparable with that of the simple radial circuits is obtained. The low-voltage tie breaker between complementary bus sections represents the only feature which modifies the operating procedure.

Voltage regulation is reduced under normal operating conditions as a result of reduced transformer loading. Voltage regulation under emergency operating conditions is only slightly inferior to that of the simple radial circuits as a result of transformer operation of 125 per cent rating.

Type 4—Secondary Network (*See Figure 8*)

The secondary network system is distinguished from others in that continuously connected duplicate sources are provided to each low-voltage load-center bus. The prime source is represented by a transformer tie to the primary system while low-voltage tie circuits interconnected with one or more other prime sources constitute the emergency source. Two or more primary feeders are used, and the emergency source for one load center is derived from prime sources associated with a different primary feeder.

Provision is made for automatically clearing any particular prime source or tie circuit which becomes involved in fault without interrupting other source connections. This requires a network protector in the secondary of each transformer. A network protector is an automatic circuit breaker equipped with directional relays. The relays trip the protector whenever power flows from the low-voltage to the high-voltage terminals of the transformer. It does not trip for power flow in the opposite direction. Automatic reclosing is provided.

The required reserve capacity in primary cables and transformers is not greatly different than that for the secondary selective circuits. Loss of voltage on one primary feeder immediately results in automatic transfer of the load previously carried by that feeder to adjacent load centers by way of the interconnecting low-voltage tie circuits. Reserve transformer capacity is needed to avoid transformer loading levels in excess of 125 per cent of rating. Two primary feeders, to which the load centers are alternatively connected, would require that the normal load level per transformer be held to 63 per cent of rating. The required transformer capacity may be reduced by about 30 per cent by the use of three or more primary feeders. This can also be accomplished in two-feeder systems by the introduction of primary transfer switches in combination with suitable means for insuring prompt transfer of load-center units to healthy feeders following loss of voltage on one feeder. Transfer devices offer no economic advantage over three-feeder systems, hence are not considered because of the hazard of transfer switches.

It will be immediately apparent that the introduction of permanently connected emergency tie circuits will increase the low-voltage short-circuit current level unless the size of load-center units is simultaneously reduced. Where a number of load-center units are interconnected on the low-voltage side, careful design and specification of tie circuit impedance will be necessary to realize the most favorable economic balance. It will quite often be necessary to insert reactors in the tie circuits to obtain the desired results. The same care in system design is required in incorporating one or more additional load-center units in the network at a future date as dictated by future load conditions.

The *installed cost* of the secondary network referred to the simple radial type will be in the range of 175 to 200 per cent.

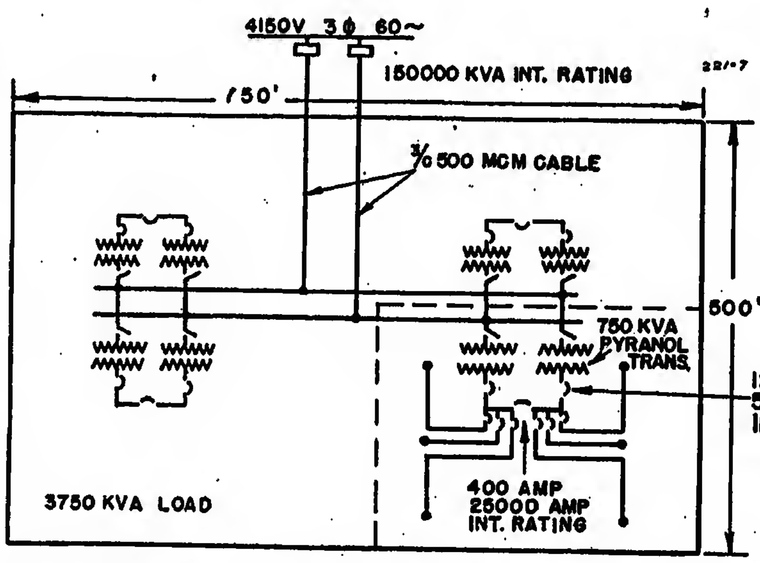

Figure 7. Schematic diagram of secondary-selective-circuit arrangement

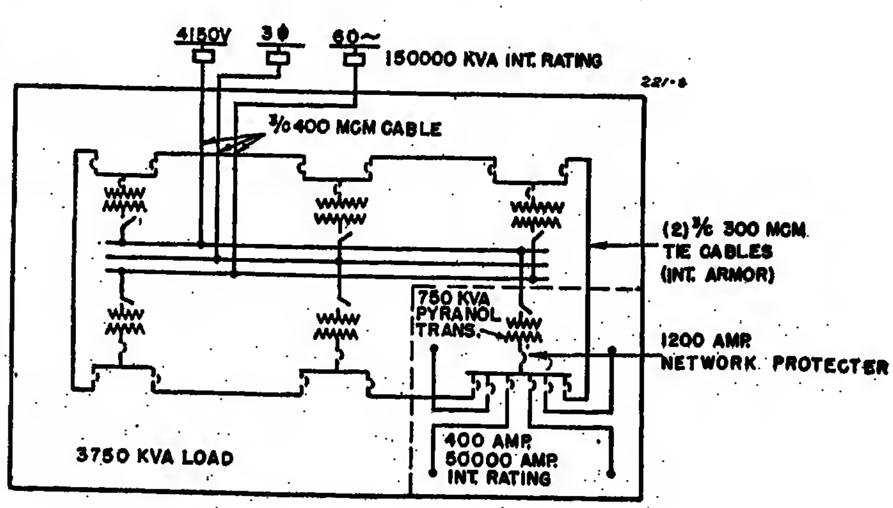

Figure 8. Schematic diagram of secondary network

The increased cost is the result of the introduction of low-voltage tie circuits and the more costly low-voltage switching equipment demanded by increased short-circuit current level.

With respect to *safety*, the secondary network, with low-voltage circuit breakers of adequate interrupting capacity, is comparable with the secondary selective, and the simple radial types. The fact that more than one source circuit must be opened to deenergize a particular load-center low-voltage bus represents some additional hazard, unless highly trained personnel is available.

The increased low-voltage short-circuit level to be expected with the secondary network is opposed to the interests of safety. Higher short-circuit current levels mean more violent disruptive effects at the point of fault. It may also jeopardize the safety of nearby branch circuit-switching units and individual load controllers unless the system is carefully checked and designed to avoid such a possibility.

Service reliability is of the highest order to the load-center low-voltage bus. A primary feeder or transformer unit may be deenergized without incurring interruption of service to any load center. Electrical faults in primary feeders or transformers will be automatically removed without service interruption except for a momentary voltage depression during the time the faulty element is being severed from the system.

Operating simplicity is sacrificed in the secondary network. In general any system incorporating multiple paralleled branches introduces operating complications. Should primary feeders originate from different high-voltage bus sections, as they should preferably do, voltage or phase-angle differences between these two sources will cause circulating currents which increase the loading on some load-center transformers and may create many perplexing problems for the operating departments. To deenergize a particular load-center low-voltage bus requires that two or more source circuits be opened. The maintenance and adjustment of network protectors with their associated network relays require greater skill than do conventional air circuit breakers.

Voltage regulation is good but not significantly superior. The normal load regulation may be either above or below the secondary selective circuit, depending on the particular form being considered. The regulation under emergency operation is likely to be inferior to the secondary selective form due to voltage drop in the low-voltage tie circuits.

It excels in the ability to accept heavy motor starting currents without light flicker which is directly the result of higher short-circuit current levels. This feature will be of value, however, only if motor starting currents approach that value which will produce light flicker. For instance, across-the-line starting of a 25-horsepower motor on a 440-volt system having a short-circuit current level of 25,000 amperes will result in a voltage drop of only one per cent. Since this would be judged to represent no noticeable flicker effect even with incandescent lighting, an increase in short-circuit current level could not be credited with improving light flicker. However, when larger motors are to be started on the 480-volt system, the network acquires some additional advantage.

Summary of Comparative Performance

Comparative installed-cost and electrical-performance characteristics of the various forms of distributed load-center systems are condensed in Table I. Qualities which are incapable of numerical evaluation are rated in terms of letters, *A* representing the best, *B* the next best, and so on.

The system cost comparisons are based on the representative load area expressly defined in the early part of this paper. While deviations from this basic load condition will influence the specific values to some degree, all systems will be similarly affected.

In every case, air circuit breakers of adequate interrupting capacity have been used for all low-voltage switching operations. Cascade arrangements[5] are used where it permits savings on breaker cost. All systems have been designed to provide individual control of the same number of secondary feeder circuits. An average unit feeder capacity of 150 kva (about 200 amperes at 440 volts) has been selected as representing a reasonable value commensurate with operating flexibility and ease of installation.

The selection of load-center unit ratings has been made with optimum installed cost as the objective.

Application of Limiters

For the purpose of diminishing the installed first cost, particularly in the case of the secondary network system, the substitution of limiters for air circuit breakers has been proposed.

To realize the service reliability of which the system is capable, of course, demands that the fault-current interrupting ability be unquestionably established under service conditions.

The application of limiters without proper isolating switches seriously impairs safety and operating flexibility. To deenergize any part thereof requires either that the entire network be deenergized or the particular section be isolated by literally cutting the energized conductors. The former would nullify the service continuity rating which the network systems claims as its chief advantage. The latter constitutes a serious hazard to operating personnel.

All repairs, additions or modifications made after the system is initially energized must be worked "hot". Although such practice is quite common in the utility industry, its successful application depends on a maintenance crew unusually skilled in handling electrical circuits and kept in practice by continual experience. The usual industrial plant would be unlikely to maintain a competent group of such skilled men and would afford insufficient practice to maintain proficiency.

The usual limiters incorporate no positive operation indicator. Tie circuits may have been divorced from the system as a result of internal fault without warning to the operating department and thus constitute a hazard to service continuity under emergency operating conditions.

Selection of Circuit Arrangement

The problem of selecting that circuit arrangement which will satisfy application requirements becomes primarily one of balancing service reliability against installed cost. It should, however, be borne in mind that a system, theoretically not perfect, but with the best possible type of equipment, is better than a system more perfect on paper, but with second-rate apparatus, such as a fusible element instead of a breaker.

Service reliability requirements will vary widely for various service conditions. The requirements for warehouses and storerooms will be low, although the ability to restore excitation to the more important circuits is obviously advantageous. General manufacturing plants operating on a piece-rate basis have observed that electrical-service outages of as much as twenty or thirty minutes rarely result in diminished output for that day. A few industrial processes are seriously influenced by service interruption for any significant interval, such as wire enameling and glass working.

In these more exacting applications, the

secondary network system may be justified, although even an allowable outage interval of two or three seconds will permit application of the secondary selective circuits with automatic transfer, at considerably less cost.

For all but the most exacting requirements, the secondary-selective-circuit arrangement should find general if not universal application in industry in view of these outstanding merits.

1. Moderate Installed Cost

Based on maintaining full system load during emergency operation, the cost is moderately greater than that of the minimum tolerable system arrangement. The increased cost above the simple radial system is largely invested in active material (primary cables and transformers) which return benefits in the form of improved voltage regulation, reduced operating temperature, lower losses, and the ability to meet unusual temporary peak load demands without distress.

For areas which allow a lower order of service reliability, first cost can be reduced by curtailing load during emergency operation. A 40 per cent load reduction during emergency operation allows system first cost to be reduced to within about 10 per cent of the simple radial circuit. No change in load-center size or design is needed, the result being accomplished merely by assigning a larger normal load block to the particular load center.

2. High Order of Safety

All secondary switching operations affecting service are performed with low-voltage air circuit breakers of adequate interrupting capacity. The disconnecting switches on the primary of the transformers need only be operated when completely deenergized.

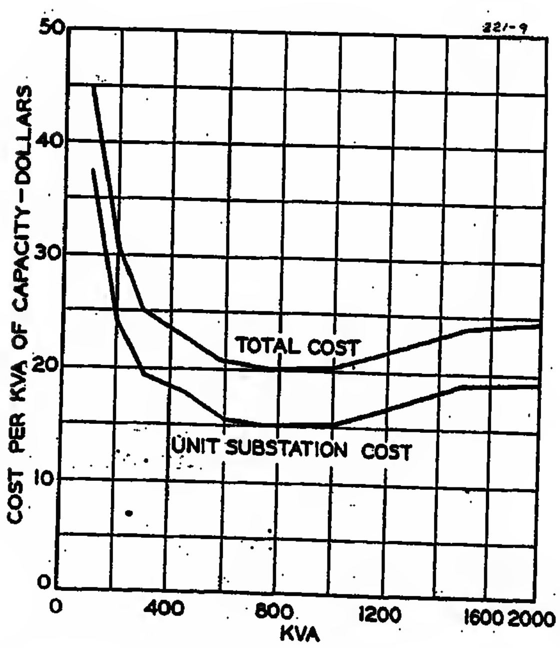

Figure 9. Cost of load-center distribution as a function of transformer size

480 volts

3. Good Service Reliability

Each secondary feeder circuit has access to two low-voltage sources derived from different primary feeders. Automatic transfer may be readily incorporated to limit service interruption to an interval of one or two seconds.

4. Simple to Operate

The operating simplicity of the simple radial system is obtained. There is no question as to the proper switching operation required to meet a particular situation. Each duplex load-center unit is self-contained and independent of others.

5. Voltage Regulation Is of the Best

The normal voltage regulation is entirely comparable with that of any other system, although the difference between any of the distributed load-center systems is actually not significant.

Appendix

Optimum Size of Load-Center Unit

The most economical size of unit substation is determined principally by the cost of the unit substation itself. This point is illustrated in Figure 9, which shows the cost per kilovolt-ampere of the small capacity of a radial load-center distribution system and the cost per kilovolt-ampere of the load-center unit.

The smaller load-center units are more expensive, because small equipment is inherently more expensive per kilovolt-ampere. The larger load-center units become increasingly expensive because of the large switchgear required to handle the high short-circuit current accompanying larger transformer banks. The optimum size of transformers lies between these two limits and for 480-volt secondaries 600-, 750-, and 1,000-kva units are most economical.

The shape of these curves of Figure 9 is accentuated by cable costs. For the smaller units more primary cable but less secondary cable is required. For the larger units less primary cable is required, but there is a very material increase in the amount of secondary cable necessary to transmit the power over the larger load area. This point is illustrated in Figure 10.

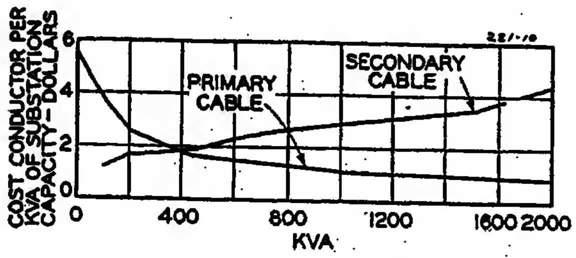

Figure 10. Cable cost as a function of transformer size

Load density affects the over-all system costs, principally because of the effect on cable cost. The total installed cost per kilovolt-ampere of load-center distribution system for load densities 2 volt-amperes to 20 volt-amperes per square foot inclusive are shown in Figure 11. The range of load densities studied should cover most average factory installations. It is interesting to note that, regardless of load densities, the shape of the curves is the same, and the optimum size of units is not affected.

The kilowatt losses per kilovolt-ampere capacity is substantially constant over the range of units from 100 to 1,500 kva.

The above curves have all been for 480-volt secondaries. When lower-voltage secondaries are used, the cost per kilovolt-ampere of the system is higher, because of the great amount of secondary cable required and because of the increased cost of secondary switchgear. This results in most economical sizes of transformers for 240-volt or 120/208-volt circuits, being 300 to 600 kva.

Figure 12 shows the comparative cost of 120/208-volt load-center radial system compared with 480-volt system.

Voltage Regulation and Short-Circuit Current Level

The normal voltage regulation of a distribution system will be controlled primarily by transformer regulation and voltage drop in low-voltage circuits.

Transformer regulation will be in the order of one per cent at 1.0 power factor and three to four per cent at 0.8 power factor at rated current and correspondingly less at lower currents.

The voltage regulation in low-voltage circuits is a function of conductor configuration, current loading and length of run. Using three-conductor or three single-conductor cables in conduit, in sizes ranging from 1/0 to 500,000 at current levels approaching the thermal rating, the voltage regulation, on the basis of 440 volt, three-phase, three or four-wire service, will be in the order of one-half to three-fourths per

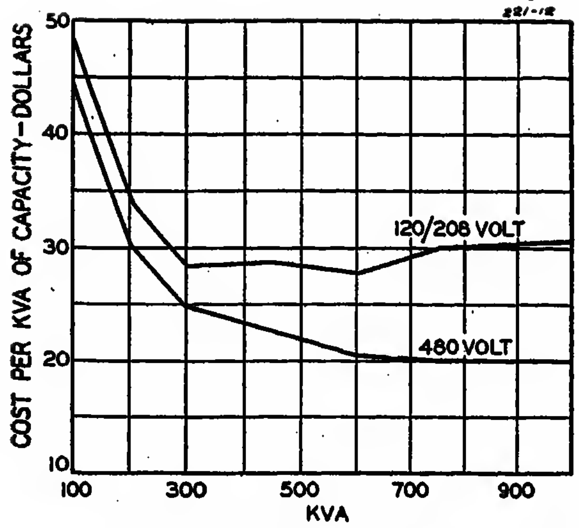

Figure 12. Comparative costs of 120/208-volt and 480-volt load-center distribution systems

cent per hundred feet of transmission, and will be more or less independent of power factor in the range of 0.7 to 0.9 lagging. At lower operating voltages, the per cent voltage regulation will be correspondingly increased.

Separation of conductors increases the reactive voltage drop and increases the voltage regulation by increasingly greater amount as the power factor deviates from unity in the lagging direction.

Incremental voltage or flicker-influence factor goes hand in hand with short-circuit level. The greater the short-circuit current the lower will be the abrupt voltage change resulting from a given low-power-factor abruptly applied load.

However, increased short-circuit current level means increased low-voltage switching-equipment expense, more violent disturbance associated with an electrical fault, and restricted application of conventional motor starters. It is therefore advisable to design for the lowest short-circuit current level commensurate with best overall economy and freedom from light flicker. No benefit can be claimed, as far as light flicker is concerned, for increasing the short-circuit current above that required for freedom from flicker.

The magnitude of abrupt voltage dip which can be permitted if the frequency of the occurrence is of the order of a few per hour is about two per cent for incandescent and about four per cent for fluorescent lighting.

Table II shows the required short-circuit current level to permit full-voltage starting of general-purpose induction motors for two per cent and four per cent voltage dip respectively on a 440-volt, three-phase system.

Table II. Required Short-Circuit Current Level for Limited Voltage Dip With Across-the-Line Motor Starting

Motor Rating (Horsepower)	2% Dip (Amperes)	4% Dip (Amperes)
15	7,500	3,750
30	15,000	7,500
50	25,000	12,500
100	50,000	25,000

Effect of Load-Density Variation

Variation in load density influences the mean length of run (*MLR*) between the load-center bus and the utilization machine. The *MLR* directly affects the investment cost in low-voltage distributing circuits (about two to four dollars per kilovolt-ampere per 100 foot at 440 volts) and the voltage regulation (about one-half to three-fourths per cent per 100 foot at 440 volts with closely spaced conductors).

The area associated with a given load center will be directly proportional to load-center rating and inversely proportional to load density. It follows that the *MLR* will vary in like manner except as the square root of load-center rating and load density, since the length of run is governed by the lineal dimension of the sides. Expressed mathematically, this becomes

$$MLR = K\sqrt{\frac{L.C.\ \text{rating}}{\text{load density}}}$$

assuming, of course, that the shape of the load area remains unchanged.

Low-voltage circuit runs generally follow a rectangular course coinciding with the building form rather than a direct diagonal path to the subdistribution point which increases the length of run by 40 per cent for square load areas.

To enable rapid evaluation of low-voltage *MLR*, the attached Figure 13 has been prepared, giving the horizontal *MLR* as a function of load density for various load-center ratings, based on rectangular configuration. To this must be added the vertical lengths almost invariably involved. For floor or underfloor installation, a 10-foot allowance (5 feet at each end) is reasonable. For overhead installation, a 15- to 30-foot allowance would generally be expected.

Transient Characteristics of Current Transformers During Faults

C. CONCORDIA
MEMBER AIEE

C. N. WEYGANDT
ASSOCIATE AIEE

H. S. SHOTT
ASSOCIATE AIEE

THE factors involving current-transformer performance that affect the operation of protective equipment have recently received considerable attention.[1-3] The fact that the transient performance may be greatly different from the steady-state performance has been recognized, but little quantitative data on transient performance have been published. Data from oscillograph records of tests and from approximate analytical methods have definitely indicated the magnitudes of the expected steady-state errors and at the same time conveyed the thought that the transient errors would be very much larger. This paper presents some of the results of a study of current-transformer transient performance that has been made on the differential analyzer with the effects of transformer saturation more accurately considered.

While the information presented herewith is neither a complete coverage of the subject nor even a complete summary of what has been done to date by the authors, it has seemed desirable to publish it now for the general benefit of the interested engineers. More specifically the data presented apply to current transformers such as might be encountered in bus-differential protection. The magnitude of expected error under various conditions of application was studied for a wide range of transformers of the conventional bar-type construction and of the bushing type, but it is possible to present only a small part of these results here because of space limitations. Most of the data presented here on the bushing-type transformer was for a transformer physically larger than would be normally used, in order that the data would show what improvement can be affected through increase in size.

Certain broad assumptions have been made regarding the distribution of fault current between circuits, the degree of similarity of the various transformers, and so on, since all combinations of possible operating conditions cannot be considered in a study of this type. However, the data will be useful as a basis for judging the expected performance of existing and contemplated installations, particularly since the effects of variations of such important factors as the magnitudes of fault current, size of transformer, number of transformers, and time constant of the d-c component of fault current have been studied. In addition to the factors involving the current, the data have been referred to a base involving a factor which is called the transformer size constant. This size constant depends upon the physical construction of the transformer and the total secondary resistance both of the winding and of the burden. With this information the data already presented can be translated to apply to other transformers if the physical dimensions and the secondary loading are known.

The results were recorded as reproductions of the error current in the differential-relay circuit versus time during periods of large through-fault currents, and a portion of these results is summarized here as a function of the governing factors mentioned above, with respect to the application possibilities of instantaneous overcurrent and of time-delay overcurrent relays. For other types of relays, such as those having harmonic restraint,[4] d-c restraint, percentage differential restraint, and so on, it will probably be necessary to consider each application on its own merits, at least until a time when the response of these relays to transient currents of nonsinusoidal wave form can be specified in a more generalized form. Field and laboratory tests which have been made have shown good agreement with the results of the differential-analyzer study, although it has not been possible to cover the complete range by test.

Conclusions

From the data presented here, as well as from the large amount of data taken which could not be included, the following conclusions may be drawn:

1. The concept of transformer size constant has been introduced. The transient performance of two transformers having the same size constants and saturation characteristics will be practically identical when the primary current, in ampere turns per unit of core length, is the same for both. Of two transformers having the same size constant the one having the longer magnetic circuit will give better performance for the same value of primary current.

2. Data have been obtained to show the calculated differential-circuit error currents, that appear as a result of transformer saturation, for a wide range of magnitudes of through-fault current, transformer size constant, d-c time constant of the primary circuit, and number of transformers in the group.

3. When conventional current transformers are used, the magnitude of differential-error current with faults of ten or more times rated current can be from 30 per cent to 75 per cent or larger, depending on the size, even at a high-voltage bus where the d-c time constant of the fault current may be only two or three cycles.

4. From a study of the differential-error current curves obtained, it is apparent that time-delay settings of only three or four cycles will not insure proper operation, when simple time-delay relays are used for bus-differential protection; very much greater delays may be necessary.

5. The differential-error currents are particularly severe at a bus where the fault current has a very long d-c time constant. For these applications it is not practical to design conventional current transformers large enough to insure that they will not saturate at the larger values of fault current. Therefore, there is a definite field for the new air-gap current transformer recently introduced.[5]

The differential analyzer at the Moore School of Electrical Engineering, University of Pennsylvania, was used to solve the equations.

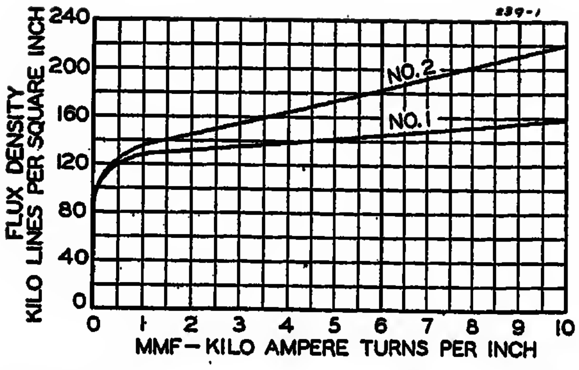

Figure 1. Saturation characteristic of the mutual flux path

ferential-error current depends greatly on the number of transformers in the group.

Analysis of Current-Transformer Performance

The performance of a current transformer can be determined from the voltage equation of its secondary circuit

$$10^{-8}\frac{d\psi}{dt}=i_2r_2+L_2\frac{di_2}{dt} \qquad (1)$$

where

$\psi=N_2\phi$ is the flux linkages of the secondary due to the mutual flux
N_2 = the number of secondary turns
ϕ = the number of flux lines mutual to both the primary and secondary windings
i_2 = the secondary current in amperes
r_2 = resistance of the secondary circuit, including that of the burden, in ohms
L_2 = secondary leakage inductance plus the inductance of the burden in henrys
t = time in seconds

Equation 1 is integrated to give

$$\frac{\phi}{10^8}=\int\frac{r_2}{N_2}i_2\,dt+\frac{L_2}{N_2}i_2+\frac{\phi_0}{10^8} \qquad (2)$$

where the constant of integration is proportional to the residual flux ϕ_0.

Another relation is that the magnetomotive force acting on the core is proportional to the primary ampere turns less the secondary ampere turns, or, for a transformer having only one turn in the primary

$$N_2i_2=i_1-\frac{hl}{0.4\pi} \qquad (3)$$

where

i_1 = primary current in amperes
$h/0.4\pi$ = magnetomotive force acting on the core in ampere turns per inch of core length
l = mean length of core in inches

The flux mutual to the primary and secondary windings can be written as

$$\phi=A\beta \qquad (4)$$

where

A = area of core in square inches
β = flux density in the core in lines per square inch

Upon substituting the expressions for the secondary current i_2 and the mutual flux ϕ of equations 3 and 4 into equation 2, there is obtained a general equation for determining the performance of a single transformer, including the effects of its burden, when the primary current is known.

$$\frac{A\beta}{10^8}=\int\frac{r_2}{N_2^2}\left(i_1-\frac{hl}{0.4\pi}\right)dt+\frac{L_2}{N_2^2}\left(i_1-\frac{hl}{0.4\pi}\right)+\frac{A\beta_0}{10^8} \qquad (5)$$

Dividing through by the factor r_2l/N_2^2, there is obtained a more convenient form,

$$C\beta=10^8\int\left(\frac{i_1}{l}-\frac{h}{0.4\pi}\right)dt+10^8\frac{L_2}{r_2}\left(\frac{i_1}{l}-\frac{h}{0.4\pi}\right)+C\beta_0 \qquad (6)$$

where the factor, $C=AN^2/r_2l$ turns² inch ÷ ohms, is defined as the transformer size constant.

If the secondaries of current transformers applied to bus differential protection are connected in parallel, through a differential-relay circuit of negligible impedance, the above equations can be used to determine the performance of each transformer separately. Furthermore, previous work has shown that the transformer errors due to the residual flux and to the flux associated with L_2 are small compared with the errors caused by the flux associated with R_2. For a through fault at a bus of $n+1$ feeders and transformers, transformer 1 carries total fault current and in view of the above assumptions its performance is given by:

$$C\beta_1=10^8\int\left(\frac{i_1}{l}-\frac{h_1}{0.4\pi}\right)dt \qquad (7)$$

It is further assumed that all transformers have identical size constants and saturation characteristics and that the fault current is equally divided between the other n transformers. The equation for each of the n transformers is

$$C\beta_n=10^8\int\left(\frac{i_1}{nl}-\frac{h_n}{0.4\pi}\right)dt \qquad (8)$$

The current through the differential-relay circuit is equal to the secondary current of transformer 1 less the sum of the secondary currents of the other n transformers. Referred to the primary this error current is:

$$\frac{i}{l}=\left(\frac{i_1}{l}-\frac{h_1}{0.4\pi}\right)-n\left(\frac{i_1}{nl}-\frac{h_n}{0.4\pi}\right) \qquad (9)$$

$$=\left(\frac{nh_n}{0.4\pi}-\frac{h_1}{0.4\pi}\right)\text{ amperes per inch of core length}$$

$C=16{,}700$ turns² inch/ohms
$T=0.265$ second

The total fault current is of the form

$$\frac{i_1}{l}=\frac{I_1}{l}[(\cos\alpha)\epsilon^{-t/T}-\cos(\omega t+\alpha)] \tag{10}$$

where

I_1/l = crest value of symmetrical component, amperes per inch of core length
T = time constant of the d-c component in seconds
α = determines the magnitude of the initial offset
$\omega=2\pi f$

Equations 7–10 were solved on the University of Pennsylvania's differential analyzer[6,7] to determine the error current in the differential-relay circuit as a function of the magnitudes of through-fault current, d-c time constant, number of transformers, and transformer size constant. The primary current i_1/l (equation 10), was generated by the machine and formed one component of the secondary current. This secondary current was integrated to determine the mutual flux density β according to equation 8, and β in turn moved an index in the β direction of the saturation curve as plotted on an analyzer input table. An operator manually controlled the index in the direction of

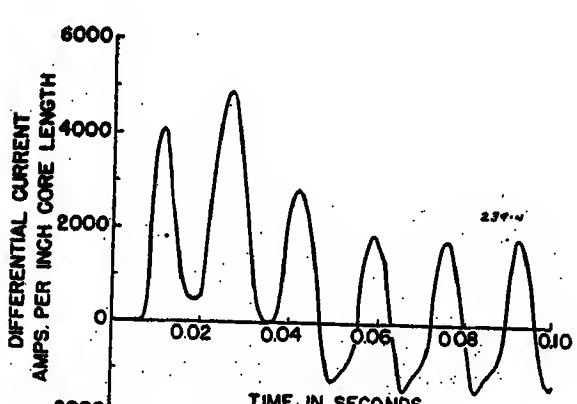

Figure 4. Differential-error current for transformers having saturation characteristic 2

$C=16{,}700$ turns² inch/ohms
$T=0.265$ second

magnetizing force H so as to keep the index on the saturation curve and, at the same time, move the exciting current component of the secondary current in proportion. The primary and exciting currents were added to form the integrand of equation 8. Two saturation characteristics were used as shown on Figure 1. Curve 1 is for silicon steel core material and was used for most of the cases considered. Curve 2 is for a transformer in which air forms a considerable part of the mutual core area in parallel with the iron. These two curves cover an extreme range of saturation characteristics for conventional current transformers. For the very high degrees of saturation which cause the large errors observed, the effects of hysteresis are negligible, and were not considered in this study. Other studies of similar transient circuit performance with iron saturation which have been made have also indicated that consideration of hysteresis is not necessary to explain the fundamental phenomena.

Results

The differential-relay error currents have been determined for a wide range of through-fault currents, transformer size, and d-c time constant. One set of results shows the error currents for the case in which the total through-fault current in one transformer is equally divided between two other transformers. The differential analyzer was set up so that the results for the case of one transformer versus three, one versus five, and one versus an infinite number, were also obtained at the same time. The data obtained for the case of one transformer versus an infinite number show in addition to the differential current which might flow in this case the absolute error current of the transformer under study. The constants for the bar-type current transformer, and for the bushing-type transformer, studied are tabulated in Table I. Data have also been obtained for very large and very small transformers having size constants $C=200{,}000$ and $C=4{,}170$, respectively.

The following sections describe that part of the data which is presented in this paper. The effects of variations of such important factors as the magnitudes of fault current, the d-c time constant, the number of transformers, and the transformer size constant, are shown.

Magnitude of Fault Current

Figure 2 shows the error currents (referred to the primary) as obtained with transformer A (Table I). The total through fault current in one transformer

$C=16{,}700$ turns² inch/ohms

(which will be designated as transformer 1) is equally divided between five other transformers. The fault current is completely offset and has a relatively long d-c time constant of $T=0.265$ second. The magnitudes of fault currents are given in terms of the rms value of its symmetrical

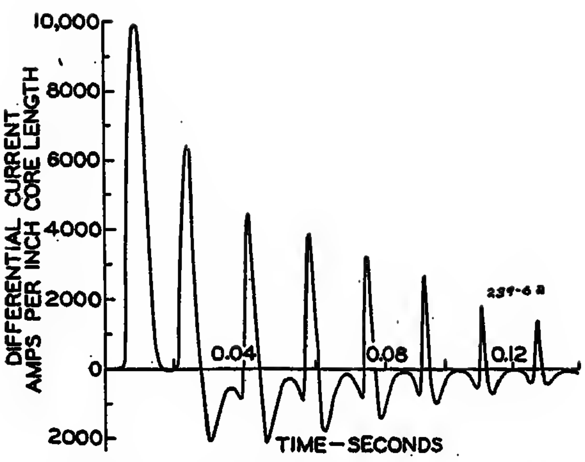

Figure 6a. C=16,700 turns² inch/ohms

Figure 6. Effect of transformer size constant

Through-fault current, completely offset. Saturation curve 1. Symmetrical component of fault current equal to 3,950 amperes per inch core length. One transformer versus five

T = 0.0424 second

a-c component. This value multiplied by $2\times\sqrt{2}$ is equal to the maximum instantaneous fault current for a completely offset wave.

For a small fault current having a symmetrical component of 269 rms amperes per inch core length (Figure 2a) the differential-error current is proportional to the saturation ampere turns of transformer 1, since the other transformers do not saturate when subjected to only one fifth of this value of total fault current. It is seen that several cycles are required for the d-c component of core flux to build up to the point where the saturation is appreciable. The error current has a large d-c component and the a-c component is primarily of fundamental frequency.

The other curves of Figure 2 show the effects of larger fault currents. With these larger currents all the transformers saturate, and the differential-error current is equal to the saturation ampere turns of transformer 1 less the sum of the saturation ampere turns of the other five transformers. As the magnitude of fault current is increased, the d-c component of core flux reaches a higher value in less time. That is, all the transformers lose their ability to transform the d-c component of fault current in a shorter time. This is demonstrated by the curves of Figure 2 in that the d-c component of differential-error current decays at a greater rate for the larger values of fault current. The wave form of a current through the differential relay becomes more distorted due to the greater degree of saturation associated with the larger fault current.

The maximum possible error, equal to the total fault current, occurs when the accuracy of transformer 1 collapses, and the others transform perfectly. Even with the large fault current of Figure 2e the maximum possible error is almost attained during the first cycle, because transformer 1 saturates at a much greater rate than the others, and its accuracy is destroyed before the saturation in the other transformers becomes appreciable. Another interesting fact is that the differential current is of relatively good wave form although completely or nearly completely offset during this period, but that the wave form becomes greatly distorted after the other current transformers saturate.

Smaller D-C Time Constants

Error currents obtained with completely offset fault currents having smaller d-c time constants are given on Figure 5. The transformer size constant, C=16,700 turns² inch/ohms, is the same as used before. Maximum instantaneous fault current, neglecting the decay of d-c component in the first half-cycle, is equal to 5,590 amperes per inch core length. Even with the very short time constant of T=0.0106 second, the maximum error is approximately 90 per cent of the maximum a-c component of fault current. The error current does disappear at a faster rate for the smaller d-c time constants. As a matter of interest, the value of rms symmetrical component of fault current is 12.4 times rated for the particular transformer listed in Table I as representative of this size constant. However, another transformer of identical size constant might have a different rating.

Effect of Transformer Size Constant

The curves of Figure 6 give an interesting relation, showing the comparative results for three installations operating under similar conditions but having transformers of different size constants. Although the assumed fault current is the same in amperes per inch core length for all three cases it may not be the same in actual amperes or in times rated current. For the installation having transformers of smaller size constant, C=16,700, all six transformers become highly saturated. Therefore, the d-c component of error current decays quite rapidly, and then the harmonic content of the a-c component

Through-fault current, completely offset. Saturation curve 1. Symmetrical component of fault current equal to 1,975 amperes per inch core length

$C = 16{,}700$ turns² inch/ohms

becomes large. The maximum instantaneous fault current is large for the first cycle or two, but the harmonic components of a-c error current are small during this time. For the larger size transformers, $C=50{,}000$, five of the transformers are only moderately saturated. As before the a-c and d-c components of error current are large, but the d-c component does not decay so rapidly, and the harmonic content is small. With the hypothetically large transformer installation, $C=200{,}000$, the error current is small only because the fault current is of sufficiently low value such that none of the transformers is appreciably saturated.

Figure 6a is compared with Figure 5c to show the effect of doubling the fault current when the d-c time constant is $T=0.0424$ second, and the transformer size constant is $C=16{,}700$ turns² inch/ohms. The maximum error current is slightly more than doubled. Again, the higher degree of saturation obtained in the other five transformers with the larger fault current causes the d-c component of error current to decay more rapidly, and the harmonic content becomes greater.

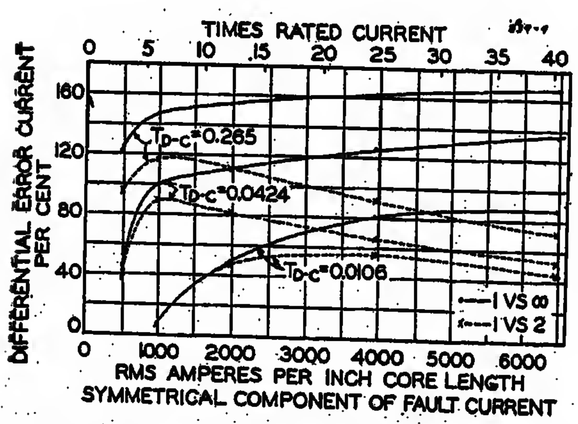

Figure 9. Maximum rms error current over one-cycle interval as a function of the magnitude of fault current and of the d-c time constant

Through-fault current, completely offset. Saturation curve 1

$C=16{,}700$ turns² inch/ohms

Figure 13 shows the maximum differential-error currents (rms for one cycle) for a range of fault current and transformer size. The effect of variation in the saturation characteristic is also shown for one size (Curves C and C'). All of the error currents are large except for the largest transformer size with rather small fault currents.

Different Numbers of Transformers

Most of the data presented above were for a condition of one transformer versus five. Figure 7 shows the error currents for one transformer versus two, one versus three, one versus five, and one versus an infinite number. The results are all for the transformer size constant $C=16{,}700$ and a reasonably small d-c time constant of $T=0.0848$ second. The rms symmetrical component of fault current, 3,950 amperes per inch core length, is quite large being 24.7 times normal for the typical transformer of this size constant as listed in Table I. For one transformer versus two, all transformers are highly saturated. As the number of transformers is increased, the saturation

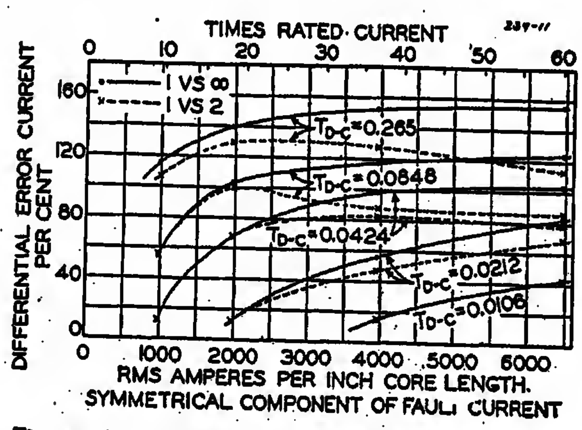

Figure 11. Maximum rms error current over one-cycle interval as a function of the magnitude of fault current and of the d-c time constant

Through-fault current, completely offset. Saturation curve 1

$C=50{,}000$ turns² inch/ohms

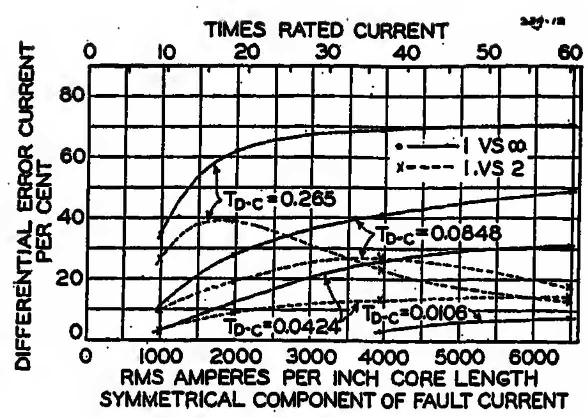

Figure 12. Rms a-c component of error current over 12-cycle interval as a function of the magnitude of fault current and of the d-c time constant

Through-fault current, completely offset. Saturation curve 1

$C=50{,}000$ turns² inch/ohms

in all except transformer 1 becomes less, and the harmonic component of error current decreases. For the case of one transformer versus an infinite number (which is the same as one versus a perfect transformer), the a-c and d-c components are both large, the d-c component decays slowly, and the harmonics are very small.

Figure 7c, as compared to Figure 5d, again shows the effect of doubling the fault current for a transformer size constant $C=16{,}700$, one transformer versus five, but with a d-c time constant of 0.0848 second.

Figures 6a, 7c, and 2e show the effects of different d-c time constants in the same manner as the curves of Figure 5, and under the same conditions except for a larger fault current.

Degree of Offset

The error current of Figure 3 is for the same conditions as Figure 2d except that the d-c offset is only one half. The symmetrical component of fault current is the same in the two cases, but the maximum instantaneous fault current (and maximum possible error current) is 4,193 amperes per inch core length for Figure 3 as compared to 5,590 for Figure 2d. Although the magnitudes of the a-c and d-c components of error current are appreciably smaller, the d-c component decays at a slower rate because of less saturation. The percentage harmonic content appears to be about the same.

Saturation Characteristic

Figure 4 is also for the same conditions as Figure 2d, except that the transformers were assumed to have saturation characteristic 2, Figure 1. The maximum error currents are about the same, but the a-c component is somewhat smaller, particularly after the first two cycles. In general, the conclusions arrived at

with either of these two very different saturation curves were about the same, so that they should also be valid for most other saturation curves obtainable with conventional current transformers.

Application

The character of the differential-relay current varies widely depending upon the size constant and number of transformers involved, and upon the magnitude of the fault current and its d-c time constant. For this reason it is difficult to summarize the accumulated data for all the various types of relays used, especially since the response of these relays to transient currents of this nature is not very well known.

Results can be plotted in a form which will serve to indicate the expected performance of either instantaneous or time-delay relays. For instance, Figure 8 summarizes the effect of variation of the d-c time constant for the transformer size $C=$ 16,700 for fully offset through current having a symmetrical rms component of 1,975 amperes per inch core length. The rms value of the completely offset wave is therefore equal to $\sqrt{3}\times 1{,}975$. The maximum rms differential-error current over a one-cycle interval can be taken as a measure of the current which determines the operation of an instantaneous relay. The rms a-c component of error current over the 12 cycles interval that gives the largest value is taken as a measure of the current that would determine the operation of an induction-type time-delay relay with the time setting of approximately 0.2 second. The curves were plotted for one transformer versus two and for one transformer versus an infinite number thus covering the entire expected range of operation. The data taken from Figure 5, for one transformer versus five, would lie between the two plotted curves.

Figure 9 gives more complete data for the instantaneous error currents of the same size transformer. The effects of the magnitude of fault current over a wide range are shown for three different values of d-c time constant. The fault current in rms amperes per inch core length is perfectly general. The times-rated current applies only to the particular transformer selected as representative of this size constant $C=16{,}700$. It is seen that the error current is small only in a range of very small d-c time constant and reasonably small fault current. Likewise, Figure 10 gives similar data applicable to time-delay relays. The time delay is quite effective for the smaller d-c time constants.

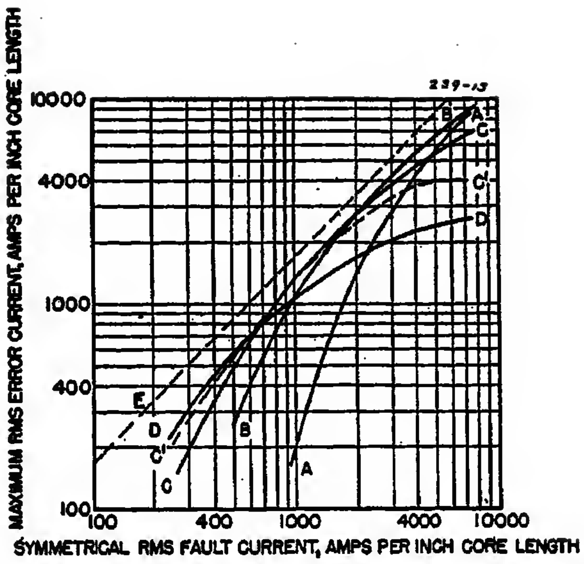

Figure 13. Differential-error current (rms over one cycle)

One transformer versus three. Through fault—fully offset. D-c time constant=0.265 second

Curve *A*—Saturation characteristic 1, $C=$ 200,000 turns² inches/ohms

Curve *B*—Saturation characteristic 1, $C=$ 50,000 turns² inches/ohms

Curve *C*—Saturation characteristic 1, $C=$ 16,670 turns² inches/ohms

Curve *C'*—Saturation characteristic 2, $C=$ 16,670 turns² inches/ohms

Curve *D*—Saturation characteristic 1, $C=$ 4,170 turns² inches/ohms

Curve *E*—Current for 100 per cent error

The data of Figures 11 and 12 are similar to that of Figures 9 and 10, except that they are for the larger transformer size constant $C=50{,}000$ turns² inch/ohms. The times-rated fault current applies only to the particular transformer listed in Table I. The advantages of using larger transformers are apparent.

Admittedly this summary is not perfectly accurate and may not be the correct measure for determining the response of these relays. It is valuable as being indicative of definite trends.

For the high-speed relays that depend upon percentage, harmonic, or d-c restraint for proper operation, the analysis is more complicated. Their characteristics are such that each application requires special consideration and the accumulated data are valuable as a basis for selecting the proper relay characteristics.

Air-Gap-Core Current Transformers

The ideal solution of using current transformers large enough to insure almost perfect accuracy up to the maximum value of through-fault current is not practical because of the excessive size and cost. A new current transformer, as described by Kennedy and Sinks,[5] has been developed for high-speed bus-differential protection. This transformer, which has air gaps in the mutual flux path, has constant ratio and phase-angle errors up to the point where the iron paths saturate. By selecting transformers that maintain a linear characteristic up to the maximum value of fault current, the a-c component of primary current is always reproduced with the same degree of accuracy. Very little of the d-c component is transformed, but this is not required for differential protection. Simple overcurrent relays can be used since differential-error currents appear only because of improper matching of the linear characteristics. The size and cost is not much greater than that of the standard current transformers ordinarily used.

The Doubly Fed Machine

C. CONCORDIA

GABRIEL KRON
ASSOCIATE AIEE

SYNCHRONOUS machines, operating with a-c excitation on both stator and rotor are used in many applications, for example, as induction frequency converters, as power and instrument Selsyn drives, and as variable speed power drives. Reference 1 has mentioned particularly the variable speed fan drive, and presented equations for the small oscillations of one such doubly fed machine. Reference 2 has also previously given the equations of hunting of the doubly fed machine (part XIV, section IV) in connection with the general study of oscillations of rotating machines. However, since the present authors have been using in their own work equations which seem to them to be more convenient and simpler in form for calculations, and since it now seems desirable to present not only general equations but also some of the more fundamental and significant performance characteristics of these machines, it is thought that this paper may now be appropriate. The form of the equations developed possesses the additional novelty of facilitating the setting up of equivalent circuits for hunting on the a-c network analyzer, and allowing the quick determination of the damping and synchronizing torques directly by wattmeter readings.

In this paper there are presented:

1. A general analysis of the doubly fed machine, in a form believed to be particularly convenient for the study of rotor hunting and for the interconnection of two or more machines.

2. An example showing the transient electrical characteristics under three-phase short circuit.

3. Examples showing the characteristic damping and synchronizing torques during hunting at various speeds and loads.

4. Equivalent electrical circuits for hunting which have been found to be of considerable help in the determination of the machine performance during small oscillations by means of the a-c network analyzer.

Paper 42-4, recommended by the AIEE committee on electrical machinery, for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted October 6, 1941; made available for printing October 28, 1941.

C. Concordia and S. B. Crary are in the central station engineering department and Gabriel Kron is consulting engineer with General Electric Company, Schenectady, N. Y.

Results

1. The general equations are derived in appendix I and are summarized in equations 14, 23, and 24. Attention is called particularly to the compact derivation and the simplicity of the final equations made possible by the simultaneous use of complex variables in the general transient analysis and also a complex angular variation.

2. Equations 26, 27, 29, and 30, appendix II, give the transient three-phase short-circuit currents of a doubly fed machine or induction frequency converter. It is of interest here that

(*a*). The steady-state short-circuit currents are determined principally by the short-circuit or transient reactance.

(*b*). The d-c component is of the same form as that for short circuit of a synchronous machine.

(*c*). There is no transient component of fundamental frequency short-circuit current, such as would be observed in a synchronous machine; instead, the corresponding transient current is of rotor speed frequency and is moreover very small.

3. Figures 1, 2, and 3 show curves of damping and synchronizing torques for the hunting of a particular doubly fed motor. Some of the curves were calculated and some measured on the network analyzer, using the equivalent circuits of appendix IV. The damping torque is seen to be negative up to very small slips, and indeed becomes most negative at a slip somewhat greater than the frequency of hunting. It is evident that, because of the inherent negative damping characteristic of these machines, either load damping must be depended upon, or special precautions must be taken, if stable operation is to be obtained.

4. Figure 3 shows the equivalent circuits and a tabulation of the direct power and reactive kva measurements which determine the damping and synchronizing torque coefficients during hunting. The circuits are derived in a companion paper "Equivalent Circuits for the Hunting of Electrical Machinery"[3] by one of the authors.

Appendix I. Derivation of Transient and Hunting Equations

(*a*). The equations of a two-phase rotating machine (see Figure 4; and see also reference 4, equations 10 and 11, for the relations between these two phase quantities and the usual three-phase machine quantities) referred to axes connected to the stator and rotor, are:

$$e_{as}=r_s i^{as}+p\psi_{as} \qquad e_{dr}=r_r i^{dr}+p\psi_{dr}$$
$$e_{bs}=r_s i^{bs}+p\psi_{bs} \qquad e_{qr}=r_r i^{qs}+p\psi_{qr}$$

or,

$$\boldsymbol{e}=\boldsymbol{R}\cdot\boldsymbol{i}+p\boldsymbol{\psi} \tag{1}$$

where the flux-linkage vector is $\boldsymbol{\psi}=\boldsymbol{L}\cdot\boldsymbol{i}$. In a machine with smooth air gap the self and mutual inductances are:

$$\boldsymbol{L}=\begin{array}{c|cccc} & a_s & b_s & d_r & q_r \\ \hline a_s & L_s & & M\cos\theta_2 & -M\sin\theta_2 \\ b_s & & L_s & M\sin\theta_2 & M\cos\theta_2 \\ d_r & M\cos\theta_2 & M\sin\theta_2 & L_r & \\ q_r & -M\sin\theta_2 & M\cos\theta_2 & & L_r \end{array} \tag{2}$$

where θ_2 is the angle of the machine rotor. Hence the equations are $\boldsymbol{e}=\boldsymbol{Z}\cdot\boldsymbol{i}$, where $\boldsymbol{Z}=\boldsymbol{R}+p\boldsymbol{L}$, or

$$\boldsymbol{Z}=\begin{array}{c|cccc} & a_s & b_s & d_r & q_r \\ \hline a_s & r_s+L_sp & & pM\cos\theta_2 & -pM\sin\theta_2 \\ b_s & & r_s+L_sp & pM\sin\theta_2 & pM\cos\theta_2 \\ d_r & pM\cos\theta_2 & pM\sin\theta_2 & r_r+L_rp & \\ q_r & -pM\sin\theta_2 & pM\cos\theta_2 & & r_r+L_rp \end{array} \tag{3}$$

(*b*). Multiply the second and fourth of equations 3 by j and add them to the first and third respectively, to obtain a new set of equations

$$e = Z \cdot i \tag{4}$$

where now

$$Z = \begin{array}{c|cc} & s & r \\ \hline s & r_s+L_s p & Mp\epsilon^{j\theta_2} \\ r & Mp\epsilon^{-j\theta_2} & r_r+L_r p \end{array} \tag{5}$$

and

$$\begin{aligned} e_{as}+je_{bs}&=e_s & \qquad i^{as}+ji^{bs}&=i^s \\ e_{dr}+je_{qr}&=e_r & \qquad i^{dr}+ji^{qr}&=i^r \end{aligned} \tag{6}$$

Hence the four equations with real coefficients may be expressed as two equations with complex coefficients. These equations check with reference 2, page 74, equation 23. (For the process see reference 2, page 147.)

Torque

(*a*). The electromagnetic torque upon the rotor of an electrical machine is

$$T_e = i^{dr}\psi_{qr} - i^{qr}\psi_{dr} \tag{7}$$

If $i^{dr}+ji^{qr}=i_r$, and $\psi_{dr}+j\psi_{dr}=\psi_r$, then

$$T_e = \text{real part of } [(i^{dr}-ji^{qr})(-j)(\psi_{dr}+j\psi_{qr})]$$

$$= -ji^{r*}\psi_r = i^{r*}B_r \tag{8}$$

where i^{r*} is the conjugate of i^r and $B_r = -j\psi_r$ = flux-density wave of the rotor. Then from equation 5,

$$\psi_r = M\epsilon^{-j\theta}i^s + L_r i^r \tag{9}$$

Therefore, for a smooth machine:

$$T_e = \text{real part of } (-jM\epsilon^{-j\theta}i^s i^{r*}) \tag{10}$$

(*b*). The same expression for the torque may also be found from the relation:[2]

$$T = \text{real part of } i^* \cdot B = i^* \cdot G_s \cdot i$$

where the torque tensor is

$$\left.\begin{aligned} G &= \begin{array}{c|cc} & s & r \\ \hline s & & \\ r & -jM\epsilon^{-j\theta} & -jL_r \end{array} \\ G_s &= \begin{array}{c|c} & s \\ \hline r & -jM\epsilon^{-j\theta} \end{array} \end{aligned}\right\} \tag{11}$$

Transformation to Axes on Stator Flux

The stator flux rotates with a velocity $p\theta_1$ with respect to the stator (Figure 5) and the rotor flux rotates with $p\theta_3$ with respect to the rotor. The rotor itself rotates with $p\theta_2$. Hence the applied voltages are:

$$e_s = E_s\epsilon^{j\theta_1} \quad \text{and} \quad e_r = E_r\epsilon^{j\theta_3} \tag{12}$$

Let two new axes s' and r' be introduced, both rotating with the stator flux. That is, let

$$\left.\begin{aligned} i^s &= i^{s'}\epsilon^{j\theta_1} \\ i^r &= i^{r'}\epsilon^{j\theta_1}\epsilon^{-j\theta_2} = i^{r'}\epsilon^{j(\theta_1-\theta_2)} \\ C &= \begin{array}{c|cc} & s' & r' \\ \hline s & \epsilon^{j\theta_1} & \\ r & & \epsilon^{j(\theta_1-\theta_2)} \end{array} \end{aligned}\right\} \tag{13}$$

By $C_t^* \cdot Z \cdot C$ (where the p in Z refers to C but not to C_t^*), $C_t^* \cdot G \cdot C$, and $C_t^* \cdot e$, or by $Z' = C_t^* \cdot Z \cdot C + C_t^* \cdot L \cdot pC$

$$Z' = \begin{array}{c|cc} & s' & r' \\ \hline s' & r_s+L_s(p+jp\theta_1) & M(p+jp\theta_1) \\ r' & M[p+j(p\theta_1-p\theta_2)] & r_r+L_r[p+j(p\theta_1-p\theta_2)] \end{array} \qquad e' = \begin{array}{c|c} s' & E_s \\ r' & E_r\epsilon^{j\delta} \end{array} \tag{14}$$

$$G_s' = \begin{array}{c|cc} & s' & r' \\ \hline s' & & \\ r' & -jM & \end{array} \qquad \delta = \theta_2+\theta_3-\theta_1$$

Or, writing out the equations

$$\begin{aligned} &[r_s+L_s(p+jp\theta_1)]i^{s'} + M(p+jp\theta_1)i^{r'} = E_s \\ &M[p+j(p\theta_1-p\theta_2)]i^{s'} + \\ &\qquad \{r_r+L_r[p+j(p\theta_1-p\theta_2)]\}i^{r'} = E_r\epsilon^{j\delta} \end{aligned} \tag{15}$$

Torque = real of $(-jMi^{s'}i^{r'*})$

where

$$E_s = ji^{f_1}M_1p\theta_1 = jE_1 \qquad E_r = ji^{f_3}M_3p\theta_3 = jsE_3$$

Steady State

In the steady state $p=0$, $p\theta_1=\omega$, $p\theta_3 = p\theta_1 - p\theta_2 = s\omega$, and $\omega L = X$. Equation 15 then becomes:

$$\left.\begin{aligned} Z' &= \begin{array}{c|cc} & s' & r' \\ \hline s' & r_s+jX_s & jX_m \\ r' & jsX_m & r_r+jsX_r \end{array} \\ e' &= \begin{array}{c|c} s' & jE_1 \\ r' & jsE_3\epsilon^{j\delta} \end{array} \end{aligned}\right\} \tag{16}$$

The steady-state currents i^s and i^r required in the hunting equations of the next section, as well as the steady-state torque-angle characteristic, can be calculated from equation 16. In terms of the applied voltages, the currents are:

$$\left.\begin{aligned} i^{s'} &= \frac{jE_1\left(\frac{r_r}{s}+jX_r\right)+X_mE_3\epsilon^{j\delta}}{(r_s+jX_s)\left(\frac{r_r}{s}+jX_r\right)+X_m^2} \\ i^{r'} &= \frac{j(r_s+jX_s)E_3\epsilon^{j\delta}+X_mE_1}{(r_s+jX_s)\left(\frac{r_r}{s}+jX_r\right)+X_m^2} \end{aligned}\right\} \quad (17$$

However, in many cases the stator voltage, current, and power factor, instead of both applied voltages and the angle may be assigned. Then either equation 16, or more simply the equivalent circuit shown later, can be used to calculate δ, i^r and E_3.

Hunting Equations—Small Changes in the Complex Variables

(*a*). In setting up the equations of hunting of polyphase machines, two different methods may be followed:

1. The polyphase complex equations are first changed to real equations and the latter are subjected to small changes in the variables.
2. The polyphase equations are left unchanged in complex form and are subjected to small changes in the complex variables.

The second method will be followed in this paper, as it is a more compact analytical procedure.

(*b*). Let $p\theta_2 = p\theta_{20} + \Delta p\theta_2$ and so forth; then equation 15 or 14 with the use of the compound tensor (reference 2, page 116, equation 32),

$$\begin{array}{c|cc} & \Delta i & \Delta\theta \\ \hline \Delta e & Z & G \cdot ip - \frac{\partial e}{\partial \theta} \\ \Delta T & -i^* \cdot (G+G_t^*) & \end{array} \tag{18}$$

give the equations of hunting as:

$$Z' = \begin{array}{c|ccc} & s & r & \theta \\ \hline s & r_s+L_s(p+jp\theta_1) & M(p+jp\theta_1) & \\ r & M[p+j(p\theta_1-p\theta_2)] & r_r+L_r[p+j(p\theta_1-p\theta_2)] & -j(Mi^s+L_ri^r)p+sE_3\epsilon^{j\delta} \\ \theta & jMi^{r*} & -jMi^{s*} & \end{array} \tag{19}$$

where the real part of the last row is $-\Delta T_e$.

Steady Hunting

During steady hunting let $p = kh\omega$, where h is the per unit oscillation frequency and k plays the same role as j. That is $k^2=-1$, but kj cannot be combined. Then equations 19 become:

$$Z' = \begin{array}{c|ccc} & s & r & \theta \\ \hline s & r_s+X_s(kh+j) & X_m(kh+j) & \\ r & X_m(kh+js) & r_r+X_r(kh+js) & -j(X_mi^s+X_ri^r)kh+sE_3\epsilon^{j\delta} \\ \theta & jX_mi^{r*} & -jX_mi^{s*} & \end{array} \tag{20}$$

or, writing the equations out:

$$\begin{aligned} &[r_s+X_s(kh+j)]\,\Delta i^s + X_m(kh+j)\,\Delta i^r = 0 \\ &X_m(kh+js)\,\Delta i^s + [r_r+X_r(kh+js)]\,\Delta i^r = \\ &\qquad jkh(X_mi^s+X_ri^r)\,\Delta\theta_2 - sE_3\epsilon^{j\delta}\,\Delta\theta_2 - \\ &\qquad\qquad jX_mi^{r*}\,\Delta i^s + jX_mi^{s*}\,\Delta i^r = \Delta T_e \end{aligned} \tag{21}$$

where

$s = 1-v$ = per unit rotor average slip

$\delta = \theta_2+\theta_3-\theta_1$

Only the real part of the last equation (ΔT) is taken.

In calculating ΔT, first the j component is discarded as usual after rationalization

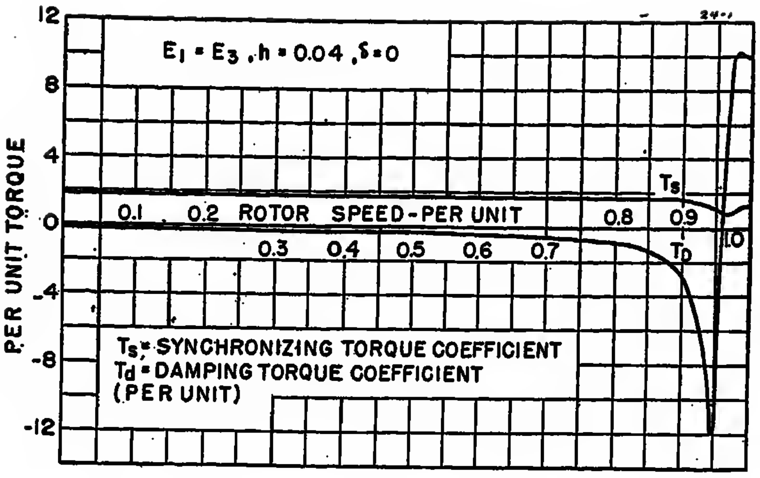

Figure 1. Damping- and synchronizing-torque coefficients of a typical doubly fed machine at no load

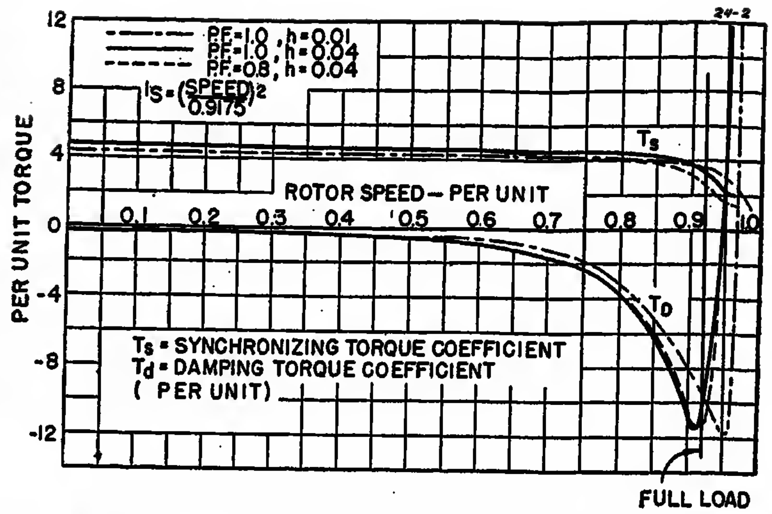

Figure 2 (right). Damping- and synchronizing - torque coefficients of a typical doubly fed machine

Effect of oscillation frequency and power factor. Load torque proportional to speed squared

so that ΔT is expressed in terms of k only (and not j). Then the $k-s$ in the denominator are rationalized, so that the synchronizing and damping torque coefficients are given by:

$$\Delta T = T_s + khT_D \tag{22}$$

Two separate symbols j and k are used in this procedure, in order to distinguish between the complex numbers introduced by the original use of the complex j currents, voltages, and fluxes as variables, and the further complex k numbers introduced by the use of the complex (exponential) rotor angular variation. It may readily be shown that at any stage one may revert to real transient voltage equations and have only the complex numbers due to the complex angular variation.

Eliminating Δi^s

If the row and column of s is eliminated from equation 20, or the stator current change Δi^s is eliminated from 21, then

$$Z' = \begin{array}{c|c|c} & r & \theta \\ \hline r & r_r + r_s''s + khX_r'' + j(sX_r'' - khr_s'') & khB_r + sE_s\epsilon^{j\delta} \\ \theta & -B_r^* + i^{r*}(r_s'' + jX_r'') & \end{array} \tag{23}$$

where

$$B_r = -j(X_m i^s + X_r i^r) = -j\psi_r$$

$$r_s'' = \frac{r_s X_m^2}{D'}$$

$$X_r'' = X_r - \frac{X_m^2}{D'} X_s(1-h^2) - khr_s''$$

$$D' = (r_s + khX_s)^2 + X_s^2$$

If again the rotor current Δi^r (row and column of r in equation 23) is eliminated, then the final equation for the torque change is:

$$\Delta T = \text{real of} \left[-\frac{(khB_r + sE_s\epsilon^{j\delta})[-B^* + i^{r*}(r_s'' + jX_r'')]}{r_r + r_s''s + khX_r'' + j(sX_r'' - khr_s'')} \right] \tag{24}$$

The phrase "real" and the asterisk (the conjugate symbol) refer to j and not to k. Both r_s'' and X_r'' are independent of the slip. First the ks are treated as algebraic symbols and the js are eliminated. Afterward the ks are treated as the complex operator k (where $k^2 = -1$). After rationalizing, equation 22 holds for the torque change of the doubly fed machine. Also, if the rotor impressed voltage E_s is zero, the equations apply to the small oscillations of a standard polyphase induction motor.

Appendix II. Three-Phase Short Circuit

In order to illustrate the characteristics of the doubly fed machine under transient conditions, three-phase short circuits on both stator and rotor in turn, neglecting initial loading, will be considered.

(a). Stator Short Circuit

Applying, by superposition, a stator voltage E_s, to equations 14 or 15, we obtain for the stator three-phase short-circuit current the operational expression:

$$i^{s'} = \frac{E_s}{r_s + L_s(p + j\omega_1) - \left\{ \dfrac{M^2(p + j\omega_1)(p + j\omega_3)}{r_r + L_r(p + j\omega_3)} \right\}} \tag{25}$$

where ω_1, ω_2, ω_3 are the constant stator frequency, rotor speed, and rotor frequency, respectively.

Taking for simplicity the stator resistance $r_s = 0$, this current may be written as:

$$i^s = i^{s'}\epsilon^{j\omega_1 t} = \frac{E_s\epsilon^{j\omega_1 t}}{j\omega_1\left[L_s - \dfrac{j\omega_3 M^2}{r_r + j\omega_3 L_r}\right]} - \frac{E_s}{j\omega_1\left[L_s + \dfrac{j\omega_2 M^2}{r_r - j\omega_2 L_r}\right]} + \frac{r_r(L_r - L_r')E_s\epsilon^{-\frac{r_r}{L_r'}t + j\omega_2 t}}{L_s(j\omega_2 L_r' - r_r)(j\omega_3 L_r' + r_r)} \tag{26}$$

where $L_r' = L_r - \dfrac{M^2}{L_s}$ = transient inductance viewed from the rotor terminals.

If the stator resistance r_s is considered, but rotor resistance $r_r = 0$, the short-circuit current becomes:

$$i^s = i\epsilon^{s'j\omega_1 t} = \frac{E_s}{r_s + j\omega_1 L_s'}\left(\epsilon^{j\omega_1 t} - \epsilon^{-\frac{r_s}{L_s'}t}\right) \tag{27}$$

where

$$L_s' = L_s - \frac{M^2}{L_r} \qquad \omega_1 L_s' = x_s'$$

In general, there are three components of current, stator fundamental frequency (ω_1), speed frequency (ω_2), and direct current. Note that with zero rotor resistance the speed frequency term disappears, leaving only the fundamental and d-c components in equation 27. The "d-c component" decays exponentially to zero, just as in case of a synchronous machine short circuit, but the usual transient component of alternating current is replaced by the speed frequency term.

(b). Rotor Short Circuit

Similarly applying a rotor voltage E_r in equations 14 or 15, the rotor short-circuit current becomes:

$$i^r = \frac{E_r}{r_r + L_r(p + j\omega_3) - \left\{ \dfrac{M^2(p + j\omega_3)(p + j\omega_1)}{r_s + L_s(p + j\omega_1)} \right\}} \tag{28}$$

Whence, with $r_{\text{rotor}} = 0$

$$i^r = i^{r'}\epsilon^{j\omega_3 t} = \frac{E_r\epsilon^{j\omega_3 t}}{j\omega_3\left[L_r - \dfrac{j\omega_1 M^2}{r_s + j\omega_1 L_s}\right]} - \frac{E_r}{j\omega_3\left[L_r - \dfrac{j\omega_2 M^2}{r_s + j\omega_2 L_s}\right]} - \frac{r_s(L_s - L_s')E_r\epsilon^{-\frac{r_s}{L_s'}t - j\omega_2 t}}{L_r(r_s + j\omega_2 L_s')(r_s + j\omega_1 L_s')} \tag{29}$$

and with $r_{\text{stator}} = 0$, but $r_{\text{rotor}} \neq 0$,

$$i^r = i^{r'}\epsilon^{j\omega_3 t} = \frac{E_r}{r_r + j\omega_3 L_r'}\left(\epsilon^{j\omega_3 t} - \epsilon^{-\frac{r_r}{L_r'}t}\right) \tag{30}$$

The three components of current are again the fundamental (ω_3), d-c, and speed frequency (ω_2) components, but now the presence of the speed frequency term depends on the stator resistance, and the d-c decrement depends on the rotor resistance.

In case of an induction frequency converter connected between two parts of a power system, it is evident that the converter may be approximately represented simply as a reactance (the machine short-circuit reactance). Since $E_r/E_s \cong \omega_3/\omega_1$ and $L_s' \cong L_r'$ on a one-to-one turn ratio basis, the rotor and stator short-circuit currents will be nearly equal in amperes, and will also be equal in per unit if the kva base is taken proportional to the frequency of the current being considered. Thus in a network diagram involving a 25 by 60 cycle converter, all the 25-cycle system reactances may be expressed on a kva base 25 by 60

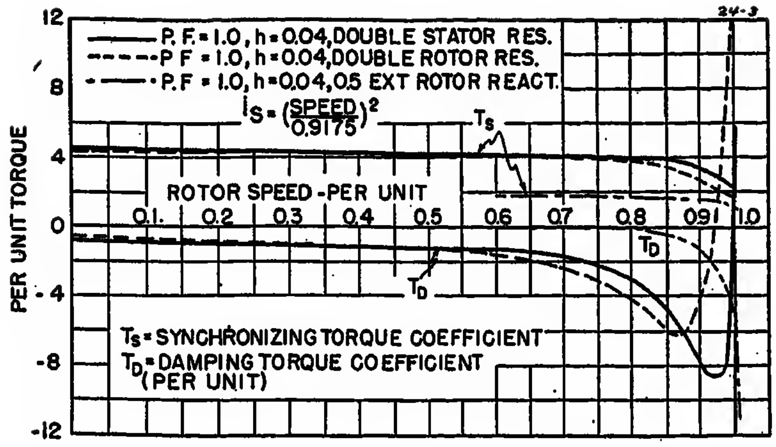

Figure 3. Damping- and synchronizing-torque coefficients of a typical doubly fed machine

Effect of change in stator and rotor resistance and in rotor reactance in machine of Figure 2

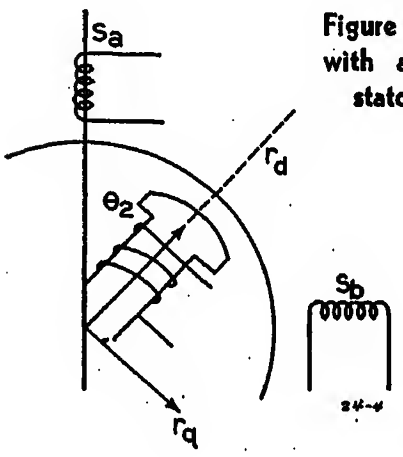

Figure 4. Machine with axes fixed in stator and rotor

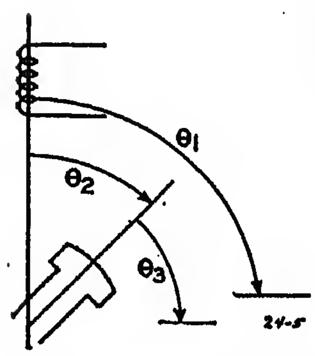

Figure 5. Machine with rotating reference axes

times as great as that for the 60-cycle system, to obtain a common diagram suitable for short circuit calculations on either part of the system.

Appendix III. Damping and Synchronizing Torque—Example

Several more or less typical curves of damping and synchronizing torque coefficients as a function of rotor speed are shown in Figures 1, 2, and 3. The machine of Figure 1 has all reactances and the stator resistance about twice as great as those of Figure 2, so that with an appropriate change of scale the effect of a change in rotor resistance may be estimated. Figure 2 shows the rather slight effect of a change of stator terminal power factor, and also the effect of oscillation frequency h in shifting the point at which maximum negative damping occurs. Figure 3 shows, for the machine of Figure 2 with an oscillation frequency of $h=0.04$, the effects of doubling the stator and rotor resistances in turn, and also the effect of a greatly increased rotor leakage (or added external) reactance.

Appendix IV. Equivalent Circuits for Hunting

Figure 6 gives equivalent circuits[3] which represent the doubly fed machine during rotor hunting as well as in the steady state. In using these equivalent circuits as set up on the a-c network analyzer, the required voltages are first read from the steady-state (upper) circuit and used as indicated to compute the voltages to be applied in the hunting (lower) circuit. The total steady-state torque as well as the components of the synchronizing (T_s) and damping (T_d) torque coefficients may then be read directly on a watt and reactive voltampere meter, according to the table of formulas shown under the circuits. Note that the formulas are based on the use of a watt- and varmeter which reads e^*i to form the complex expression $W+jQ$, where W is the wattmeter reading, and Q is the varmeter reading, both here and in Figure 6. As a simple example, consider a single generator supplying a reactive load unit. If generated voltage and current flowing out of the generator are measured, the watts will be positive and the vars will be negative.

The equivalent circuits are based on the stationary axes equations given previously by one of the authors in reference 2, page 146, rather than on the rotating axes equations derived in the paper. The reason for this is that the rotating axes formulas are simpler for hand calculations, while the stationary axes equations are simpler for equivalent circuit representation. The use of rotating axes leads to d-c steady-state quantities, so that only hunting frequency terms arise during the entire calculation of either the current or torque changes, while with stationary axes the steady-state quantities are of fundamental frequency, and fundamental plus hunting and fundamental minus hunting frequency currents and voltage changes must be separately considered. On the other hand, the rotating axis equations require four separate equivalent circuits (with two meshes each) in place of three. It should be remarked that in general the choice of proper reference axes is very important if the simplest method of solution is to be had, and that the best axes depend on not only the apparatus being analyzed, but also on the aspect or particular problem being considered and on the method of solution to be used (that is, hand or network analyzer).

Figure 6. Equivalent circuits for determination of steady-state and hunting torques

Equivalent Circuits for the Hunting of Electrical Machinery

GABRIEL KRON
ASSOCIATE AIEE

Synopsis: A general method is given to establish equivalent circuits for the determination of the hunting characteristics—such as damping and synchronizing torques—of standard types of electrical machines. The method is illustrated by setting up steady-state and hunting equivalent circuits for the salient-pole synchronous machine having amortisseur windings and for the doubly fed single-phase Selsyn with unbalanced windings, special cases of which are the capacitor motor and doubly fed polyphase motor. A companion paper, "The Doubly Fed Machine," contains a detailed study of the characteristics of one of the equivalent circuits as measured on the a-c network analyzer.

UNTIL recently the study of damping torque has been confined to synchronous machines and rotary converters. Operation of these machines without hunting has been obtained by the use of properly designed amortisseur or pole-face windings.

Now, however, a large number of systems of rotating machines are being put into use, in which altogether new and critical problems of hunting occur. In a number of cases, such as power Selsyn systems, and variable speed wind tunnel drives, exact and thorough going analysis of the hunting possibilities has been necessary before satisfactory operation could be secured. The purpose of this paper, therefore, is to present methods for more complete and ready analysis of these modern systems of interconnected rotating apparatus, so that hunting difficulties can be predicted and provided for in advance of installation.

The determination of the damping and synchronizing torques with standard methods involves an inordinate amount of analysis and calculation. The following equivalent circuits not only offer a clear physical picture of the interrelated phenomena taking place during small oscillations, but also enable one to get a quick numerical answer, either by the use of the a-c network analyzer, or by standard circuit methods.

The only practical equivalent circuits hitherto available were those of induction machines having symmetrical windings and running at a constant speed.[1,2] Recently steady-state equivalent circuits have been established for machines with asymmetrical windings, such as the capacitor motor,[4] also for machines with asymmetrical magnetic structure such as the salient-pole synchronous machine.[5] The extension in this paper from steady-state to hunting performance involves chiefly the application of a more complex voltage expression upon the network, and not any significant change in the network itself.

By a practical equivalent circuit is understood here one that allows the determination of not only the currents flowing and voltages appearing in every winding of the machine, but also the torques, as the speed or angle varies. The circuit must also allow the approximate consideration of the effect of saturation and iron loss.

Results

The equivalent circuits of the salient-pole alternator of Figure 1 and the necessary measurements to be made are shown in Figure 2, while those of the doubly fed single-phase Selsyn of Figure 3 are shown in Figure 4. Similar networks and measurements of other standard machines are shown on Figures 5 to 9. A detailed study of Figure 8 is undertaken in a companion paper, "The Doubly Fed Machine," showing numerous performance curves measured on the a-c network analyzer.

In all these equivalent circuits it should be noted that:

1. All equivalent circuits consist of a positive and a negative sequence network.

2. The asymmetry in the direct and quadrature axis windings appears as a single mutual impedance between the positive and the negative sequence network.

3. The asymmetry in the magnetic structure (the saliency) appears as a single mutual impedance, not only between the sequence networks, but also between the stator and rotor windings as well.

Also it should be noted that:

1. The hunting networks are the same as the steady-state networks, except that the resistances are divided by different constants.

2. Where two hunting networks are needed in place of one, the second differs from the first only in having the frequency of hunting h replaced by $-h$.

3. All impressed voltages on the hunting networks are measured off the steady-state network.

4. The steady-state torques and also the damping and synchronizing torques are measured directly by a wattmeter.

A Principle to Establish Models for Physical Systems

In setting up steady-state and hunting equivalent circuits for the various types of machines in a systematic manner, it has been found, as was to be expected, that only such collection of terms in the equations could be physically reconstructed or measured by instruments that formed a tensor. Geometric objects and other nontensor invariants could not be physically represented. Vice versa, it was also found that an equivalent circuit always gave a set of equations that formed a tensor equation.

It can be stated as an engineering principle that: A set of equations expressing

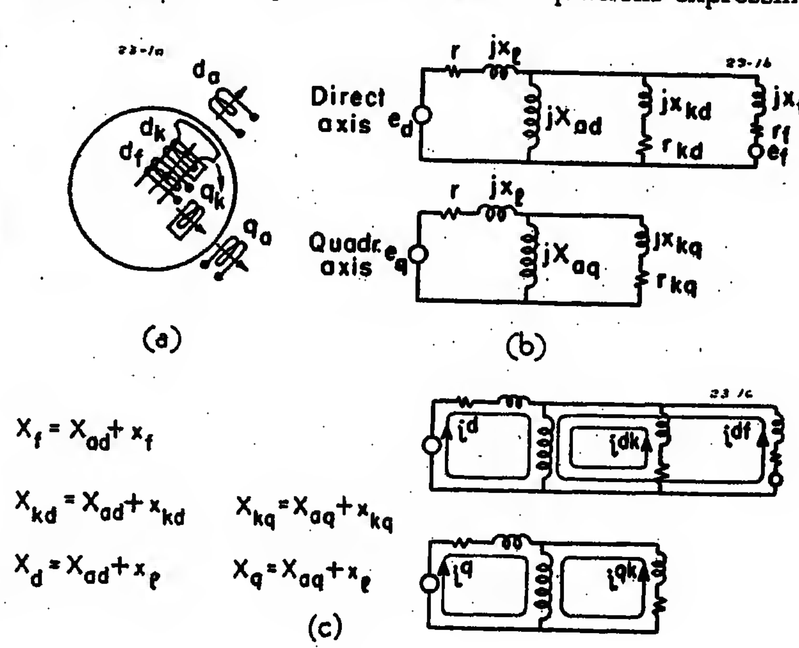

Figure 1. Reference axes and constants of the synchronous machine

Paper 42-3, recommended by the AIEE committee on electrical machinery, for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted October 6, 1941; made available for printing November 3, 1941.

GABRIEL KRON is consulting engineer in the engineering general department of General Electric Company, Schenectady, N. Y.

the performance of a physical system (be it electrical, mechanical, thermal, or any other system) may be represented by a model (equivalent circuit) only if the equations are tensor equations. That is, only tensors have physical existence, and only tensors can be measured. Vice versa, measurable physical entities always appear in the mathematical analysis as tensors.

This principle is only a consequence of previous statements that to explain the behavior of a physical system in terms of actually existing measurable physical entities, the system must be analyzed in terms of tensors. The equations of performance of simpler systems, such as stationary networks, automatically come out in a tensor form, whether they are so recognized or not, but that is not the case in more complex phenomena, such as the hunting of rotating machines. Tensors appear automatically only in special cases, while in others measurable concepts must be introduced either by experience or by the methods of tensor analysis.

Appendix I. Rules to Establish Equivalent Networks

The Determination of Torque on a Network

(*a*). When the rotor of an electrical machine rotates, at any one instant, four voltages appear in each of its windings (if all reference axes rotate with the same speed, including zero speed)

$$\mathbf{e}=\mathbf{R}\cdot\mathbf{i}+p\boldsymbol{\phi}+p\theta\mathbf{B} \quad \Big| \quad e_{\bar\alpha}=R_{\bar\alpha\beta}i^{\beta}+p\phi_{\bar\alpha}+p\theta B_{\bar\alpha}$$
$$\mathbf{e}=\mathbf{R}\cdot\mathbf{i}+p\mathbf{L}\cdot\mathbf{i}+p\theta\mathbf{G}\cdot\mathbf{i} \quad \Big| \quad e_{\bar\alpha}=R_{\bar\alpha\beta}i^{\beta}+pL_{\bar\alpha\beta}i^{\beta}+p\theta G_{\bar\alpha\beta}i^{\beta} \qquad (1)$$

where

$\mathbf{e}$ = impressed voltages
$\mathbf{R}\cdot\mathbf{i}$ = resistance drops
$p\boldsymbol{\phi}$ = induced voltages
$p\theta\mathbf{B}$ = voltage generated by cutting the rotor flux-density wave $\mathbf{B}$

The instantaneous torque on the rotor is the real part of

$$T=\mathbf{i}^{*}\cdot\mathbf{B}=\mathbf{i}^{*}\cdot\mathbf{G}\cdot\mathbf{i} \quad \Big| \quad T=i^{\alpha}B_{\bar\alpha}=i^{\alpha}G_{\bar\alpha\beta}i^{\beta} \qquad (2)$$

(*b*). The voltage equation 1 may be written

$$\mathbf{e}=\mathbf{Z}\cdot\mathbf{i} \quad \Big| \quad e_{\bar\alpha}=Z_{\bar\alpha\beta}i^{\beta} \qquad (3)$$

where the transient impedance tensor is defined as

$$\mathbf{Z}=\mathbf{R}+\mathbf{L}p+p\theta\mathbf{G} \quad \Big| \quad Z_{\bar\alpha\beta}=R_{\bar\alpha\beta}+L_{\bar\alpha\beta}p+p\theta G_{\bar\alpha\beta} \qquad (4)$$

In rotating machinery $\mathbf{G}$, hence $\mathbf{Z}$ is asymmetrical.

If the impedance tensor $\mathbf{Z}$ is symmetrical it is often possible to establish a stationary network whose performance is also $\mathbf{e}=\mathbf{Z}\cdot\mathbf{i}$. In all standard electrical machines it is possible to introduce a transformation $\mathbf{C}$ that changes the asymmetrical $\mathbf{Z}$ to a symmetrical $\mathbf{Z}'$, thereby allowing the establishment of an equivalent network.

The selection of the form of $\mathbf{C}$ depends on the desired reference frame to be employed and the desired form of the equivalent circuit. Hence $\mathbf{C}$ is different for different types of machines and interconnected systems.

(*c*). Since the equivalent network—when found with the aid of $\mathbf{C}$—corresponds to the equation of voltage 1 all the individual voltages $\mathbf{R}\cdot\mathbf{i}$ or $p\theta\mathbf{B}$ can be found on the network. Hence on all equivalent networks the rotor flux-density vector $\mathbf{B}$ appears as a set of differences of potential $\mathbf{E}$ (to a suitable scale) and can be easily traced on the network by reading the components of $\mathbf{G}\cdot\mathbf{i}$.

The torque then is given (in synchronous watts) by the wattmeter readings

$$\text{Torque}=T=\text{real part of } \mathbf{i}^{*}\mathbf{B}=\mathbf{i}^{*}\cdot\mathbf{E} \qquad (5)$$

where

$$\mathbf{E}=\mathbf{G}\cdot\mathbf{i} \qquad (6)$$

It has to be remembered that:

1. If in a product $\mathbf{i}$ and $\mathbf{E}$ are of different frequencies, then $\mathbf{i}\mathbf{E}^{*}$ is divided by two, giving the peak of the oscillating torque.
2. If both $\mathbf{i}$ and $\mathbf{E}$ are of the same frequency (including zero frequency) or if only one of them is of zero frequency, then $\mathbf{i}\mathbf{E}^{*}$ is not divided by two.

The Equations of Small Displacements

(*a*). When the rotor oscillates for any cause, θ becomes $\theta_0+\Delta\theta$, $\mathbf{i}$ becomes $\mathbf{i}_0+\Delta\mathbf{i}$, and so on, so that the above two equations become

$$\mathbf{e}+\Delta\mathbf{e}=\mathbf{R}(\mathbf{i}+\Delta\mathbf{i})+p(\boldsymbol{\phi}+\Delta\boldsymbol{\phi})+p(\theta+\Delta\theta)(\mathbf{B}+\Delta\mathbf{B}) \qquad (7)$$

$$T+\Delta T=\text{real part of } -(\mathbf{i}+\Delta\mathbf{i})^{*}\cdot(\mathbf{B}+\Delta\mathbf{B})+Mp^{2}(\theta+\Delta\theta) \qquad (8)$$

(where now T represents applied torque, hence the minus sign).

Subtracting the steady-state equations and neglecting second-order infinitesimals, the equations of small displacements are

$$\Delta\mathbf{e}=\mathbf{R}\cdot\Delta\mathbf{i}+p\Delta\boldsymbol{\phi}+p\theta\Delta\mathbf{B}+\Delta p\theta\mathbf{B} \qquad (9)$$

$$\Delta T=-(\mathbf{i}^{*}\cdot\Delta\mathbf{B}+\Delta\mathbf{i}^{*}\cdot\mathbf{B})+Mp^{2}\Delta\theta \qquad (10)$$

(The phrase "Real part of" will be left out in the following.)

Or in terms of constants

$$\Delta\mathbf{e}=\mathbf{R}\cdot\Delta\mathbf{i}+\mathbf{L}\cdot p\Delta\mathbf{i}+p\theta\mathbf{G}\cdot\Delta\mathbf{i}+\Delta p\theta\mathbf{G}\cdot\mathbf{i}$$
$$\Delta T=-(\mathbf{i}^{*}\cdot\mathbf{G}\cdot\Delta\mathbf{i}+\Delta\mathbf{i}^{*}\cdot\mathbf{G}\cdot\mathbf{i})+Mp^{2}\Delta\theta \qquad (11)$$

(*b*). The equation of small displacement may be written as

$$\Delta\mathbf{e}=\mathbf{Z}\cdot\Delta\mathbf{i}+\Delta p\theta\mathbf{G}\cdot\mathbf{i}$$

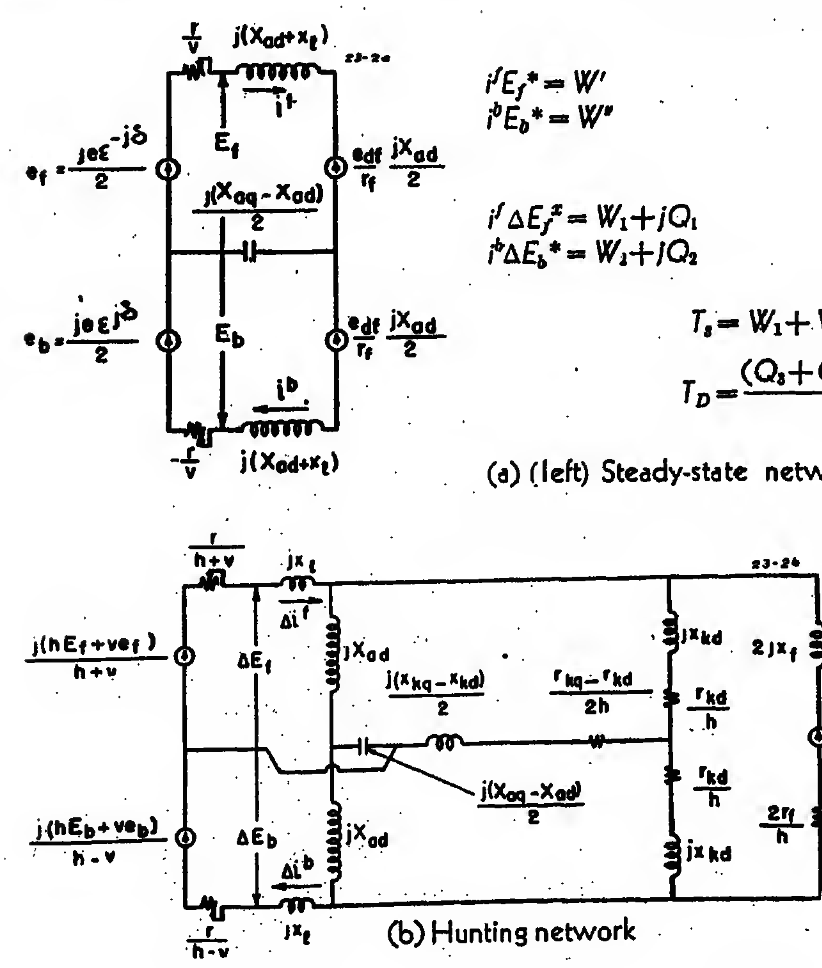
or

$$\boxed{\mathbf{Z}\cdot\Delta\mathbf{i}=\left(\frac{\partial\mathbf{e}}{\partial\theta}-\mathbf{B}p\right)\Delta\theta} \qquad (12)$$

where $\mathbf{Z}$ is defined in equation 4.

Hence during small oscillations the transient impedance tensor $\mathbf{Z}$ of any machine is the same as the $\mathbf{Z}$ during constant speed. However, two sets of impressed voltages appear:

1. $-\mathbf{B}\Delta p\theta$ representing the internal generated voltages due to cutting the steady-state rotor flux-



$$i^{f}E_{f}^{*}=W' \qquad i^{b}E_{b}^{*}=W'' \qquad T=W'+W''$$

$$i^{f}\Delta E_{f}^{*}=W_1+jQ_1 \qquad i^{b}\Delta E_{b}^{*}=W_2+jQ_2$$

$$\Delta i^{f}E_{f}^{*}=W_3+jQ_3 \qquad \Delta i^{b}E_{b}^{*}=W_4+jQ_4$$

$$T_s=W_1+W_2+W_3+W_4$$

$$T_D=\frac{(Q_3+Q_4)-(Q_1+Q_2)}{h}$$

density B by the oscillating speed change $\Delta p\theta$. This voltage appears in every machine.

2. $\partial e/\partial\theta$ representing the oscillation of the steady-state impressed voltage e. This voltage appears only in slip ring machines where e is a function of θ.

Also small voltage changes Δf may be impressed from outside.

Steady Hunting

(*a*). When the frequency of oscillations—say in spontaneous hunting or in driving a reciprocating load—is $h\omega$, and p is to be replaced by $jh\omega'$, care has to be exercised if the transient Z contains the complex operator j. Such cases can be analytically treated by introducing an additional complex operator k for $p = kh\omega'$ as shown in the companion paper "The Doubly Fed Machine." However to establish equivalent networks it is advisable to use a physical reference frame that does not introduce j in the transient Z, so as to avoid using equivalent networks with two sets of frequencies.

(*b*). In replacing p by $jh\omega'$ (assuming no j in the transient Z) two cases have to be distinguished (reference 7, page 119) depending on the reference frame used:

1. The steady-state currents i are constant. Then all p in equation 12 are replaced by $jh\omega$.

2. The steady-state currents i are of fundamental frequency. In such a case two sets of hunting equations are established:

(*a*). The currents Δi are of fundamental plus hunting frequency. Then all p in Z are replaced by $j(1+h)\omega$ and p in $Bp\Delta\theta$ by $jh\omega$.

(*b*). The currents Δi are of fundamental minus hunting frequency. Then all p in Z become $j(1-h)\omega$ and p in $Bp\Delta\theta$ becomes $-jh\omega$. That is h assumes a negative value.

(*c*). The hunting-frequency electrical torque ΔT comes out as a complex number

$$\Delta T = \frac{\partial T}{\partial \theta}\Delta\theta = (T_s + jhT_D)\Delta\theta \tag{13}$$

where T_s is the synchronizing-torque coefficient and T_D the damping-torque coefficient. If one of them is negative, the system is unstable. In calculating T_s and T_D only

$$C = \frac{1}{2}\begin{array}{c} \\ d \\ q \end{array}\begin{array}{cc} f & b \\ \hline 1 & 1 \\ -j & j \end{array} \qquad \gamma = \begin{array}{c} \\ d \\ q \end{array}\begin{array}{cc} d & q \\ \hline & -1 \\ 1 & \end{array}$$

$\Delta T/\Delta\theta$ is needed, hence in the impressed voltage $\Delta\theta$ may be left out or assumed to be any convenient constant.

If $\Delta\theta$ is given, the oscillating-frequency torque is

$$\Delta T = \Delta\theta\sqrt{T_s^2 + (hT_D)^2} \tag{14}$$

(*d*). Once p is replaced by $jh\omega$, and so on, it is permissible to introduce a C containing j.

Steps to Reduce Z to a Symmetrical Form

(*a*). In machines with sinusoidal space waves the torque tensor G may be expressed along any reference frame as

$$G = \gamma\cdot L \quad | \quad G_{\alpha\beta} = \gamma_\alpha{}^\gamma L_{\gamma\beta} \tag{15}$$

where γ is the rotation tensor. (Reference 7, page 62.) Hence the impedance tensor may be written as

$$Z = R + (pI + p\theta\gamma)\cdot L \tag{16}$$

where I is the unit tensor. The tensors R, I, and L are symmetrical in any reference frame, but γ is not. It is assumed that Z contains no j.

(*b*). To establish an equivalent network it is necessary to bring Z to a symmetrical form. Three steps are to be made:

1. Replacing p by $j\omega$ and $p\theta$ by $v\omega$,

$$Z = R + (I - jv\gamma)\cdot jX = R + n\cdot jX \tag{17}$$

where n contains the speed v as a parameter

$$n = I - jv\gamma \tag{18}$$

2. Bringing Z to a symmetrical form consists chiefly of discovering a transformation C that changes the rotation tensor γ to a diagonal form. When the physical reference axes have been judiciously selected and also are at right angles in space, one such C is that of the method of symmetrical components

$$\gamma' = \begin{array}{c} \\ f \\ b \end{array}\begin{array}{cc} f & b \\ \hline j & \\ & -j \end{array} \tag{19}$$

where $\gamma' = C_t{}^*\cdot\gamma\cdot C$. This step brings γ, hence n to a diagonal form. Except for the scalars n, the matrix of Z is now symmetrical.

Since the sequence axes are hypothetical axes, their introduction does not change the frequency of any quantity, and it is immaterial whether first the ps are replaced by $jh\omega$ and then are the sequence axes introduced or first the sequence axes are introduced, and then the ps are replaced by $jh\omega$.

3. Dividing the equation of voltage $e = Z\cdot i$ by n (or each equation by an appropriate scalar)

$$e' = n^{-1}\cdot e = (n^{-1}\cdot R + jX)\cdot i = Z'\cdot i \tag{20}$$

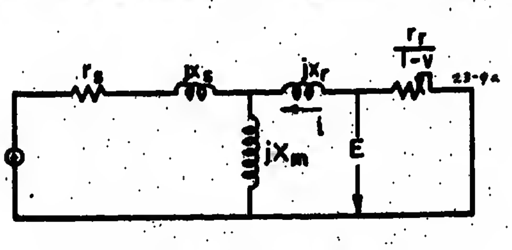
where Z' now is symmetrical. The resistances and the impressed voltages are functions of the speed v.

To find the torque, not only Z but also G must be transformed by C. Then $\omega G\cdot i = E$ is traced on the network. The torque is the real part of $i\cdot E^*$, that is the sum of the wattmeter readings.

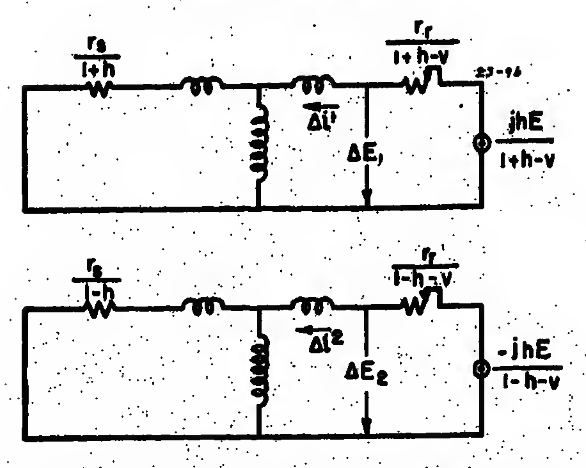
Steps to Establish the Steady-State Networks

1. The transient Z of the machine is first set up along a reference frame that gives a symmetrical Z.

2. The torque tensor G and impressed voltage vector e are also found along the same reference frame.



(a) Steady-state network



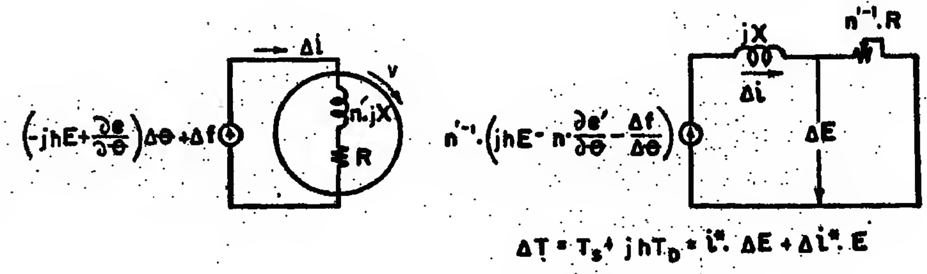
(b) Hunting networks (for torque formulas see Figure 8c)

Figure 9. The polyphase induction motor

Figure 10. Compound machines and their compound networks

(a) Steady-state machine and its equivalent network

(b) Hunting machine and its equivalent network



3. Replace p in $\boldsymbol{Z}$ by $j\omega$ (where ω may be zero).

4. Divide $\boldsymbol{Z}$ by $\boldsymbol{n}$.

5. Establish the steady-state network.

6. The impressed voltages are $\boldsymbol{e}'=\boldsymbol{n}^{-1}\cdot\boldsymbol{e}$.

7. The differences of potential $\boldsymbol{E}=\omega\boldsymbol{G}\cdot\boldsymbol{i}$ are indicated on the equivalent circuit.

8. The steady-state torque is the real part of $\boldsymbol{i}^*\cdot\boldsymbol{E}$.

Steps to Establish the Hunting Networks

1. Replace p in $\boldsymbol{Z}$ by $j\omega'$ (where ω' is $h\omega$ or $(1\pm h)\omega$ as indicated in a previous section).

2. Divide $\boldsymbol{Z}$ by $\boldsymbol{n}'$.

3. Establish the corresponding network or networks. They are the same as the steady-state network except that the resistances are divided by different constants $\boldsymbol{n}'$.

4. The voltages impressed on the hunting networks are

$$\Delta\boldsymbol{e}'=\boldsymbol{n}'^{-1}\cdot\left(jh\boldsymbol{E}-\boldsymbol{n}\cdot\frac{\partial\boldsymbol{e}'}{\partial\theta}-\frac{\Delta\boldsymbol{f}}{\Delta\theta}\right)\qquad(21)$$

where $\boldsymbol{E}$ and $\boldsymbol{e}'$ appear on the steady-state network, $\Delta\boldsymbol{f}$ is any outside impressed voltage change and h may be plus or minus. Also $\boldsymbol{n}\cdot\partial\boldsymbol{e}'/\partial\theta=\partial\boldsymbol{e}/\partial\theta$.

5. On the hunting network the differences of potential $\Delta\boldsymbol{E}=\omega\boldsymbol{G}\cdot\Delta\boldsymbol{i}$ are determined (they exist across the same junction-pairs as $\boldsymbol{E}$).

6. The following watts W and vars Q are measured

$$\Delta T/\Delta\theta=W+jQ=\boldsymbol{i}\cdot\Delta\boldsymbol{E}^*+\Delta\boldsymbol{i}\cdot\boldsymbol{E}^*=T_s+jhT_D\qquad(22)$$

7. The sum of the wattmeter readings is the synchronizing torque T_s and the sum of the varmeter readings (divided by h) is the damping torque T_D.

It should be remembered that:

1. By convention the varmeter reading $W+jQ$ is $\boldsymbol{i}\cdot\boldsymbol{E}^*$ and not $\boldsymbol{i}^*\cdot\boldsymbol{E}$; hence a negative Q gives positive T_D.

2. While $\boldsymbol{i}$ and $\boldsymbol{E}$ in the actual machine are rotating vectors $\boldsymbol{i}=(A+jB)\epsilon^{j\omega t}$; ΔT, also $\boldsymbol{i}$ and $\boldsymbol{E}$ in the networks are single-phase quantities, $\boldsymbol{i}=$real of $(C+jD)\epsilon^{j\omega t}$. When the frequency of a ΔT expression is $-\omega_h$ it represents a negative T_D.

Hence if the frequency of ΔT is $-\omega_h$ the varmeter reading Q keeps its sign. If ΔT is $+\omega_h$, the sign of Q is reversed.

3. If a ΔT expression is the product of two sinusoidal waves, one half of the product is the torque change.

Compound Networks

Just as ordinary equations may be represented physically by equivalent networks, analogously a set of tensor equations may also be represented physically by equivalent networks (see reference 6, page 480) in which each coil represents a whole network and each current represents several mesh-currents. Figure 10 shows the general form of steady-state and hunting networks for all machines in which no relative velocity exists between the reference axes.

Appendix II. The Salient-Pole Synchronous Machine

The Primitive Machine

Let the constants of the synchronous machine of Figure 1a be assumed as shown in Figures 1b and c. Its $\boldsymbol{Z}$, $\boldsymbol{G}$, and $\boldsymbol{e}$ tensors (or those of the primitive machine with five axes) have been given in reference 7, page 42 as (using X for inductance L in per unit as is customary in the per-unit system)

$$\boldsymbol{Z}=\begin{array}{c|ccccc} & d_f & d_k & q_k & d_a & q_a\\ \hline d_f & r_f+X_fp & X_{ad}p & & X_{ad}p & \\ d_k & X_{ad}p & r_{kd}+X_{kd}p & & X_{ad}p & \\ q_k & & & r_{kq}+X_{kq}p & & X_{aq}p\\ d_a & X_{ad}p & X_{ad}p & -X_{aq}p\theta & r+X_dp & -X_qp\theta\\ q_a & X_{ad}p\theta & X_{ad}p\theta & X_{aq}p & X_dp\theta & r+X_qp\end{array}\qquad(23)$$

$$\boldsymbol{G}=\begin{array}{c|ccccc} & d_f & d_k & q_k & d_a & q_a\\ \hline d_a & & & -X_{aq} & & -X_q\\ q_a & X_{ad} & X_{ad} & & X_d & \end{array}\qquad(24)$$

$$\boldsymbol{e}=\begin{array}{ccccc} d_f & d_k & q_k & d_a & q_a\\ \hline e_{df} & & & p\theta e\sin\delta & p\theta e\cos\delta\end{array}\qquad(25)$$

where $\delta=\theta-\theta_{\text{bus}}$. All the five reference axes are rigidly attached to the field and rotate with it. (Note the change in sign of $p\theta$.)

The machine is assumed to be connected to an infinite bus running at the same speed $p\theta$ as the field.

Reduction to Symmetrical Form

Let symmetrical components be introduced by the following transformation

$$\begin{aligned}i^{df}&=i^{df}\\ i^{dk}&=(i^{fk}+i^{bk})/2\\ i^{qk}&=-j(i^{fk}-i^{bk})/2\\ i^{da}&=(i^{fa}+i^{ba})/2\\ i^{qa}&=-j(i^{fa}-i^{ba})/2\end{aligned}\qquad(26)$$

$$\boldsymbol{C}=\frac{1}{2}\begin{array}{c|ccccc} & d_f & f_k & b_k & f_a & b_a\\ \hline d_f & 2 & & & & \\ d_k & & 1 & 1 & & \\ q_k & & -j & j & & \\ d_a & & & & 1 & 1\\ q_a & & & & -j & j\end{array}\qquad(27)$$

If now:

1. $\boldsymbol{C}_t^*\cdot\boldsymbol{Z}\cdot\boldsymbol{C}=\boldsymbol{Z}'$, $\boldsymbol{C}_t^*\cdot\boldsymbol{G}\cdot\boldsymbol{C}=\boldsymbol{G}'$ and $\boldsymbol{C}_t^*\cdot\boldsymbol{e}=\boldsymbol{e}'$ are calculated,

2. p is replaced by jh and $p\theta$ by v where v is the per-unit velocity of the machine,

3. $\boldsymbol{Z}'$ is multiplied by $\boldsymbol{n}'^{-1}$ where the value of $\boldsymbol{n}'$ is given in equation 28.

$$\boldsymbol{n}'=\begin{array}{c|ccccc} & d_f & d_k & q_k & d_a & q_a\\ \hline d_f & h & & & & \\ f_k & & h & & & \\ b_k & & & h & & \\ f_a & & & & h+v & \\ b_a & & & & & h-v\end{array}\qquad(28)$$

The results are

$$\boldsymbol{n}'^{-1}\cdot\boldsymbol{Z}'=1/4\times\begin{array}{c|ccccc} & d_f & f_k & b_k & f_a & b_a\\ \hline d_f & 4\left(\dfrac{r_f}{h}+jX_f\right) & 2jX_{ad} & 2jX_{ad} & 2jX_{ad} & 2jX_{ad}\\ f_k & 2jX_{ad} & (r_{kd}+r_{kq})/h+j(X_{kd}+X_{kq}) & (r_{kd}-r_{kq})/h+j(X_{ad}-X_{aq}) & j(X_{ad}+X_{aq}) & j(X_{ad}-X_{aq})\\ b_k & 2jX_{ad} & (r_{kd}-r_{kq})/h+j(X_{ad}-X_{aq}) & (r_{kd}+r_{kq})/h+j(X_{kd}+X_{kq}) & j(X_{ad}-X_{aq}) & j(X_{ad}+X_{aq})\\ f_a & 2jX_{ad} & j(X_{ad}+X_{aq}) & j(X_{ad}-X_{aq}) & 2r/(h+v)+j(X_d+X_q) & j(X_d-X_q)\\ b_a & 2jX_{ad} & j(X_{ad}-X_{aq}) & j(X_{ad}+X_{aq}) & j(X_d-X_q) & 2r/(h-v)+j(X_d+X_q)\end{array}\qquad(29)$$

The same result is found if first p is replaced by $jh\omega$, then $\boldsymbol{C}$ is introduced.

$$\boldsymbol{G}=\frac{1}{4}\begin{array}{c|ccccc} & d_f & f_k & b_k & f_a & b_a\\ \hline f_a & 2jX_{ad} & j(X_{ad}+X_{aq}) & j(X_{ad}-X_{aq}) & j(X_d+X_q) & j(X_d-X_q)\\ b_a & -2jX_{ad} & -j(X_{ad}-X_{aq}) & -j(X_{ad}+X_{aq}) & -j(X_d-X_q) & -j(X_d+X_q)\end{array}\qquad(30)$$

$$\boldsymbol{e}=\begin{array}{ccccc} d_f & f_k & b_k & f_a & b_a\\ \hline e_{df} & & & jve\epsilon^{-j\delta}/2 & -jve\epsilon^{j\delta}/2\end{array}\qquad(31)$$

$$=\begin{array}{ccccc} d_f & f_k & b_k & f_a & b_a\\ \hline e_{df} & & & ve_f & -ve_b\end{array}\qquad(32)$$

where e_f and e_b appear on the steady-state network of Figure 2a derived in reference 5.

The Hunting Equivalent Network

(*a*). The equivalent circuit of hunting (with per-phase constants) corresponding to Z' is shown in Figure 2b. It is established in the same manner as the steady-state network shown in reference 5.

It should be noted that at least two negative resistances are needed, one for each network. Such negative resistances may be used in conjunction with the a-c network analyzer. If no negative resistances are at hand, the networks of Figure 2 may be changed in a manner similar to that shown in reference 5, Figures 3b, 6, and 7.

(*b*). The components of $\Delta E = G' \cdot \Delta i'$ are shown in Figure 2b.

$$\Delta E = \frac{1}{4}\begin{array}{c|l|}
\cline{2-2}
f_a & 2jX_{ad}\Delta i^{df} + j(X_{ad}+X_{aq})\Delta i^{fk} + j(X_{ad}-X_{aq})\Delta i^{bk} + j(X_d+X_q)\Delta i^{fa} + j(X_d-X_q)\Delta i^{ba} \\
\cline{2-2}
b_a & -[2jX_{ad}\Delta i^{df} + j(X_{ad}-X_{aq})\Delta i^{fk} + j(X_{ad}+X_{aq})\Delta i^{bk} + j(X_d-X_q)\Delta i^{fa} + j(X_d+X_q)\Delta i^{ba}] \\
\cline{2-2}
\end{array} \qquad (33)$$

$$= \begin{array}{ccccc}
d_f & f_k & b_k & f_a & b_a \\
\hline
\multicolumn{1}{|c|}{} & \multicolumn{1}{c|}{} & \multicolumn{1}{c|}{} & \multicolumn{1}{c|}{\Delta E_f} & \multicolumn{1}{c|}{\Delta E_b} \\
\hline
\end{array} \qquad (34)$$

(*c*). To find the impressed voltages Δe on the hunting network, let equation 31 be differentiated

$$\frac{\partial e}{\partial \theta} = \begin{array}{ccccc}
d_f & f_k & b_k & f_a & b_a \\
\hline
\multicolumn{1}{|c|}{} & \multicolumn{1}{c|}{} & \multicolumn{1}{c|}{} & \multicolumn{1}{c|}{-jve_f} & \multicolumn{1}{c|}{-jve_b} \\
\hline
\end{array} \qquad (35)$$

Hence the resultant Δe is

$$\Delta e = n'^{-1}\left(jhE - \frac{\partial e}{\partial \theta} - \frac{\Delta f}{\Delta \theta}\right) \qquad (36)$$

$$\Delta e = \begin{array}{ccccc}
d_f & f_k & b_k & f_a & b_a \\
\hline
\multicolumn{1}{|c|}{-\dfrac{\Delta e_{df}}{h\Delta\theta}} & \multicolumn{1}{c|}{} & \multicolumn{1}{c|}{} & \multicolumn{1}{c|}{\dfrac{j(hE_f+ve_f)}{h+v}} & \multicolumn{1}{c|}{\dfrac{j(hE_b+ve_b)}{h-v}} \\
\hline
\end{array} \qquad (37)$$

On the field an impressed hunting-frequency voltage Δe_{df} may exist.

(*d*). By measuring the watts of $i^* \cdot E$ and the watts and vars of $i^* \cdot \Delta E + \Delta i^* \cdot E$ as shown on Figure 2c, the steady-state torque (per phase), also the damping and synchronizing torques are found. (Note the change in sign of T_D and T_s due to that of $\Delta p\theta$.)

In per unit on Figure 2a the impressed voltages $je/2$ and $e_{df}jX_{ad}/2r_f$ are $1/\sqrt{2}$.

Appendix III. The Single-Phase Instrument-Selsyn

The Primitive Machine

Let a single-phase induction motor be considered (Figure 3a) in which the ratio of the cross-phase to the main-phase turns is a. Let it be assumed that the impedances of the two stator windings differ by $Z = R + Lp + 1/pC$. Also on both stator and rotor windings let unbalanced voltages be impressed. (To simplify the equations the saliency of the stator will be neglected here, but is considered in Figure 4.)

The transient Z, G, and e of such a machine is [the primitive machine with four windings (reference 7, page 43, or reference 4)].

$$Z = \begin{array}{c|c|c|c|c|}
 & d_s & q_s & d_r & q_r \\
\hline
d_s & r_s+L_sp & & Mp & \\
q_s & & a^2(r_s+L_sp+Z) & & aMp \\
d_r & Mp & aMp\theta & r_r+L_rp & L_rp\theta \\
q_r & -Mp\theta & aMp & -L_rp\theta & r_r+L_rp \\
\hline
\end{array} \qquad (38)$$

$$G = \begin{array}{c|c|c|c|c|}
 & d_s & q_s & d_r & q_r \\
\hline
d_r & & aM & & L_r \\
q_r & -M & & -L_r & \\
\hline
\end{array} \qquad (39)$$

$$e = \begin{array}{cccc}
d_s & q_s & d_r & q_r \\
\hline
\multicolumn{1}{|c|}{e_{ds}} & \multicolumn{1}{c|}{e_{qs}} & \multicolumn{1}{c|}{e_{dr}} & \multicolumn{1}{c|}{e_{qr}} \\
\hline
\end{array} \qquad (40)$$

where (if $r_s = r_{sd}$ and $l_s = l_{sd}$ = leakage reactance)

$$Z = R + Lp + \frac{1}{pC} = \left(\frac{r_{sq}}{a^2} - r_{sd} + \frac{R_c}{a^2}\right) + \left(\frac{l_{sq}}{a^2} - l_{sd}\right)p + \frac{1}{pa^2C} \qquad (41)$$

Reduction to Symmetrical Form

Let symmetrical components be introduced by the transformation

$$i^{ds} = (i^{fs} + i^{bs})/2$$
$$i^{qs} = -j(i^{fs} - i^{bs})/2$$
$$i^{dr} = (i^{fr} + i^{br})/2$$
$$i^{qr} = -j(i^{fr} - i^{br})/2$$

$$C = \frac{1}{2}\begin{array}{c|c|c|c|c|}
 & f_s & f_r & b_s & b_r \\
\hline
d_s & 1 & & 1 & \\
q_s & -j/a & & j/a & \\
d_r & & 1 & & 1 \\
q_r & & -j & & j \\
\hline
\end{array} \qquad (42)$$

By $C_t^* \cdot Z \cdot C$, $C_t^* \cdot G \cdot C$, and $C_t^* \cdot e$

$$Z = \frac{1}{2}\begin{array}{c|c|c|c|c|}
 & f_s & f_r & b_s & b_r \\
\hline
f_s & r_s+L_sp+Z/2 & Mp & -Z/2 & \\
f_r & M(p-jp\theta) & r_r+L_r(p-jp\theta) & & \\
b_s & -Z/2 & & r_s+L_sp+Z/2 & Mp \\
b_r & & & M(p+jp\theta) & r_r+L_r(p+jp\theta) \\
\hline
\end{array} \qquad (43)$$

$$G = \frac{1}{2}\begin{array}{c|c|c|c|c|}
 & f_s & f_r & b_s & b_r \\
\hline
f_r & -jM & -jL_r & & \\
b_r & & & jM & jL_r \\
\hline
\end{array} \qquad (44)$$

If the rotor is connected to the rotor of another Selsyn with infinite inertia, or with assumed constant speed

$$e = \begin{array}{cccc}
f_s & f_r & b_s & b_r \\
\hline
\multicolumn{1}{|c|}{e_{fs}} & \multicolumn{1}{c|}{(1-v)e_{fr}\epsilon^{j\delta}} & \multicolumn{1}{c|}{e_{bs}} & \multicolumn{1}{c|}{(1+v)e_{br}\epsilon^{-j\delta}} \\
\hline
\end{array} \qquad (45)$$

$$= \begin{array}{cccc}
f_s & f_r & b_s & b_r \\
\hline
\multicolumn{1}{|c|}{e_{fs}} & \multicolumn{1}{c|}{(1-v)e_f} & \multicolumn{1}{c|}{e_{bs}} & \multicolumn{1}{c|}{(1+v)e_b} \\
\hline
\end{array}$$

Since the reference axes are stationary the frequency of the hunting currents is $(1+h)\omega$ and $(1-h)\omega$.

1. Replacing first p by $j(1+h)\omega$ $p\theta$ by $v\omega$, and dividing Z_1' by n_1'

$$n_1' = \begin{array}{c|c|c|c|c|}
 & f_s & f_r & b_s & b_r \\
\hline
f_s & 1+h & & & \\
f_r & & 1+h-v & & \\
b_s & & & 1+h & \\
b & & & & 1+h+v \\
\hline
\end{array} \qquad (46)$$

$$Z_1' = \frac{1}{2}\begin{array}{c|c|c|c|c|}
 & f_s & f_r & b_s & b_r \\
\hline
f_s & \dfrac{r_s}{1+h}+jX_s+\dfrac{Z_1}{2} & jX_m & -\dfrac{Z_1}{2} & \\
f_r & jX_m & \dfrac{r_r}{1+h-v}+jX_r & & \\
b_s & -\dfrac{Z_1}{2} & & \dfrac{r_s}{1+h}+jX_s+\dfrac{Z_1}{2} & jX_m \\
b_r & & & jX_m & \dfrac{r_r}{1+h+v}+jX_r \\
\hline
\end{array} \qquad (47)$$

where the mutual impedance of the sequence axes Z_1 may have the form

$$Z_1 = \frac{R}{1+h} + jX_L - \frac{jX_c}{(1+h)^2} \qquad (48)$$

2. Replacing p by $j(1-h)\omega$ and dividing Z_2' by n_2', the resultant Z_2' is the same as Z_1', except $+h$ everywhere is replaced by $-h$.

The same result is found if first p is replaced by $j(1 \pm h)\omega$ then C is introduced.

The Hunting Equivalent Networks

The corresponding two equivalent networks are given in Figure 4b showing also $\Delta E_1=\omega G'\cdot\Delta i_1$ and $\Delta E_2=\omega G'\cdot\Delta i_2$. The saliency of the d axis is taken care of by the addition of a condenser $j(X_{mq}-X_{md})$ common to all four meshes, as in the case of the salient-pole synchronous machine, Figure 2b.

The voltages impressed on the hunting networks are by

$$\Delta \mathbf{e}'=\mathbf{n}'^{-1}\cdot\left(Ep-\frac{\partial e}{\partial\theta}\right) \tag{49}$$

$$\Delta e_1'=\begin{array}{c|c|c|c} f_s & f_r & b_s & b_r \\ \hline & \dfrac{j[hE_f-(1-v)e_f]}{1+k-v} & & \dfrac{j[hE_b+(1+v)e_b]}{1+h+v} \end{array} \tag{50}$$

$$\Delta e_2'=\begin{array}{c|c|c|c} f_s & f_r & b_s & b_r \\ \hline & \dfrac{j[-hE_f-(1-v)e_f]}{1-h-v} & & \dfrac{j[-hE_b+(1+v)e_b]}{1-h+v} \end{array} \tag{51}$$

The torques are the real parts of

$$\Delta T=i^*\cdot(\Delta E_1+\Delta E_2)+(\Delta i_1+\Delta i_2)^*\cdot E \tag{52}$$

By measuring watts and vars, the torques per phase are found by the formulas shown in Table I.

Table I. Torque Formulas for the Single-Phase Motors of Figures 4–7

$i^f E_f^*=W'$	$i^b E^{b*}=W''$	$T=W'+W''$
$i^f\Delta E_{f1}^*=W_1+jQ_1$	$i^b\Delta E_{b1}^*=W_5+jQ_5$	
$i^f\Delta E_{f2}^*=W_2+jQ_2$	$i^b\Delta E_{b2}^*=W_6+jQ_6$	
$\Delta i^{f1}E_f^*=W_3+jQ_3$	$\Delta i^{b1}E_b^*=W_7+jQ_7$	
$\Delta i^{f2}E_f^*=W_4+jQ_4$	$\Delta i^{b2}E_b^*=W_8+jQ_8$	
$T_s=\dfrac{W_1+W_2+W_3+W_4+W_5+W_6+W_7+W_8}{2}$	$T_D=\dfrac{(Q_2+Q_3+Q_6+Q_7)-(Q_1+Q_4+Q_5+Q_8)}{2h}$	

Special Cases

1. *The Capacitor Motor.* The rotor-impressed voltages e_{fr} and e_{br} are zero, Figure 5.

2. *Polyphase Induction Motor on Unbalanced Voltages.* $Z=0$, Figure 6.

3. *The Single-Phase Induction Motor.* The rotor-impressed voltages are zero and $Z=\infty$, Figure 7.

4. *The Doubly Fed Induction Motor.* $Z=0$ and $a=1$. Also $e_{bs}=e_{br}=0$ and the negative-sequence networks are missing, Figure 8. This case is illustrated in detail in the companion paper.[3]

5. *The Polyphase Induction Motor.* $Z=0$, the negative-sequence networks are missing and the rotor-impressed voltage e_{fr} is also zero, Figure 9.

Appendix IV. More General Cases of Hunting

Machines With Arbitrary Reference Frames

When a relative velocity $p\theta'$ exists between the stator and rotor reference axes (as in interconnected slip ring machines such as Selsyns) the equation of voltage has an additional term $p\theta'V\cdot i$ in it, so that

$$e=(R+Lp+p\theta G+p\theta' V)\cdot i=Z\cdot i \tag{53}$$

The equation of hunting then is

$$Z\cdot\Delta i=\left[\frac{\partial e}{\partial\theta}-(G+V)\cdot ip\right]\Delta\theta=\left(\frac{\partial e}{\partial\theta}-E'p\right)\Delta\theta \tag{54}$$

However V is not a tensor and it cannot be physically represented.

In some cases (in machines with symmetrical structures) V may be changed into a tensor by assuming all reference axes to rotate at the same speed. But in case of interconnected synchronous machines or instrument Selsyns that assumption cannot be made.

Tensorial Form of the Hunting Equation

It is well-known that while the equation of Lagrange or its generalization, equation 53

$$e_\alpha=R_{\alpha\beta}i^\beta+a_{\alpha\beta}\frac{di^\beta}{dt}+\Gamma_{\beta\gamma,\alpha}i^\beta i^\gamma \tag{55}$$

is a tensor equation, the equation of small oscillations (derived from it by replacing x^α by $x^\alpha+\Delta x^\alpha$ and i^α by $i^\alpha+\Delta i^\alpha$) equation 54, or

$$\Delta e_\alpha=R_{\alpha\beta}\Delta i^\beta+a_{\alpha\beta}\frac{d(\Delta i^\beta)}{dt}+\Gamma_{\beta\gamma,\alpha}\Delta i^\beta i^\gamma+\Gamma_{\beta\gamma,\alpha}i^\beta\Delta i^\gamma+\frac{\partial\Gamma_{\beta\gamma,\alpha}}{\partial x^\delta}i^\beta i^\gamma\Delta x^\delta \tag{56}$$

is no longer a tensor equation. That is Δi^β itself is not a vector (tensor of rank one) nor can the various terms be grouped to form tensors. Hence, no physical model (equivalent circuit) can be established to represent these equations in the general case.

The tensorial form of the equation of small oscillations of dynamical systems in general and of electrical machinery in particular is[9]

$$\delta e_\alpha=R_{\alpha\beta}\delta i^\beta+a_{\alpha\beta}\frac{\delta(\delta i^\beta)}{dt}+K_{\delta\gamma\beta\alpha}i^\delta i^\beta dx^\gamma+R_{\gamma\beta\alpha}i^\beta dx^\gamma \tag{57}$$

where $K_{\delta\gamma\beta\alpha}$ is the Riemann-Christoffel curvature tensor and δi^β represent "absolute" or "covariant" differentials. This is the hunting equation whose equivalent circuit has to be established and this is the equation that fits the hunting equivalent circuits of machines having general reference axes.

Saturated Synchronous Machines Under Transient Conditions in the Pole Axis

REINHOLD RÜDENBERG
MEMBER AIEE

1. Introduction

THE performance of synchronous machines in steady-state operation, as well as in the transient state, is substantially determined by magnetic saturation in their iron circuits.[13,14,20] It is well-known that high initial and sustained short-circuit currents develop under widely different conditions of saturation and that large capacitive loading is unstable but for the effect of saturation.

The transition from one state of operation to another under the influence of changing saturation will be considered in this paper, and we will develop the transient phenomena from the magnetic characteristic of the machine. We fix our attention on the direct or pole axis since the fields in the quadrature axis of the rotor act essentially independently, according to Blondel's theorem.[6] The solution becomes obvious if we concentrate the saturation at the pole cores of the rotor and confine ourselves at first to symmetrical three-phase conditions in the stator and to constant speed of the machine. The analysis is simple[9] if the rotor consists of laminated cores surrounded only by exciting coils. It becomes more involved if damper windings or solid steel rotors are used having paths for eddy-current formation.

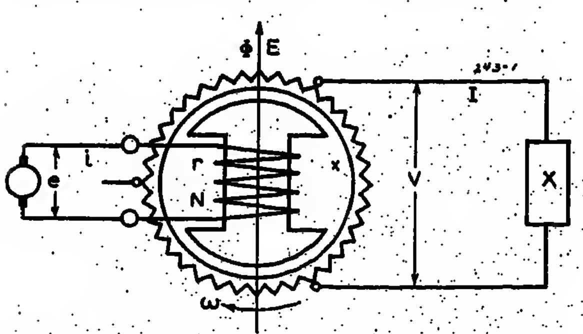

Figure 1. Constants of stator, rotor, and magnetic circuits of synchronous machine

2. Change With Time of the Main Flux

We consider first the stator circuit in Figure 1. The terminals with voltage V are loaded by an impedance X which, for simplicity, is shown with one phase only and may be purely reactive so that we have to consider only the pole axis of the machine. Consequently, the stator resistance may be neglected. Since higher harmonics are of secondary importance, we consider the phenomena of fundamental stator frequency only. With leakage reactance x, the external current I requires an internal electromotive force

$$E = V + xI = (X+x)I \tag{1}$$

This relation holds only if the amplitude variation of the current with time is slow compared with the harmonic variation due to the frequency ω,

$$\frac{dI}{dt} \lesssim \omega I \tag{2}$$

an assumption which will be verified later. With internal resistance and external active load, equation 1 remains unchanged in form, except that it then has a vector significance.

Secondly, we consider the rotor circuit in Figure 1. The external excitation voltage e is given either as constant or as a known function of time. With resistance r, number of turns N, and rotor pole flux Φ, the exciting current i in the transient state is determined by

$$e(t) = ri + N\frac{d\Phi}{dt} \tag{3}$$

This expression can be transformed by introducing the electromotive force E rather than the flux Φ, both always being proportional,

$$\Phi/\Phi_0 = E/E_0 \tag{4}$$

If we denote the rated values of flux Φ_0, stator voltage E_0 and rotor voltage e_0, the last term of equation 3 equals either of the two following expressions:

$$N\frac{d\Phi}{dt} = T_m\frac{dE}{dt} = e_0 T_p\frac{d(E/E_0)}{dt} \tag{5}$$

Herein

$$T_m = N\Phi_0/E_0 \tag{6}$$

is a time constant of the complete machine which has the advantage of being constant entirely independent of the magnetic saturation, while

$$T_p = N\Phi_0/e_0 \tag{7}$$

is a time constant of the rotor poles with their field windings, which has a simpler physical significance and is constant so long as the rated rotor values remain unchanged.

The rotor circuit-equation 3 now becomes, using equation 7,

$$e(t) = ri + e_0 T_p\frac{d(E/E_0)}{dt} \tag{8}$$

It is expedient to take for Φ in equation 3 the total pole-core flux which is linked completely with the exciting winding. The electromotive force E in equation 4 corresponds to this flux, which is regarded, as usual, as the main flux of the machine to which also the magnetic characteristic is related. Hence the difference between electromotive force E and terminal voltage V is caused by the leakage fluxes of both stator and rotor and thus x in equation 1 defines the sum of stator and rotor

Paper 42-43, recommended by the AIEE committee on basic sciences for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted August 1, 1941; made available for printing December 19, 1941.

REINHOLD RÜDENBERG is professor of electrical engineering in the graduate school at Harvard University, Cambridge, Mass.

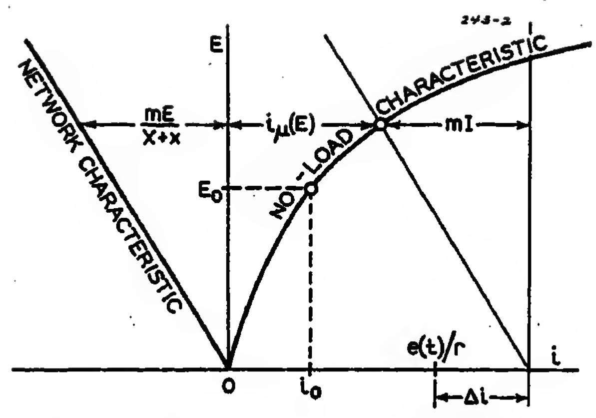

Figure 2. Internal and external excitation characteristics

leakage reactances,[7] both related to the stator circuit.

Thirdly, we consider the magnetic circuit of the machine in the direct or pole axis. With open stator terminals, the correlation of electromotive force E and exciting current i is given as "no-load characteristic" by the functions

$$E=E(i) \text{ or } i=i(E) \tag{9}$$

The rotor leakage at no load may be included herein.

With loaded machine the armature reaction of the current I causes a change of the resultant excitation. We can express this change by mI if m is a numerical factor expressing the effective turn ratio of stator and rotor windings, including the correction due to leakage and the effect of phase displacement in case of active load. If we consider the demagnetizing effect of inductive current as positive, the magnetic characteristic under load[1] is given by the function

$$E=E(i-mI) \tag{10}$$

which can be inverted to

$$i=i_\mu(E)+mI \tag{11}$$

This relation for the total exciting current i is represented by Figure 2. Herein $i_\mu(E)$ is that part of the exciting current which is needed for the magnetization of the internal main synchronous flux and mI is that part which is necessary for the magnetization of the electric stator circuit and which is transferred through the machine to the external load.

Not only the first but also the second part of the current in equation 11 is dependent solely on the electromotive force E, corresponding to the main flux Φ. We see this immediately by equation 1 since

$$I=\frac{E}{X+x} \tag{12}$$

This is represented at the left-hand side of Figure 2, and we will denote this line as the "network characteristic." With constant external and internal impedances this characteristic is a straight line through the origin, as shown in Figure 2. Its slope in terms of stator voltage and current is given merely by

$$X+x$$

If now we insert the stator current of equation 12 in equation 11, and the rotor current of equation 11 in equation 8, and define the rated exciting current i_o by

$$e_o=ri_o \tag{13}$$

we obtain the final relation for our problem

$$T_p\frac{d(E/E_o)}{dt}=\frac{e(t)/r-[i_\mu(E)+mE/(X+x)]}{i_o} \tag{14}$$

Thus, the change with time of the relative stator voltage E/E_o of the machine is determined by the difference of the fictitious steady-state or ohmic rotor current, namely e/r, under the impressed voltage $e(t)$, and the sum of the actual internal and external magnetizing currents necessary to produce the voltage E. This difference, indicating a current of unbalance, is denoted by Δi in Figure 2 and is obtained by drawing a parallel to the network characteristic through the working point on the no-load characteristic. If the difference Δi is positive, the voltage E increases; if Δi is negative, the voltage decreases. In both cases the rate of change is inversely proportional to the time constant T_p of the rotor.

Since the right-hand side of equation 14 depends only on the two variables t and E, we can solve this differential equation graphically for many problems. It is convenient to write equation 14 in a purely numerical form, namely

$$\frac{d(E/E_o)}{d(t/T_p)}=\frac{e(t)}{e_o}-\frac{\Sigma i(E)}{i_o} \tag{15}$$

where the last term on the right-hand side represents the excitation current of the entire internal plus external magnetic characteristic, as shown in Figure 3a. In Figure 3b and 3c there are derived by use of equation 15 the changes with time of voltage and exciting current when the load current of the generator is suddenly decreased. Under the influence of a voltage regulator a series resistance in the shunt excitation of the exciter may be switched on and off when the voltage E passes through the rated value. The voltage curve $e(t)$ of the exciter is given in Figure 3c, and the difference at every instant between this voltage and the total exciting current, taken from the characteristic in Figure 3a, both given in relative values, determines the rate of change of the voltage E, as indicated in Figure 3b. Step by step, the complete set of curves can be derived in this way, and experiments show that such curves agree well with actual oscillograms.[5,8]

For many important phenomena, the excitation voltage e remains constant during the transient process and this simplifies the problem materially. The exciting current immediately before the instant of switching is

$$i_1=e_1/r \tag{16}$$

e_1 denoting the constant rotor voltage. The first term on the right-hand side of equations 14 and 15 now is independent of time and this relation can be written

$$T_p\frac{(dE/E_o)}{dt}=\frac{i_1}{i_o}-\frac{\Sigma i(E)}{i_o}=\frac{\Delta i(E)}{i_o} \tag{17}$$

where the difference current Δi is now dependent on the voltage E only. From Figure 4a we see that this value

$$\Delta i=i_1-i_\mu-mI \tag{18}$$

is given by the difference shown shaded between the internal magnetic characteristic of the machine and the external network characteristic, drawn backwards

Figure 3. Point-by-point derivation of voltage- and current-time curves after sudden drop of load

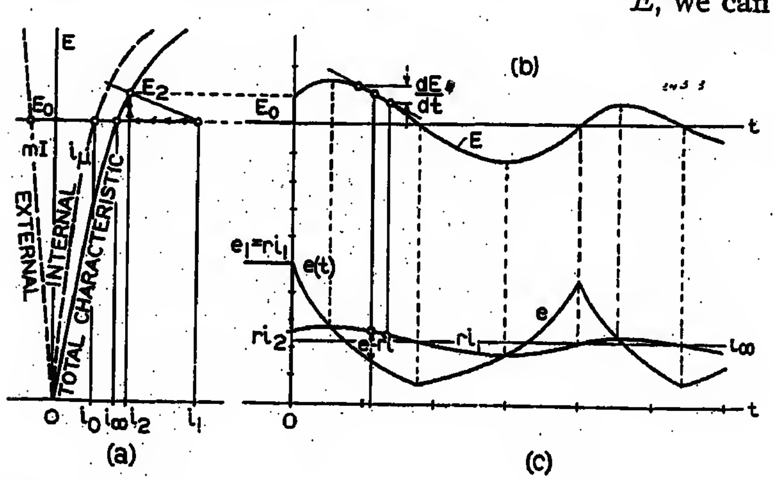

Figure 4. Derivation of transient voltages and currents at inductive loading with constant excitation voltage

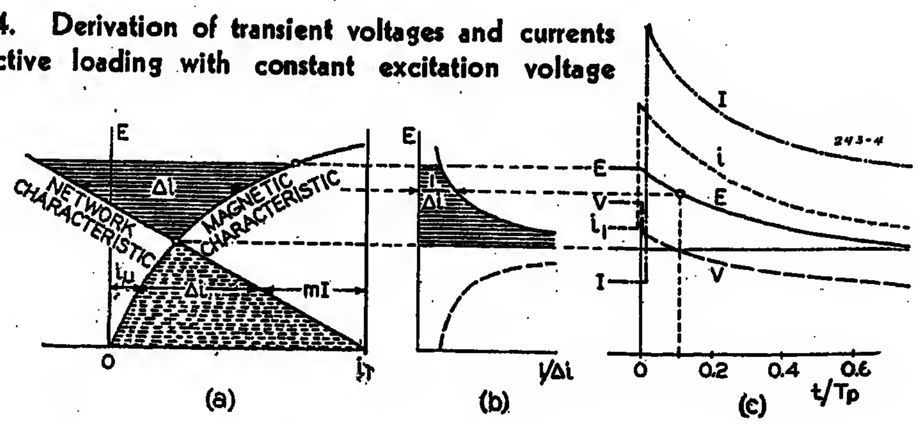

from the original exciting current i_1. For every voltage E the change with time of the voltage is determined, therefore, by the horizontal distance between the two characteristics, and the entire E curve can easily be derived graphically. We can integrate equation 17 rigorously by separation of the variables and obtain the time elapsed since the instant of switching

$$t=T_p\int\frac{d(E/E_0)}{\Delta i/i_0} \tag{19}$$

This constitutes a simple quadrature and Figure 4b and c show how the E curve plotted against time can be derived by graphical integration of an auxiliary curve, $1/\Delta i$ dependent on E.

The electromotive force E departs from the initial value which is determined by the previous operation of the machine, decreases at a rate determined by the value of Δi and approaches asymptotically the intersection of the internal and external characteristics, indicating a state of equilibrium. This new steady-state value may be approached from above or from below, depending upon the initial magnitude of the voltage E.

3. Transient Voltages and Currents

The other parameters of operation, as terminal voltage, exciting current, and stator current, can easily be determined graphically. According to equation 1, the terminal voltage V is the difference be-

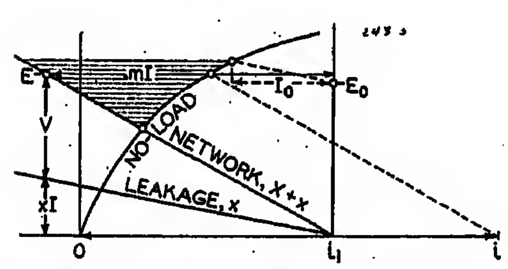

Figure 5. Three characteristics which are constant during inductive transient performance

tween electromotive force E and leakage reactance voltage xI. If, therefore, we draw in Figure 5 through the steady-state exciting current i_1 a straight line representing the leakage characteristic of the synchronous machine, with slope x rather than $X+x$ as for the network characteristic, this line subdivides the entire voltage E into two parts, namely, the terminal voltage V and the leakage voltage xI. Thus we can take the value of V for every value of E and transfer it to the time diagram, Figure 4c. While the electromotive force E is continuous at the instant of switching, the terminal voltage V jumps by an amount equal to the change of

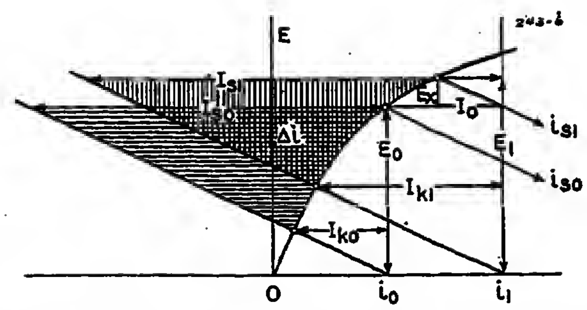

Figure 6. Unbalance of currents at sudden short circuit under two previous machine conditions

leakage voltage at the instant of switching.

The value mI for the stator current I is given in Figure 5 by the horizontal distance between the characteristic point at the value E on the network characteristic and the vertical through the exciting current i_1. This follows directly from the definition of the network characteristic. Thus the stator current I can also be plotted in the time diagram, Figure 4c. The exciting current given by equation 11 is, according to Figure 5, the value cut off the i axis at a given instant by a line through the E point at the no-load characteristic and parallel to the network characteristic. It also is transferred to Figure 4c. Stator current and rotor current behave discontinuously at the instant of switching and jump suddenly to their new values, decreasing subsequently with time to their steady-state values, which for the exciting current coincides with the magnitude prior to the switching process.

In every case it is easy to determine the correct scale for the stator current. We need only to consider the Potier triangle in Figure 5, which by its magnitude for zero power factor gives a direct measure of the rated stator current. Thus we can measure I directly, rather than mI in the rotor scale.

A significant case of operation is the sudden short circuit of a synchronous machine at its terminals. Since now there is no external reactance X, the network characteristic becomes identical with the leakage characteristic and, therefore, drops in position. This is shown in Figure 6 for two different prior exciting currents, corresponding to no-load and to full-reactive-load conditions. The equilibrium of the currents in the machine is now heavily disturbed, and thus a large difference current Δi occurs. The voltage E, therefore, decreases rapidly, and very large currents are built up, constituting in the stator an alternating current I and in the rotor a direct current i, both decreasing continuously from their initial values to the final sustained values. Hence we have developed a method for determining

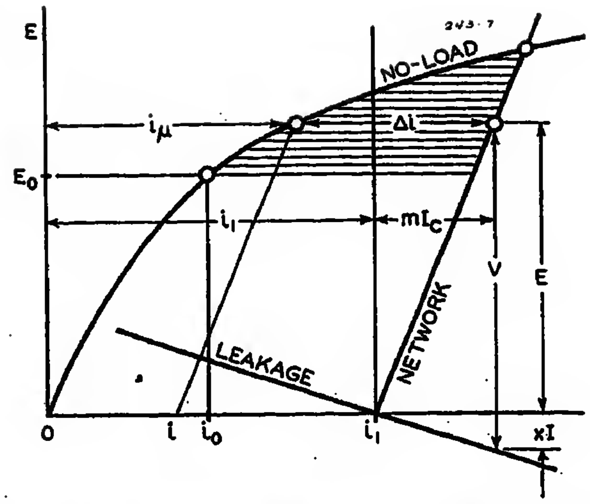

Figure 7. Three characteristics which are constant during capacitive transient performance

numerically the change with time of these currents with any given saturation of the synchronous machine. Figure 6 shows that the initial short-circuit stator currents I_s for prior no-load and full-load conditions differ only slightly, this difference being equal to the magnitude of the prior load current, though the sustained currents I_k are widely different. In any case, the value of the initial alternating short-circuit current, given by the similarity of the triangles, is

$$I_s/I_0=E/E_x \tag{20}$$

where E denotes the electromotive force at the instant of short circuit and E_x the total leakage voltage of the machine at rated current I_0.

Another interesting case is the capacitive loading of a synchronous generator. The load current now is, by equation 1

$$I=\frac{E}{-1/\omega C+x}=\frac{\omega C}{1-\omega Cx}E=-I_c \tag{21}$$

and thus changes sign. The network characteristic therefore must be drawn from the exciting current i_1 toward the right-hand side, as in Figure 7, the slope being determined by the coefficient of E in equation 21. The increment of the capacitive current due to the combined action of external capacitive reactance and internal leakage inductance is given by the denominator of this coefficient. Resonance would be approached only for very large values of the capacitance. Equation 18 can now be written in the form

$$\Delta i=i_1-i_\mu+mI_c \tag{22}$$

and we see from Figure 7 that Δi is again the horizontal difference between the no-load characteristic and the capacitive characteristic of the stator network. However, since Δi has changed its sign compared with the inductive loading of Figure 4, the voltage now increases with time toward the final value, again deter-

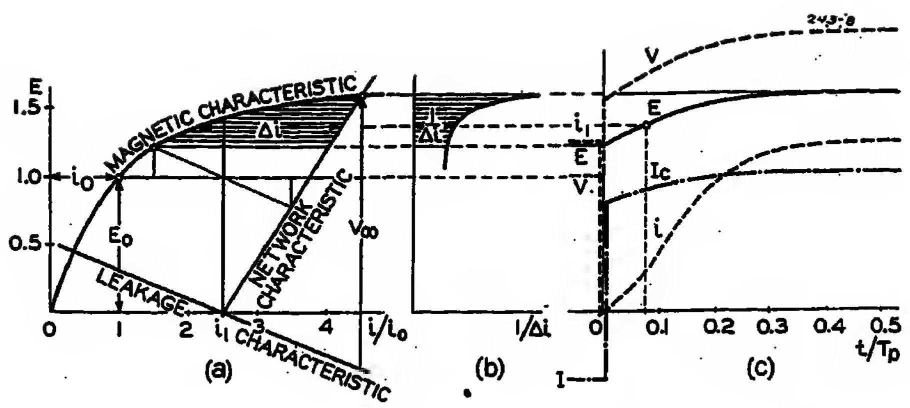

Figure 8. Derivation of transient voltages and currents at capacitive loading with constant excitation voltage

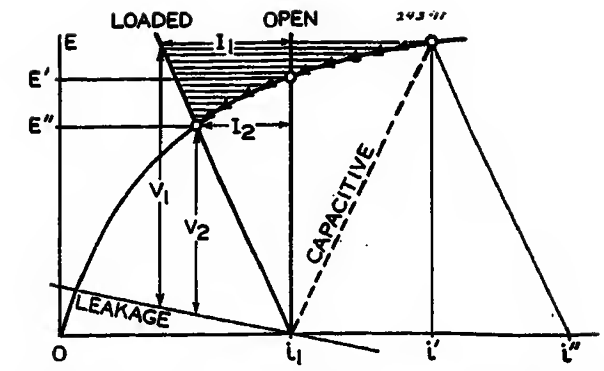

Figure 11. Interruption of capacitive load and recovery toward loaded or open-circuited condition

mined by the intersection of the two characteristics.

The terminal voltage V is always the vertical distance between network and leakage characteristics. If we lengthen the leakage characteristic in Figure 7 beyond the current i_1, we see that V becomes larger than the electromotive force E by reason of the inductive voltage rise produced by the capacitive current. A parallel line to the network characteristic through the E point on the no-load characteristic cuts off on the abscissa the magnitude of the exciting current i, as shown in Figure 7. The transient exciting current here is temporarily fairly small and even may become negative.

Figure 8 represents the sudden capacitive loading of a synchronous generator, previously under full inductive load, when the capacitance is so chosen that it would give full load under normal voltage. By drawing the inverted difference current $1/\Delta i$ and integrating this, we obtain in Figure 8c the change of voltage E with time, according to equation 19, and by graphical correlation we can add the other curves for terminal voltage V, stator current I_c and exciting current i. At the instant of switching all magnitudes, except the electromotive force E, jump to their new transient values. The exciting current returns finally to its original value i_1, and electromotive force, stator current and, particularly, terminal voltage attain high magnitudes.

We now can state the general rule for any transient change in synchronous machines with constant excitation voltage. Up to the initiation of the switching process the machine may have worked, as in Figure 9, with an exciting current i_1 and an electromotive force E, both determined by the intersection of the no-load machine characteristic with the prior load network characteristic. When the network characteristic suddenly changes by a definite amount, turning to the left-hand side with increase of inductive load or to the right-hand side with decrease of inductive load or increase of capacitive load, the working point of the machine moves along the magnetic characteristic toward the new intersection at a rate given by equation 17 or 19, which is proportional to the current difference Δi of the shaded areas in Figure 9.

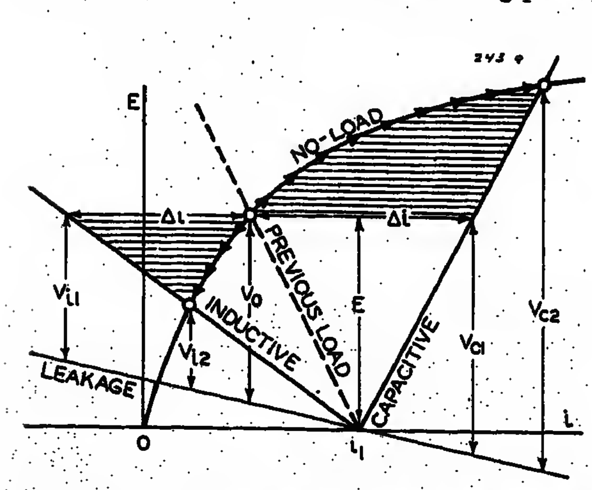

Figure 9. Unbalance of currents at sudden change of general reactive load

The phenomena occurring with removal of load of a synchronous machine are also easy to describe. If, for example, the sustained terminal short-circuit current of a generator is suddenly interrupted, as in Figure 10, the exciting current jumps temporarily to a very small value, i' or i'' according as the load changes to zero or to a finite value. The electromotive force E increases with a rate determined by the width of the shaded areas, and the momentary values of terminal voltage V and stator current I for any instant can easily be taken from the diagram by projecting from the load characteristic to the no-load and short-circuit lines. If, on the other hand, a capacitive load is switched off[4,12] as in Figure 11, the exciting current jumps temporarily to the larger value i' or i'', according to the final-load or no-load condition. Stator voltages and current can also be taken from the diagram, using the shaded areas and following the same scheme as before.

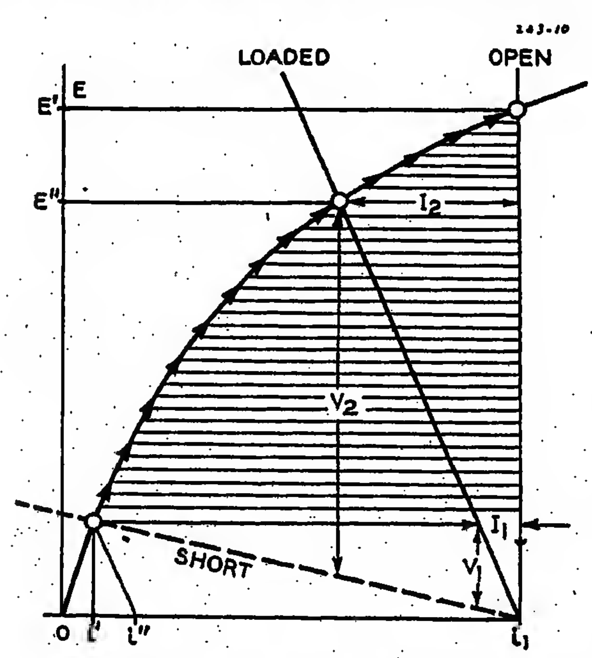

Figure 10. Interruption of short circuit and recovery toward loaded or open-circuited condition

The only magnitude of our main equations 17 and 19 which is not contained in the diagram of characteristics is the time constant T_p of the rotor pole flux. Calculations according to equation 7 and oscillographic experiments have shown that for machines of the usual design for 50–60 cycles per second, with no additional resistance in the excitation circuit, the time constant T_p varies mainly with the synchronous power generated by each pole. It is:

for	100	1,000	10,000	kva per pole
in the order of				
$T_p=$	3	6	12	seconds

With numerical values of the integral of equation 19 such as are given on the axis of abscissae in Figures 4 and 8, we realize that the actual change with time of currents and voltages is always very slow compared with the change due to the frequency 50 or 60 cycles per second. Our assumption in equation 2 is verified therefore.

However, this is true only during the transient state following the instant of switching, but is not true for the time $t=0$ at which the switching occurs. Our curves for the stator currents and voltages represent only the amplitudes of the harmonically varying magnitudes, so that a jump of these amplitudes at $t=0$ does not mean necessarily an actual discontinuity but merely a rapid variation compared to the slower succeeding change. It is well-known that other transient currents may appear which prevent a discontinuous transition between the values immediately before and immediately after $t=0$. These additional transient currents flow without impressed voltage, suffer a rapid decay, and bridge the jump of the amplitudes only at the instant of

switching. Their initial values, therefore, are given directly by the jumps of the currents and voltages in our time diagrams.

If the synchronous machine is loaded by self-inductance, either external or only internal, the superposed transient current is a decaying direct current, its time constant being that of the stator circuit. If, however, the load consists of capacitance, the superposed current is a damped oscillating current, the natural frequency being determined by capacitance and self-inductance of the machine and the load. It is well-known that the actual currents or voltages, by the additional effects of these free intermediate currents, may rise temporarily to about double the value of the original discontinuous magnitudes.

The rate of change of any curve can be expressed significantly by the value of the subtangent S. This is shown in Figure 12b with curve E which is derived from the characteristics in Figure 12a of the magnetic and electric circuits of a synchronous machine. By using equation 17 we can express the subtangent, as cut off on the asymptotic axis,

$$S=\frac{\Delta E}{dE/dt}=T_p\,\frac{\Delta E/E_o}{\Delta i/i_o} \tag{23}$$

if we denote by ΔE the difference of the momentary and final voltages, corresponding to the current difference Δi. Hence the ratio of the subtangent to the time constant of our problem is given by the ratio of the height to the width of the shaded characteristic area in Figure 12a, both measured in relative values.

Let us consider two extreme examples with different asymptotic points of equilibrium. With no load of a nonsaturated machine, we see from Figure 13a that

$$\left.\begin{aligned}&\Delta E/\Delta i=E_o/i_o\\ &\text{hence}\quad S_o=T_p\end{aligned}\right\} \tag{24}$$

or the subtangent equals the time constant. With saturation, corresponding to the dashed curve in Figure 13a, ΔE for the same Δi is smaller than before and, therefore, $S<T_p$.

With terminal short circuit of a nonsaturated machine, Figure 13b shows, with I_s for the sudden and I_k for the sustained short-circuit current, that

$$\left.\begin{aligned}&\Delta i=mI_s,\quad \Delta E=E_o\,\frac{mI_k}{i_o}\\ &\text{hence}\quad S_k=T_p\,\frac{I_k}{I_s}\end{aligned}\right\} \tag{25}$$

and the subtangent is a fraction only of the rotor-pole time constant T_p. This means that the equivalent self-inductance of the field winding is reduced by the reaction of the short-circuited armature. Thus the decay of the electromotive force and of the main flux of a machine under short-circuit conditions is more rapid than under no-load conditions in the ratio of sustained to sudden short-circuit current. With saturation, corresponding to the dashed curve of Figure 13b, Δi becomes larger for the same ΔE, and therefore S is smaller than before.

So we see that the subtangent S of the E curve is constant only for nonsaturated machines, and therefore only these machines can show an exponential decay of the voltages and also of the load- and short-circuit currents. Actual saturated machines, however, have a subtangent S which, corresponding to equation 23 and Figure 12, may be small during the initial stages and may increase toward a constant value at the final stages only, where the magnetic characteristic approaches the steady-state point linearly in the direction of its tangent. With capacitive load this rule is inverted, the subtangent decreases with higher saturation. All influences which by smaller armature reaction elevate the network characteristic, such as ohmic resistance or one- or two-terminal loading, increase the magnitude of the subtangent toward the no-load value of equation 24.

4. Effect of Damper Circuits

If the poles of a synchronous generator are equipped with damper circuits, these form for the most part a squirrel cage at the surface of the pole faces, both with salient-pole and cylindrical rotors. The total flux in the damper winding thus is identical with the flux entering the stator surface, if we neglect the very small circumferential flux in the air gap, including the damper slot flux. Between damper and field windings, however, a circumferential flux can pass to the adjacent poles, as in Figure 14. This constitutes the rotor leakage flux, in the transient part of which we are interested. A lumped damper circuit rather than a distributed winding is shown in Figure 14 in order to simplify the problem with regard to the direct or pole axis.

We denote by σ the leakage coefficient between damper and excitation windings due to the rotor leakage flux, by T_d the magnetic time constant of the damper winding, given as quotient of self-inductance and resistance, while T_p is the time constant of the exciting pole winding as before. It is well-known that, without regard to saturation, two exponential transient currents may flow in the two magnetically coupled windings, the time constants T of which are given as roots of the quadratic equation[2]

$$T^2-T(T_p+T_d)+\sigma T_pT_d=0 \tag{26}$$

Hence for small leakage, as in actual machines, the time constants are very nearly

$$T_1=T_p+T_d;\quad T_2=\frac{\sigma}{1/T_p+1/T_d}\cong\sigma T_d \tag{27}$$

where the last term on the right-hand side is a further approximation for T_2 for relatively small T_d. The primary time con-

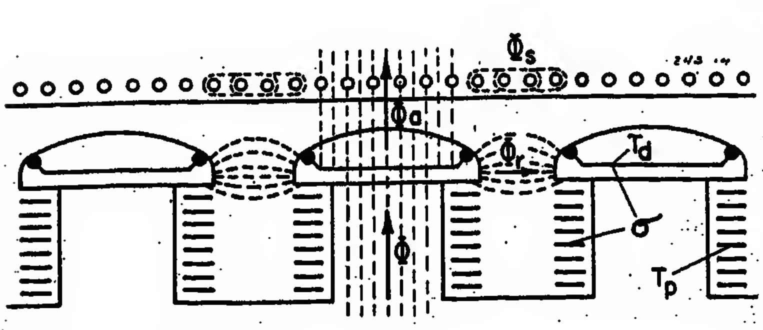

Figure 14 (lower left). Damper circuits and rotor leakage in synchronous machine

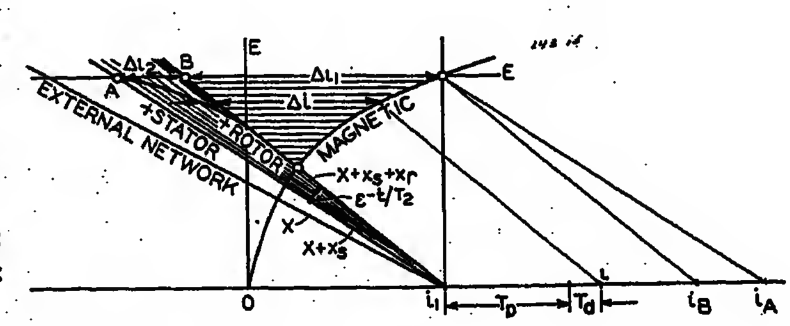

Figure 15 (right). Behavior of slow-transient main flux and rapid-transient rotor-leakage flux at inductive loading

stant T_1, given by the sum of T_p and T_d, represents the change with time of the main flux, and the secondary time constant, T_2, given by the product of two small quantities, represents the change with time of the leakage flux. Thus we can distinguish between a slow-transient main flux and a rapid-transient leakage flux. To both fluxes are correlated the respective voltages and currents in the windings.

An actual medium-sized machine may have an excitation time constant of the poles $T_p=5$ seconds, a damper time constant $T_d=1$ second, and a leakage coefficient between both rotor windings $\sigma=$ 15 per cent. Then we have the two resultant time constants

$$T_1=5+1=6 \text{ seconds}$$

$$T_2=0.15\frac{5\cdot 1}{5+1}=0.125 \text{ second}$$

T_2 being only two per cent of T_1. For current of 60 cycles per second the exponential damping for half a cycle is

$$\epsilon^{-\frac{t}{T_1}}=0.999;\quad \epsilon^{-\frac{t}{T_2}}=0.933$$

The rapid-transient rotor leakage flux flows for the most part in air, as seen by Figure 14. Hence this flux, constituting a free magnetic field which acts in addition to the main pole flux, is proportional or nearly so to its exciting currents. Therefore, it will be only slightly influenced by saturation and thus will change exponentially with time in actual machines. The leakage time constant T_2 is, therefore, a true or nearly true exponential time constant. It may vary, however, to some extent with different loading of the stator, caused by armature reaction on the damper circuit.[21]

The slow-transient main flux, on the other hand, flows through the armature and poles of the machine and is, therefore, greatly influenced by saturation of these steel parts. Thus, we cannot expect that the main time constant T_1 will affect the phenomena exponentially, but we must use it with actual machines in the way expressed graphically in our previous solution for the saturated problem by equations 17 and 19. Only we must use, instead of the previous pure excitation time constant T_p, the sum of excitation and damper time constants given by the first equation 27, T_1. Hence the main flux, or the electromotive force, is given by

$$T_1\frac{d(E/E_0)}{dt}=\frac{\Delta i}{i_0} \tag{28}$$

all other notations remaining unchanged.

Both fluxes, together, the slow-transient main-pole flux with the large saturated time constant T_1 and the rapid-transient rotor-leakage flux with the small exponential time constant T_2, constitute the armature flux entering the surface of the stator and producing in combination with the stator-leakage flux the terminal voltage and the stator current. At the instant of switching, the field winding keeps the pole flux constant, the damper keeps the air-gap armature flux constant, and thus only the stator-leakage flux can change instantaneously.

The initial values of all magnitudes can be determined by a diagram of characteristics as in Figure 15, which shows the case of sudden inductive loading of the synchronous machine. If no damper were present, there would be effective from the beginning the total network characteristic, formed by the reactances $X+x_s+x_r$, the last two terms denoting the leakage reactances of stator and rotor separately. Point B on this characteristic

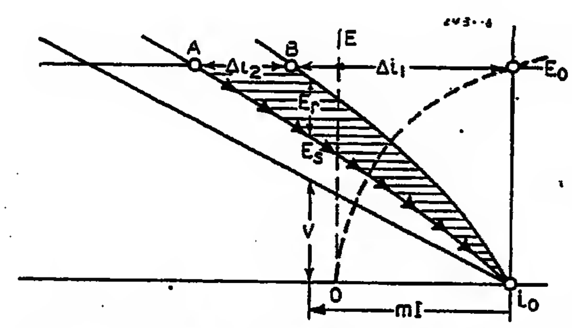

Figure 16. Effect of magnetic saturation in path of leakage flux

then would represent the current and would move down at a rate given by our previous considerations. With damper winding at the pole surfaces, however, not only the main-pole flux but also the rotor-leakage flux remains constant during the instant of switching, since the leakage flux is linked with the damper winding. Only the external field and the stator-leakage flux can vary, therefore, with the stator current, and this is represented by the line $X+x_s$ in Figure 15. This line intersects with the voltage of the constant-pole flux at point A, and this point is, therefore, the actual starting point. If the damper were as strong as the field winding, it would sustain the rotor-leakage flux for some time, and point A would gradually move down along the stator line $X+x_s$. Actually, however, the rotor-leakage flux varies with the relatively small time constant T_2 and, therefore, the effective network characteristic turns rapidly from the initial line $X+x_s$ to the final position $X+x_s+x_r$ in an exponential manner, corresponding to ϵ^{-t/T_2}. If T_2 is known, the intermediate characteristics for successive times can easily be drawn into the diagram.

The turning of this effective network characteristic corresponds to the rapid decay of the transient rotor-leakage flux. During this time, which is usually of the order of a tenth of a second, the main flux and its electromotive force E, also shown by Figure 15, have just started to move down over the shaded area at a rate given by the time constant T_1 and the current difference Δi. The smaller the external load, the steeper is the external characteristic X and the smaller is the current difference Δi to which, according to equation 28, the change of voltage with time is proportional. Thus, with known time constants and known characteristics, it is easy to trace the intermediate curve between stator and rotor lines in Figure 15 on which the point A gradually moves down toward the final intersection of network and magnetic characteristics.

If the leakage circuits of stator and rotor are saturated in any way,[15,16] we can include this effect in our considerations. Instead of straight lines, we have merely to draw curved additional stator- and rotor-leakage lines, as in Figure 16. The total network characteristic now is composed of the external reactive voltage V and the internal leakage voltages E_s and E_r, both depending on the current I with different effects of saturation. Corresponding to our previous consideration of saturated transients, Δi_2 in Figure 16 represents a current difference sustained by the damper circuit, which for some time keeps alive the rotor-leakage flux. The saturated rapid-transient variation therefore is given, corresponding to equation 17, by

$$T_2\frac{d(E/E_0)}{dt}=\frac{\Delta i_2}{i_0} \tag{29}$$

which is easy to evaluate graphically. According to this relation point A moves rapidly down to zero in a nonexponential manner, and the additional damper current Δi_2 can be determined for any time t. Meanwhile the pole flux in the main magnetic circuit decreases slowly according to equation 28 with the large time constant T_1. Its current difference Δi_1, in Figure 16, thus changes only slightly while Δi_2 drops to zero.

Since the rotor-leakage flux does not change at the instant of switching due to the effect of the damper, only the stator-leakage flux, together with the external reactive flux, can vary with the stator current, the total armature flux remaining constant. As shown in Figure 17a, the stator current I jumps, therefore, to the characteristic point A and is built up to such a magnitude that it balances not only the increase of the exciting current but also the damper current. Thus the initial

value I_A of the stator current is given in Figure 17a by the horizontal distance between the previous exciting current i_1 and the point A. The terminal voltage V is always given by the height of the external characteristic X in Figure 17a under the working point on the actual network characteristic. At the initial moment, V_A is found as the section under point A, the difference from the electromotive force E consisting in the stator-leakage voltage only, since the rotor-leakage flux does not vary at that instant. After some time, however, when the effective network characteristic has turned to its final position, the difference $E-V$ is given always by the combined stator- and rotor-leakage voltage. The slow transient part of the terminal voltage originates at the value V_B under the point B, the difference V_A-V_B being equal to the rotor-leakage voltage, and decreases toward the steady-state value V_∞.

In Figure 17b the slow transient drop of the electromotive force E and the slow and rapid transient decay of the terminal voltage V are shown following sudden loading of the machine. The electromotive force E, corresponding to the rotor-pole flux, decreases continuously from the no-load value, finally attaining the steady-state value at the intersection of both main characteristics. The terminal voltage, V, however, jumps from the no-load value, identical with the electromotive force, by an amount caused by the suddenly appearing stator-leakage drop and reaching instantaneously V_A. The rotor-leakage drop, on the other hand, does not occur suddenly but builds up gradually with the time constant T_2, and thus effects a rapid decrease of the terminal voltage to the asymptotic curve beginning with V_B and caused by the decay of the main-pole flux. The stator current follows a similar curve taken from the horizontal distances in Figure 17a and also shown in Figure 17b.

Since at the first instant the damper acts merely as a supplement to the field winding, excluding any effect of the rotor leakage, we obtain the total rotor current at the instant of switching by drawing through the working point on the magnetic characteristic, as in Figure 15, a parallel to the stator line $X+x_s$. Later, however, after the decay of the rapid-transient magnitudes, we must draw the parallel to the total network characteristic $X+x_s+x_r$. Thus the total rotor current starts with a high value i_A and approaches rapidly the slow transient current decreasing from the initial value i_B and finally reattaining the previous current i_1. Hence by the presence of the damper winding, stator current, as well as rotor current, acquires a superposed rapid-transient peak which decays exponentially with the time constant T_2, while the excitation winding causes a subsequent slow-transient decrease determined in its shape by the shaded area. The main-pole flux and the electromotive force E decrease continuously without superposed initial peak.

The total transient rotor current consists of exciting current and damper current. During the slow-transient period both are produced by the same decreasing main flux, therefore inducing the same voltage per turn in the respective windings. The subdivision of the slow-transient current into its components is, therefore, determined by the resistances or by the time constants of the exciting winding T_p and the damper winding T_d, as shown in Figure 15. The rapid-transient supplementary current Δi_2, on the other hand, induced by the decaying rotor-leakage flux, flows entirely in the damper circuit. It is understood that the damper current is measured here in the scale of the field current and may be converted to its proper value by the turn ratio.

5. Initial Conditions Under Load

If the synchronous machine at the prior condition is not open-circuited but is under load, the initial fluxes in stator and rotor are not equal. In Figure 18 the Potier-Sumec load triangle, or rather quadrangle,[3] is shown in which point a marks the magnitude of the stator flux, and b that of the rotor flux, which is larger, because of the increased rotor leakage flux under load. Figure 18 represents the phenomena occurring under a sudden short circuit near the machine terminals, so that the external characteristic vanishes completely, and only the rotor- and stator-leakage characteristics remain, both of the same order of magnitude. Without a damper, the pole flux corresponding to point b would remain constant at the instant of switching, and the current difference between B and b would move down the shaded area, according to equation 17.

This simple process is altered in two respects by the presence of a damper. First, the saturated time constant for the rotor-pole flux is increased to the value of the first equation 27, and thus the current difference Δi moves more slowly according to equation 28. Second, not only the pole flux but also the rotor-leakage flux, and therefore the total armature flux, remain constant at the instant of switching. Since this stator flux for the prior load condition is given by the point a in Figure 18, the corresponding point on the stator leakage characteristic up to which the flux can vary instantaneously is A, and, therefore, the stator current jumps from the prior value I_0 to the large value I_A. This is the instantaneous value of the stator short-circuit current and its magnitude is

$$I_A=\frac{E_0+E_s}{x_s}=\frac{E_0}{x_s}+I_0 \tag{30}$$

It exceeds the no-load instantaneous current merely by the value of the prior load current, as was also the case without damper action.

With the decay of the rapid-transient rotor-leakage flux, the characteristic line x_s turns, with an exponential time constant T_2, to the total leakage characteristic x_s+x_r. Meanwhile the main-pole flux with the electromotive force E moves down, producing a slow-transient stator current beginning at point B with the value

$$I_B=\frac{E_0+E_s+E_r}{x_s+x_r}=\frac{E_0}{x_s+x_r}+I_0 \tag{31}$$

Thus both the initial short-circuit currents are determined mainly by the prior terminal voltage E_0 and the stator- and rotor-leakage reactances.

The peak of the rapid-transient current, on the initial value of the slow-transient current, Figure 17, is given by the difference of equations 30 and 31 and is large with terminal short circuit. With distant short circuits, however, where the denominators of equations 30 and 31 contain, in addition, the external impedance, the peak is, without prior load,

$$\frac{I_A-I_B}{I_B}=\frac{x_r}{X+x_s} \tag{32}$$

a ratio indicated in Figure 17, and this excess value becomes less significant the larger the external impedance.

When evaluating the stator currents from such diagrams, it should be noted that the scales for the two currents I_A and I_B are slightly different, due to the fact that the ratio of stator current to rotor current is given mainly by the turn ratio, but is also slightly dependent on the leakages. I_A, however, is determined only by the stator leakage, while I_B is determined by both stator and rotor leakages.

We can now abandon our conception of a lumped damper winding as in Figure 14, which gives a fixed value of secondary time constant. It is well-known that multiple circuits, extended in space, as they are used with squirrel-cage dampers and also with solid cylindrical rotors, have not one single time constant but a series of

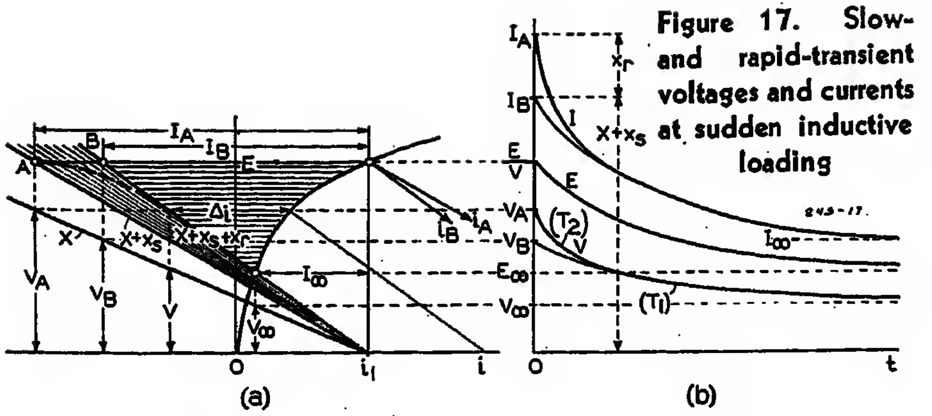

Figure 17. Slow- and rapid-transient voltages and currents at sudden inductive loading

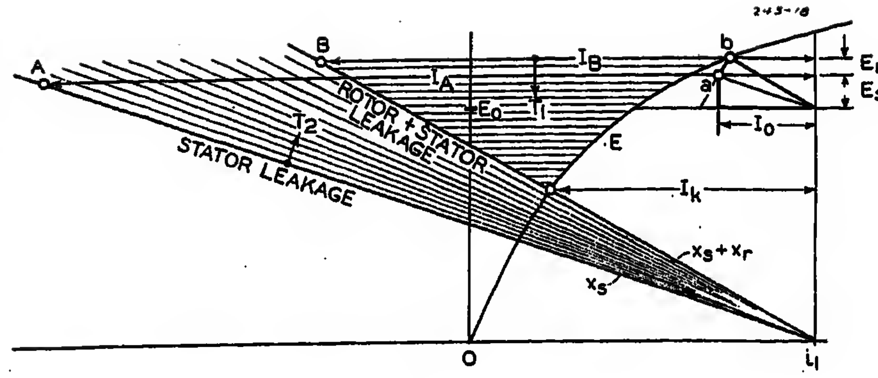

Figure 18. Influence of stator and rotor leakage at sudden short circuit of previously loaded synchronous machine with damper

exponential time constants, each belonging merely to a partial amplitude of the current. This means that the flux through distributed dampers does not decay exponentially but according to a more complicated time function, beginning rapidly and ending slowly. Thus we have to turn the effective leakage characteristic from the stator line to the rotor line in Figures 15–18, not exponentially, but quickly at first and more slowly finally, approaching the speed of the lowest rapid-transient time constant. Hence we see that the starting and ending lines of the rapid-transient period always go through the points A and B, and that only slight alterations result in the intermediate position of the effective characteristic. The initial and final values of the rapid- and of the slow-transient voltages and currents also remain unchanged.

It may be noted that the slow-transient and rapid-transient phenomena of this investigation are not identical with the transient and subtransient phenomena commonly used.[10,11,18] Figure 19 shows for a sudden short circuit the difference between the two conceptions. The "subtransient" current is usually defined as the difference between the actual change of the current with time and the "transient" exponential asymptote, which has a time constant equal to the longest subtangent. This latter curve, drawn backwards as dashed in Figure 19, lies considerably deeper than the slow-transient curve which has a smaller subtangent in the beginning due to the magnetic saturation. The "transient reactance," defined by the start I' of the slowest exponential asymptote, is therefore with saturated machines materially greater than the sum of stator- and rotor-leakage reactances, the sum giving the beginning I_B.

Let us consider some further cases which are of interest in the operation of synchronous machines. Figure 20 shows the phenomena at the clearing of a short circuit near the terminals after which the machine again supplies a certain load. The diagram contains the stator- and rotor-leakage characteristics for the prior short-circuit operation, and the network characteristic for the final operation, including stator and rotor leakages separately. At the instant of interrupting the short circuit, the rotor-pole flux starts on the magnetic characteristic at a point b given by stator-plus rotor-leakage characteristic. The pole flux and electromotive force change, according to the shaded area, with the difference current Δi between magnetic characteristic and total network characteristic. This construction is the same as would be used without damper action except that the time constant is somewhat larger, namely T_1. This gives the initial slow-transient terminal voltage V_B and the subsequent change with time, as shown in Figure 20b, up to the final voltage V_∞.

However, the actual armature flux at the instant of switching is given by the stator-leakage flux only, corresponding to point a, and this leakage flux alone can jump at the instant of switching. Thus only the stator-leakage characteristic jumps suddenly to the network stator line $X+x_s$ through point A in Figure 20a. The initial terminal voltage immediately after interruption of the short circuit is, therefore, given by V_A as the vertical difference between the two stator lines, under load and under short circuit. The difference between the two voltages V_B and V_A, corresponding to the initial rotor-leakage flux, decays rapidly with the small time constant T_2, as shown in Figure 20b. Hence, the terminal voltage, being zero during the time of short circuit, jumps with the interruption instantaneously to a value determined by the prior stator-leakage drop, then increases rapidly due to the vanishing rotor-leakage flux sustained for a short time by the damper winding,[17] and finally creeps slowly upward due to the reappearing main-pole flux of the machine.

This change with time of the recovery voltage is important in the operation of circuit breakers interrupting a short-circuit current. We see that this voltage consists of three parts, the rate of ascent of which for full interruption of the current we will compute. The first step is the instantaneous appearance of the prior stator-leakage voltage V_s at the terminals. The rate of increase is V_s/O, and this indicates that an overshooting of voltage can occur if capacitance is present in the circuit. The second step is constituted by the prior rotor leakage voltage V_r and its rate of change is determined by the small time constant as V_r/T_2. The third step, following the magnetic saturation curve with the time constant T_1, is given by equation 28. Thus the total initial rate of increase of the recovery voltage is

$$\left(\frac{dV}{dt}\right)_0 = \frac{V_s}{O} + \frac{V_r}{T_2} + \frac{E_0}{T_1}\,\frac{\Delta i}{i_0} \qquad (33)$$

Usually the second term is five to ten times as large as the third term, and, therefore, the subsequent increase of the recovery voltage is determined mainly by the rotor-leakage voltage and the rotor-leakage time constant.

The stator current flowing into the load, given by the horizontal distance between the network characteristic and the vertical through the steady-state excitation, starts with relatively small magnitudes I_A and I_B and increases slowly to its final value. The transient rotor current is again cut off on the axis of abscissae by a parallel to the final network characteristic and divides into a larger exciting current and a smaller damper current in the ratio of the time constants T_p and T_d.

The sudden capacitive loading of a synchronous generator is shown in the diagram Figure 21. An extension of our previous Figure 8, this figure shows the transition from full inductive load to full capacitive load under the influence of magnetic

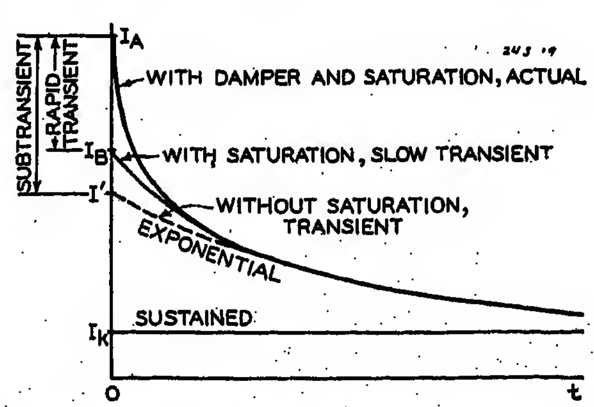

Figure 19. Comparison of slow-transient and rapid-transient phenomena with division into transient and subtransient curves

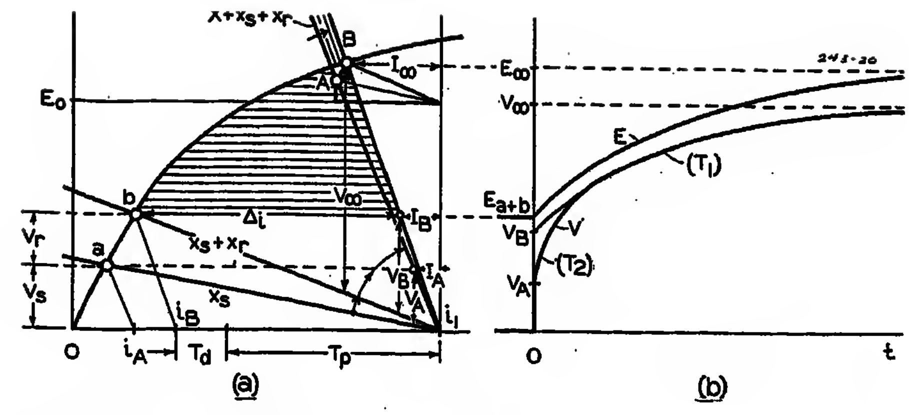

Figure 20. Interruption of terminal short circuit of synchronous machine with damper

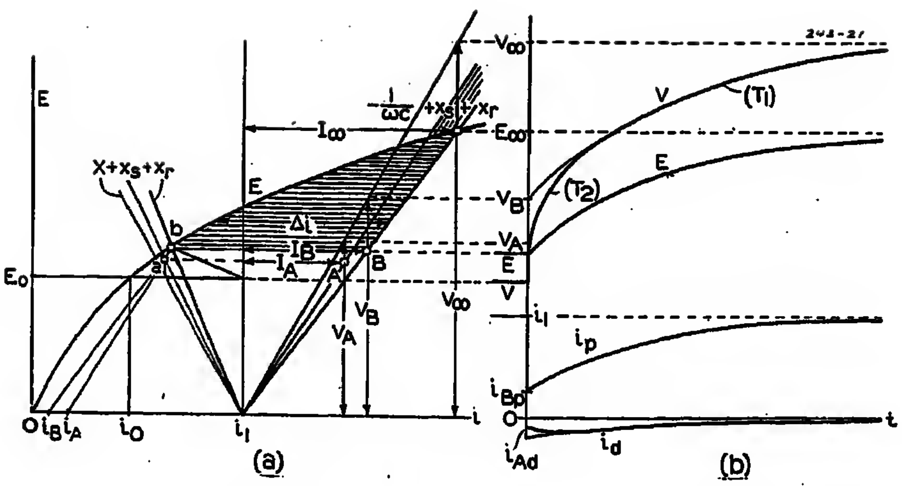

Figure 21. Capacitive loading of synchronous machine with damper

saturation and damper circuits. The slow-transient voltage is determined by the large time constant T_1 and the shaded current difference, Δi beginning between the complete network characteristics under full inductive and full capacitive load. Superposed are the rapid-transient magnitudes given by the turning of the stator line to the rotor line of the final capacitive characteristic. The terminal voltage starts with a jump from E_0 to the vertical height V_A through point A of the subsequent stator line, indicating unchanged stator flux, and approaches the rotor line through point B at constant rotor flux.

In Figure 21b the change with time of stator voltage and rotor current is represented. The voltage increase due to stator leakage is instantaneous, the increase due to rotor leakage is rapid, and the increase due to the main flux is relatively slow. The exciting current jumps to a small value and regains its prior value gradually. The stator current also jumps suddenly from the inductive to the capacitive direction and increases further to its final value, I_∞, given by the intersection of the characteristics. Actually, all discontinuities of voltage and current are smoothed by a superposed transient oscillation between the capacitance and the inductance. Since the natural period of these oscillations is always small compared even with the time constant of the damper winding, only the stator leakage is effective and determines the natural frequency.

We have assumed in the beginning that the magnetic saturation is concentrated in the rotor poles, a condition under which the Potier-Sumec quadrangle of Figure 18, for example, is a straight-line figure. If, however, the stator is also saturated in yoke and teeth, the increased rotor-leakage flux needs additional excitation by rotor saturation alone, and thus point a approaches the main magnetic characteristic. In every case, characteristics for the total stator flux and total rotor flux can be plotted separately[19] and used in an equivalent manner, as the corners of the straight-line quadrangle have been used for rotor-pole saturation only.

Although for the sake of simplicity our deductions have been confined to symmetrical, three-phase, reactive load having a straight-line external characteristic, there is no restriction in principle against using our graphical method for other conditions of load. Any active load also gives a definite correlation of voltage and stator current, except that we must consider, with respect to the armature reaction within the machine, the internal reactive component only. This can be done by methods well-known in the two-reaction theory of synchronous machines. With any kind of constant-impedance load, the external characteristic, and, therefore, the total network characteristic, including leakages, remains linear. Even unbalanced loads, as under line-to-neutral or line-to-line short-circuit conditions, can be treated in the same way except that only their positive-sequence component enters the graphical analysis. The remaining negative-sequence and zero-sequence components, on the other hand, do not interact materially with the synchronous fields of the machine if damper circuits are present.

If, finally, the load consists of other synchronous or induction motors which generate a counterelectromotive force and, therefore, prevent the external characteristic from passing through the origin, or if the load consists of transformers with magnetizing currents increasing rapidly with the voltage, the network characteristic may become flat-topped or markedly curved. Since, however, the linearity of the network characteristic does not play any part in our derivations, we see that our general method of solution remains unchanged even in such more complicated cases.

6. Summary

By reducing to the same parameter with saturation the voltage-current equations for stator, rotor, and magnetic circuits of synchronous machines, a differential equation in time for the main-pole flux and the induced electromotive force is derived, a relation easy to evaluate graphically. The difference of current between the magnetic characteristic of the machine and the electric characteristic of the stator circuit determines the rate of change of the electromotive force from which all the other slow-transient magnitudes can be derived.

For constant excitation voltage, a closed solution for the variation of flux and electromotive force is given, valid for any sudden change of load, including short-circuit, current formation or capacitive superexcitation. The combined effect of damper circuits and rotor leakage causes a superposed rapid-transient variation manifested by an additional current peak at sudden short circuits and by a rapid initial voltage rise at sudden interruptions of the circuit.

The method of solution is in principle independent of the distribution of the saturation on rotor and stator, as well as of the character of loading of the machine, be it by constant or variable impedance, by symmetrical or unbalanced currents, by active or reactive power. The common subdivision into transient and subtransient phenomena is not identical with the separation into slow- and rapid-transient effects, the physical significance of which is derived in this paper.

THE object of this paper is to present the results of an analytical study of tie-line power control. This study was made as a logical development of the general subject of power system control. Previous work[1,2] has indicated the general requirements of the prime-mover speed governors and the desirability of supplementary control to insure proper load division, frequency, and time. The general requirements of supplementary controls are given in the companion paper[3] by Crary and McClure. In most cases these controls are satisfactorily obtained as rather slow corrective adjustments to the speed-governor mechanisms, but for certain types of load a more active tie-line load controller, which will tend to suppress transient load swings also, may be required. An example of this is a rapidly varying load, such as a strip mill supplied from local generation as well as from a tie to a larger power system, in which it may be desirable to keep the load variations off the tie line as much as possible.

The characteristics and response of this kind of more active tie-line load controller have been studied in order to determine

1. The best tie-line controller and speed-governor characteristics (that is, the best controller characteristics for a given governor, and conversely the best governor characteristics for a given controller) to give the most effective tie-line power control.

2. The maximum effectiveness of the optimum controller in reducing the magnitude of tie-line power swings.

Basis of Study

The approximate torque equations for two interconnected speed-governed power systems were given in reference 2. Each system was represented as a single machine having an equivalent inertia, load-damping, and speed-governor characteristic, and the capacity of the tie line was specified by synchronizing torque and tie-line damping torque coefficients. In the present analysis the equation for one of the systems includes the additional effects of a tie-line power controller and (for a few cases) a speed droop-correction mechanism. The other system is considered to be infinitely large, that is, its electrical angle is fixed with respect to the standard frequency reference. The torque equations used and the definitions of the various system parameters are given in the appendix.

Governor Mechanism

Speed-change and tie-line controller indications are applied to an idealized governor-control mechanism[2] consisting of a two-stage amplifier with time lags T_1 and T_2 and an over-all amplification factor inversely equal to the governor regulation. The prime-mover input torque change is equal, therefore, to the output of the second stage. Since the degree of stability of this idealized system tends to be somewhat greater than that of an actual governor having more than two time lags, practically all of the results have been obtained under the least stable condition of equal time lags.[2] In certain cases, the effects of droop correction have been simulated by allowing the regulation to decrease from the transient value, R, to the steady-state value, r, at a rate defined by the time constant T_3 of the droop compensation mechanism.[1]

Tie-Line Control

In the usual type of tie-line controller, the indications are transmitted intermittently at equal time intervals to the governing system through the synchronizing motor which is operated from a constant potential source. During each of the equal time intervals, usually of the order of two second period, the motor circuit is closed a length of time proportional to the deflection of the controller galvanometer or load sensitive device at the beginning of the interval. The average effect of these impulses is to change the synchronizing-motor position, and, consequently, the magnitude of the prime-mover input correction, at a rate proportional to the deviation in tie-line power from the scheduled value. Some of the results obtained from the differential-analyzer solution of the problem include the effects of this intermittent controller.

It is assumed that when using the corresponding continuously acting controller, the type principally considered in this analysis, the control circuit will be arranged to operate the synchronizing motor at a speed proportional to the tie-line power deviation. The rate of correction is inversely proportional to the controller regulation R_t'; or, R_t' is a measure of the time required to change the synchronizing-motor position an amount equivalent

to a prime-mover torque change ΔP, when the controller is actuated by a fixed tie-line power deviation ΔP. The tie-line controller time constant T_4 is a measure of the time lag in the tie-line controller and synchronizing-motor response. Control circuits based on these principles are sometimes referred to as the "floating type" in that the correction is applied at a *rate* proportional to the change in the controlled variable, and the adjustment continues until the variable is restored to its normal value.

A "proportional type" of control is one that exerts a correcting force proportional to the change in the controlled quantity, as would be obtained, for example, with a tie-line controller that actuates a torque motor connected to the governor mechanism. The corresponding controller regulation, R_t, specifies that a tie-line power change ΔP results in a corrective indication equivalent to a prime-mover torque change $\Delta P/R_t$. A time lag T_5 is associated with this control system in the analysis.

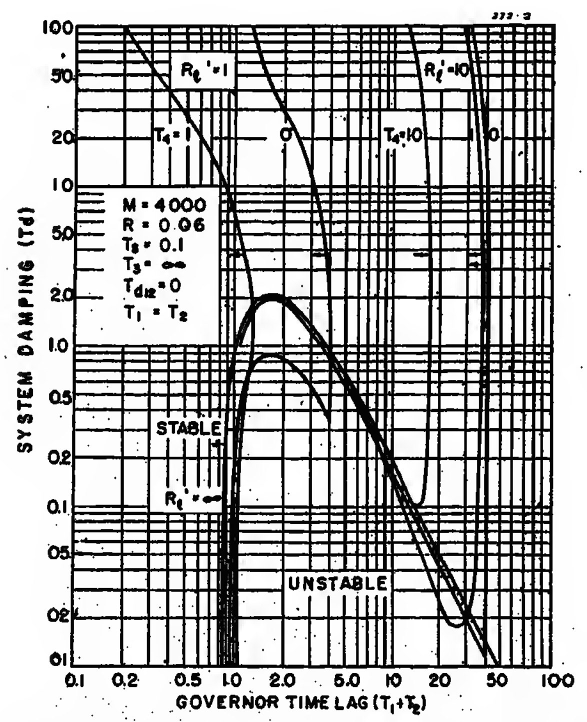

Figure 2. System stability—effect of time lag in the tie-line controller

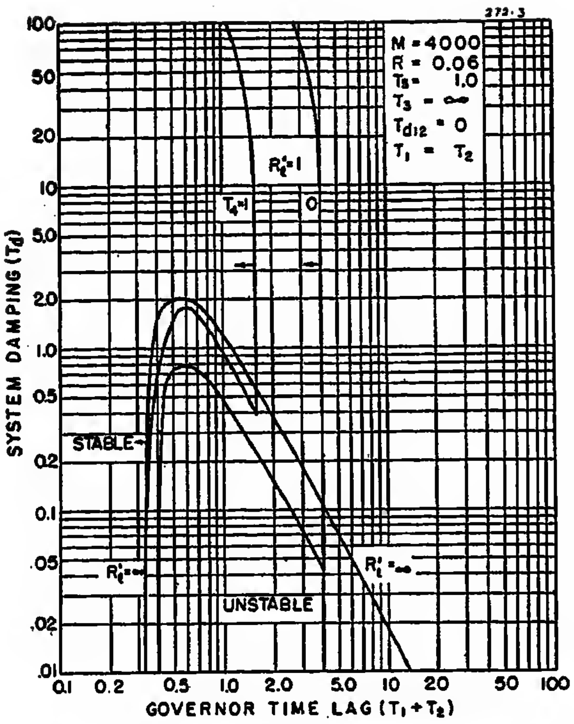

Figure 3. System stability—effects of floating type of tie-line control

Larger tie-line synchronizing power coefficient than that of Figures 1 and 2

Load-Torque Change

The distribution of load increments between two systems is determined at the first instant by the electrical characteristics. In this study the entire load-torque change ΔT has been applied directly to the smaller system; a condition that would be realized if the impedance to the smaller system from the point of load application were negligibly small with respect to the impedance to the larger system. This assumption is justified, since most of the data have been taken with a tie line of small capacity with respect to even the smaller system.

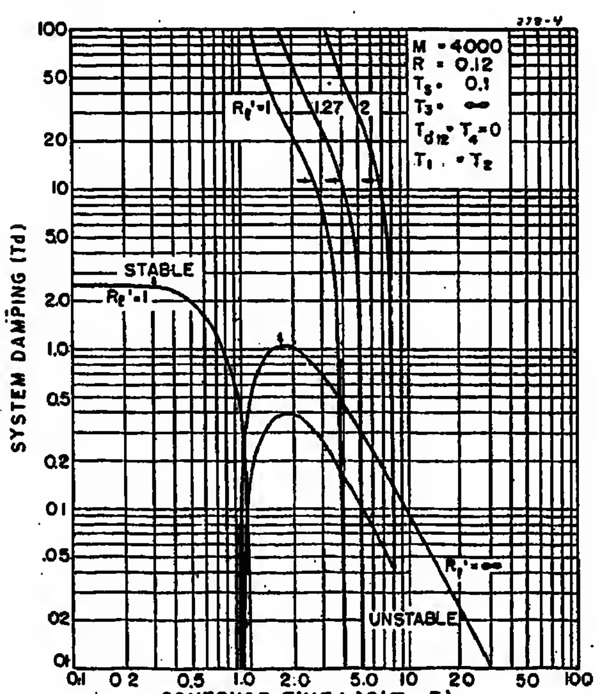

Figure 4. System stability—effects of floating type of tie-line control

Larger governor regulation than that of Figures 1 and 2

Maximum Rates of Response

In order to prevent large tie-line power swings the prime-mover power input to each system must vary with its load. The over-all power input to a group of generating units is limited, however, to a maximum rate depending upon the steam storage or hydraulic capacities of the various units. In some cases this rate may be of the order of ten per cent of the regulated capacity per minute.

Although these practical limitations have an important bearing upon the general problem of tie-line control, the ideal condition of an infinite prime-mover energy source has been assumed for the purpose of evaluating the desirable characteristics of the controller and governing systems.

Discussion of Results

One criterion for determining the optimum governor and tie-line controller characteristics is that the over-all system performance should be as stable as possible. Therefore, the effects of the various parameters upon system frequency stability have been studied. The direct calculations of stability limits are necessarily limited to those cases involving continuously acting (linear) tie-line control equipment.

Another desirable condition is that the tie-line power swings should be reduced to a minimum. The tie-line power changes for given load changes, calculated by means of the differential analyzer at the Moore School of Electrical Engineer-

ing, University of Pennsylvania, are used as a basis for the conclusions regarding this phase of the problem.

STABILITY

Figure 1 shows the required load or tie-line damping as a function of total governor time lag, with various tie-line controllers, when the tie-line capacity is relatively small ($T_s=0.1$). The effect of the tie-line controllers may be seen by comparing the corresponding curves with the one obtained for a system having no tie-line control, $R_t'=\infty$. Also shown with this reference curve, which is similar to those of Figures 3 and 4 of reference 2, are the comparable points for a system having the same transient regulation, $R=0.06$, but a steady-state regulation of $r=0.03$ following the operation of a droop-correction mechanism with a time constant five times that of the governor control system. The stability limits are not appreciably changed provided the time lag T_3 is sufficiently long.

1. *"Floating" Control.* The effect of a floating type of tie-line controller (Figure 1) with relatively slow correcting rate, $R_t'=10$ seconds, and zero time lag, $T_4=0$, is to introduce a critical value of governor time constant above which the system is unstable regardless of the value of system damping. In the range of T_1+T_2 less than the critical value, however, the unstable region is very nearly the same as that obtained with no tie-line control, $R_t'=\infty$.

With a much faster correcting rate, $R_t'=1$ second, the critical governor time lag is proportionally smaller, but the maximum value of required T_d within the stable region is reduced to less than half that required without tie-line control. The comparable points obtained for a governor having droop correction give a somewhat lower critical governor time lag. This difference appears, because R_t' has been taken as a measure of the equivalent correcting time when the controller indication is amplified only according to the transient governor regulation R, whereas the actual amplification of the adjustments increases as droop correction is applied.

The dashed curves of Figure 1 give the required tie-line damping, T_{d12}, with zero system damping, $T_d=0$, and are compared with the corresponding solid curves of required T_d with $T_{d12}=0$. With both types of damping present the curve of required total damping, T_d+T_{d12}, would lie between the two.

Introduction of time lag, T_4, in the tie-line control system (for example, in the synchronizing motor) results in a lower critical value of T_1+T_2, Figure 2, but otherwise the unstable region is not appreciably changed. Moreover, the percentage decrease of the critical governor time constant is more nearly a function of the ratio T_4/R_t' than of T_4 alone.

Figure 3 gives the required damping versus governor time lag when the tie-line capacity is much greater ($T_s=1.0$).

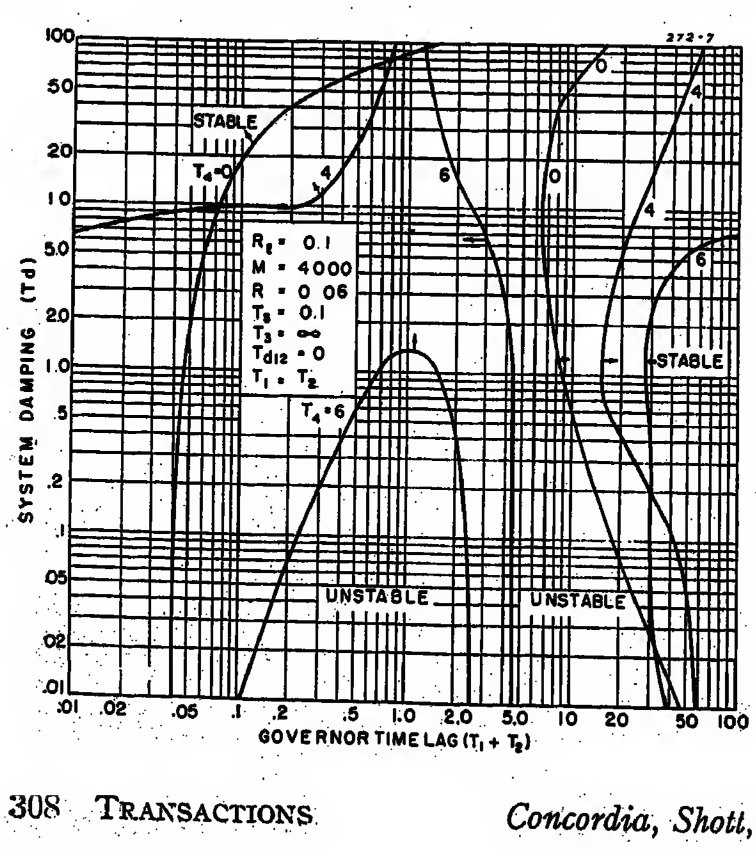

Figure 7. System stability—effect of proportional tie-line control

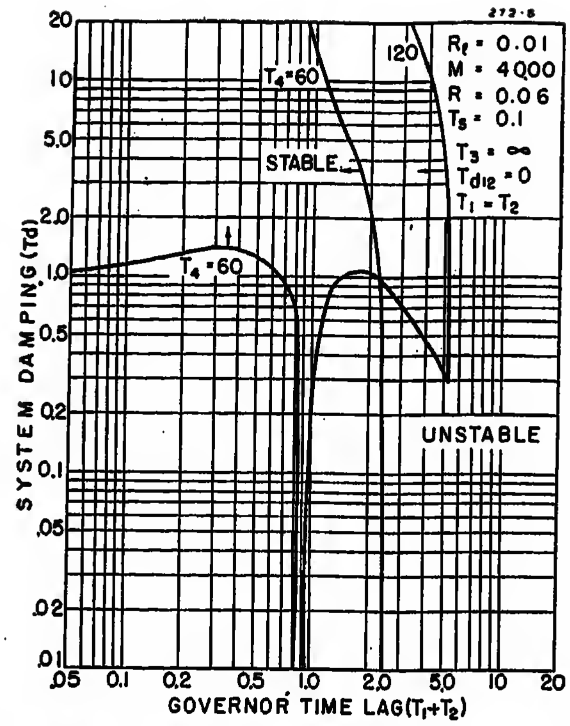

Figure 8. System stability—effect of proportional tie-line control

As shown in reference 2, and also by comparison of Figures 2 and 3, the maximum required T_d is unaffected, but the unstable region occurs in a range of lower values of T_1+T_2, when T_s is increased. The critical governor time lag introduced as a result of tie-line control is practically independent of T_s, and is approximately equal to $4R_t'$ for zero controller time lag and small system damping.

Results calculated with a larger regulation ($R=0.12$) and small tie-line capacity ($T_s=0.1$), Figure 4, are compared with those of Figures 1 and 2 for $R=0.06$. Without tie-line control ($R_t'=\infty$) the maximum required T_d is inversely proportional to the governor regulation, and the comparison of the unstable areas is similar to that of Figure 3, reference 2.

The other curves of Figure 4 indicate that the critical governor time lag is practically independent of R as well as of T_s. Furthermore, the magnitude of the maximum required T_d within the stable region decreases with increasing rate of tie-line correction. At a value of R_t' numerically equal to $MR/2\pi f$ seconds correcting time, the system becomes stable for all governor time lags less than its critical value as shown by the curve for $R_t'=1.27$. At any greater rate of correction ($R_t'=1$ is an example) however, and if the system damping is small, instability may occur in the range of small governor time lags. Therefore, the maximum allowable rate of tie-line correction (minimum R_t') is a function of governor regulation as well as of system damping and of governor time lag. Or, conversely, there is an optimum governor regulation smaller than one that causes instability, because of the above mentioned condition, and greater than one

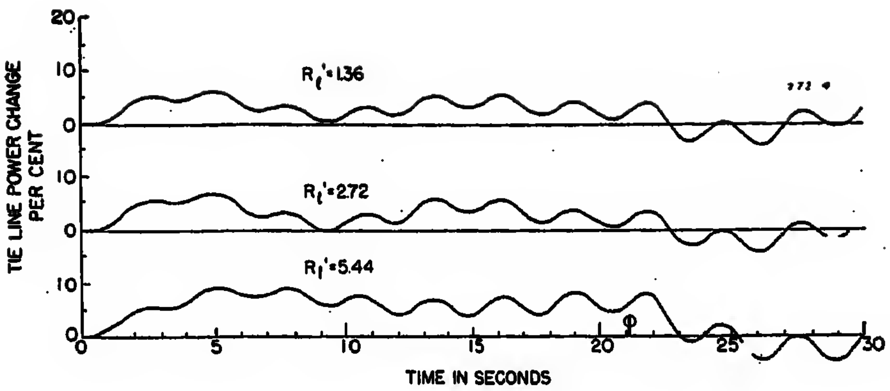

Figure 9. Floating control—magnitudes of tie-line power swings as affected by the rate of correction

$M=4{,}096$ $T_s=0.1$ $R=0.0625$
$T_d=2$ $T_1=T_2=0.53$ $r=0.03125$
$T_{d12}=0$ $T_3=5.44$ $T_4=1.06$
$\Delta T=t/42.4$ for $0<t<21.2$
$\Delta T=0.5$ for $t<21.2$

that causes instability, because of the large required T_d under normal conditions. One general rule for determining the maximum allowable rate of tie-line correction is, therefore, that R_t' should be greater than $MR/2\pi f$; that is, the possibility of an unstable region similar to the one for $R_t'=1$, Figure 4, should be avoided.

If the time lag of the governor is relatively large, instability is approached as the critical governor time lag approaches the actual time constant of the particular governing system. Under these conditions the minimum allowable R_t' is practically independent of the governor regulation, and with zero controller time lag it is approximately equal to four times the total governor time constant.

The above conclusions are substantiated by the curves of Figure 5 showing the permissible governor regulation versus correcting time of the tie-line controller for several different governor time constants and with $T_d=2$, $T_4=0$. The minimum allowable R_t' is in all cases a function of governor time constant, but for large values of governor time constant (T_1+T_2 equal to 2.12 and 4.24 seconds) it is practically independent of governor regulation.

2. *"Proportional" Control.* When the proportional type of tie-line controller is used, the steady-state change in tie-line power resulting from a load-torque change ΔT is (equation 1 of the appendix with $p=0$),

$$\Delta P=\frac{\Delta T}{1+\frac{1}{R_t}}=\frac{R_t\Delta T}{1+R_t}$$

The effects of a proportional controller with a very broad regulation, $R_t=1.0$, upon the stability limitations of the system having six per cent governor regulation and small tie-line capacity, $T_s=0.1$, are shown on Figure 6. With zero controller time lag, $T_5=0$, the region of instability and the maximum required T_d are both considerably greater than those calculated with no tie-line control. Satisfactory results are obtained, however, by adding a small amount of time lag as demonstrated by the results obtained with $T_5=1.06$ seconds. This value of controller regulation allows wide swings of tie-line power in that the load changes are equally divided between the two systems.

A controller regulation of $R_t=0.1$ is more nearly desirable in that the steady-state tie-line power change is limited to approximately nine per cent of the load change. With zero controller time lag, Figure 7, the required system damping is excessively large over the entire practical range of governor time lags. As the controller time lag is increased, the stable region in the range of small governor time lags is progressively changed until it acquires a form similar to the curves calculated with the R_t' type of controller. This effect is shown by the curves for T_5 equal to four and six seconds, Figure 7.

The response of a proportional controller with a time lag T_5 is given in the appendix as,

$$\frac{D}{R}=\frac{\Delta P}{pR_tT_5+R_t}$$

as compared to the response of the floating-type controller without time lag,

$$\frac{D}{R}=\frac{\Delta P}{pR_t'}$$

That is, for small R_t and large T_5 the product of the two is the governing factor as regards controller response, and this factor corresponds to the R_t' type of regulation.

Figure 8 is a good illustration in that the results for $R_t=0.01$ and T_5 equal to 60 and 120 seconds are similar to those of Figure 4 for the other type of control.

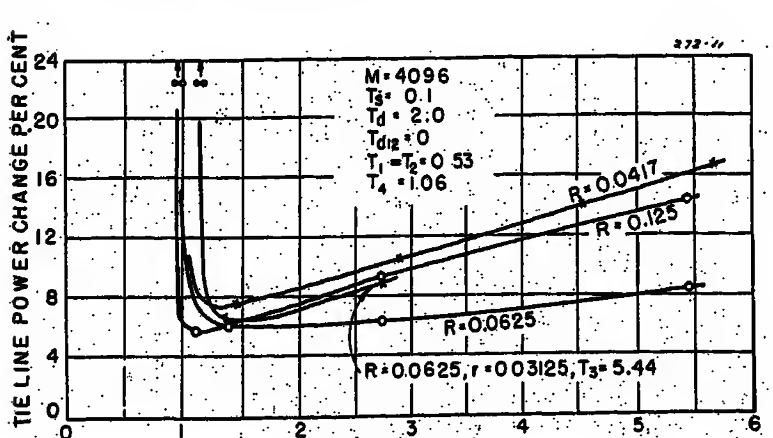

Figure 11. Floating control—tie-line power deviation as affected by the governor regulation and by the rate of tie-line correction

$T_{d12}=0$ $T_3=\infty$ $T_4=2.12$
$\Delta T=t/42.4$ for $0<t<21.2$
$\Delta T=0.5$ for $t<21.2$

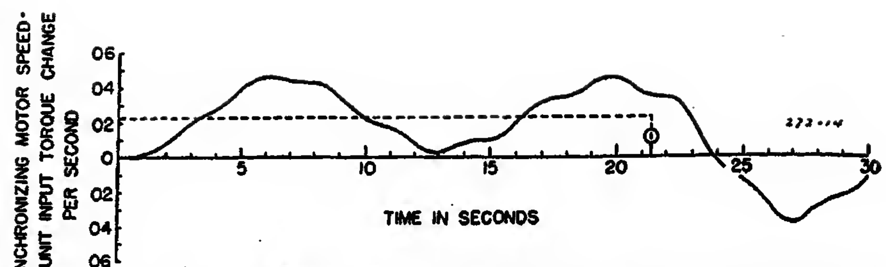

Figure 14. Floating control—rate at which the tie-line power corrective adjustment is applied to the speed governor

——— Actual - - - - - Ideal

$M=4{,}096$ $T_s=0.1$ $R=0.0625$
$T_d=2$ $T_1=T_2=0.53$ $R_t'=1.36$
$T_{d12}=0$ $T_3=\infty$ $T_4=2.12$
$\Delta T=t/42.4$ for $0<t<21.2$
$\Delta T=0.5$ for $t<21.2$

One disadvantage of proportional control is that it may require a more complicated mechanism for use with most governors. Furthermore, provision for obtaining a wide range of time lags may be required depending upon the required range of tie-line regulation.

Tie-Line Power Swings

The differential analyzer results were recorded in the form of curves of tie-line power, frequency, prime-mover torque, and controller response versus time during periods of large variable loads. A severe type of variable load, such as that furnished by a strip mill, is one in which a total variation as great as 50 per cent of the local generation capacity occurs in cycles of the order of one-minute periods. As an approximation to this condition, one set of runs was taken with a smooth load cycle in which ΔT increases at a uniform rate from zero to 0.5 per unit in 21.2 seconds, remains constant for another 10.6 seconds, decreases at a uniform rate from 0.5 to zero in another 21.2 seconds, and so on. Because the decreasing ΔT was applied from a transient condition, the magnitudes of the power swings during this period were occasionally greater than those of the increasing ΔT period. For the purposes of comparing the effects of various control characteristics on a common basis, therefore, the results presented in this paper give only the magnitudes of the swings up to the time at which the decreasing ΔT was applied. Another set of runs was taken with continuously increasing ΔT applied at a fixed rate.

1. Floating Control. Governor- and tie-line-controller time lags each equal to 1.06 seconds, system damping of $T_d=2.0$, and small tie-line capacity ($T_s=0.1$), were assumed for one set of conditions. The curves of tie-line power versus time, Figure 9, show the relative effects of three different rates of controller response for a system having a governor regulation of $R=0.0625$. The load torque ΔT was increased uniformly from zero to 0.5 per unit in 21.2 seconds (point 1 on the time scale) and was then held constant for the remainder of the time interval shown. Of the three values of R_t' used, the smallest is most effective in limiting the power deviation, but this does not mean that R_t' should be decreased further. Although the system inertia and regulation are not exactly the same as those used in the stability calculations, the minimum allowable R_t' for stable operation may be estimated by considering the location of this operating point ($T_1+T_2=1.06$ and $T_d=2.0$) within the stable regions of Figures 1 and 2.

The tie-line power swings shown in Figure 10 are for a system with the same transient regulation ($R=0.0625$), but with a steady-state regulation of $r=0.03125$ obtained by means of a droop-correction mechanism having a time lag $T_3=5.44$ seconds. The run taken with $R_t'=0.68$ second demonstrates the instability resulting from too rapid tie-line power correction. As stated previously, R_t' is a measure of the equivalent correcting time when the amplification is inversely equal to the transient regulation R.

The maximum power swings of these runs, as well as those taken with governor regulations of 0.125 and 0.0417, are compared on Figure 11. The optimum controller response is nearly equal to that corresponding to the minimum allowable R_t', and under the assumed conditions the optimum governor regulation is of the order of six per cent. The tie-line power swings are not improved by adding droop correction.

Using the approximate optimum values indicated above, $R_t'=1.36$ seconds and $R=0.0625$, the controller time lag was varied. As shown by the curves of Figure 12, T_4 should be made as small as

Figure 15. Floating control—effect of governor regulation on the tie-line power deviation for a system having larger damping factor ($T_d=10$)

$M=4{,}096$ $T_s=0.1$ $R_t'=1.36$
$T_d=10$ $T_1=T_2=0.53$ $T_4=1.06$
$T_{d12}=0$ $T_3=\infty$
$\Delta T=t/42.4$ for $0<t<21.2$
$\Delta T=0.5$ for $t<21.2$

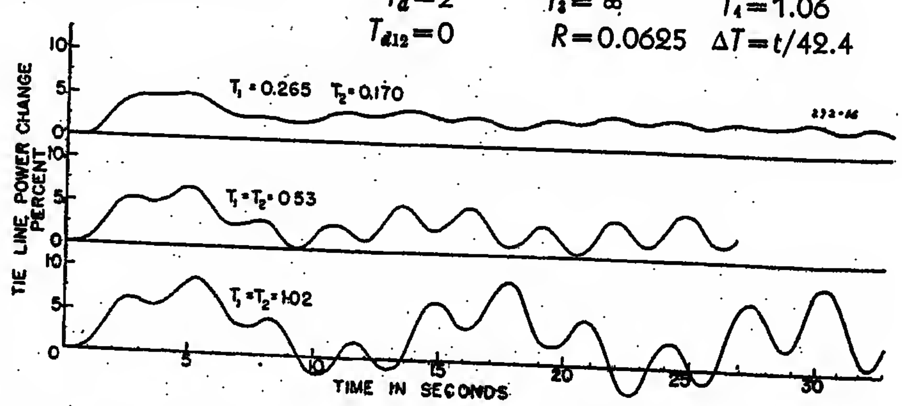
$M=4{,}096$ $T_s=0.1$ $R_t'=1.36$
$T_d=2$ $T_3=\infty$ $T_4=1.06$
$T_{d12}=0$ $R=0.0625$ $\Delta T=t/42.4$



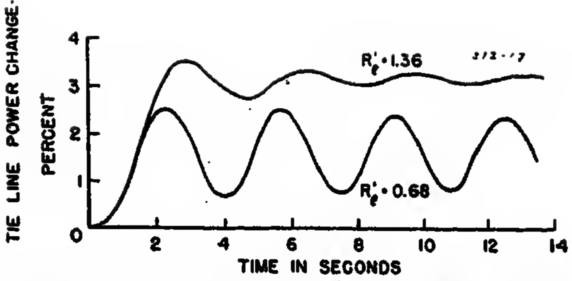


Figure 17. Floating control—effect of the rate of tie-line correction when there are no governor or controller time lags

$M=4{,}096$ $T_s=0.1$ $R=0.0625$
$T_d=2$ $T_1=T_2=0$ $T_4=0$
$T_{d12}=0$ $T_3=\infty$ $\Delta T=t/42.4$

possible. This conclusion is compatible with the results of the stability calculations.

Figures 13 and 14, curves of prime-mover input torque change versus time and of synchronizing motor speed versus time, respectively, are for the same conditions as the power swing of Figure 12 with $T_4=2.12$. All of these quantities depend, of course, upon the rate of load-torque change. In actual practice a maximum correcting rate may be imposed because of boiler limitations, and so forth, previously discussed. The dashed curves of Figures 13 and 14 may be interpreted as showing the expected response of an idealized control system having no controller or governor time lags and zero correcting time.

Natural frequency components of tie-line power swings are effectively reduced when the system damping is increased to $T_d=10$, Figure 15. The curve for $R=0.0625$ is compared with that of Figure 9 for $T_d=2$ and $R_t'=1.36$. It is observed that the maximum power swings are approximately equal. Although the larger system damping factor allows the use of a smaller governor regulation ($R=0.03125$), no appreciable over-all improvement is realized.

All of the remaining differential-analyzer runs were taken with a continually increasing load torque. For ex-

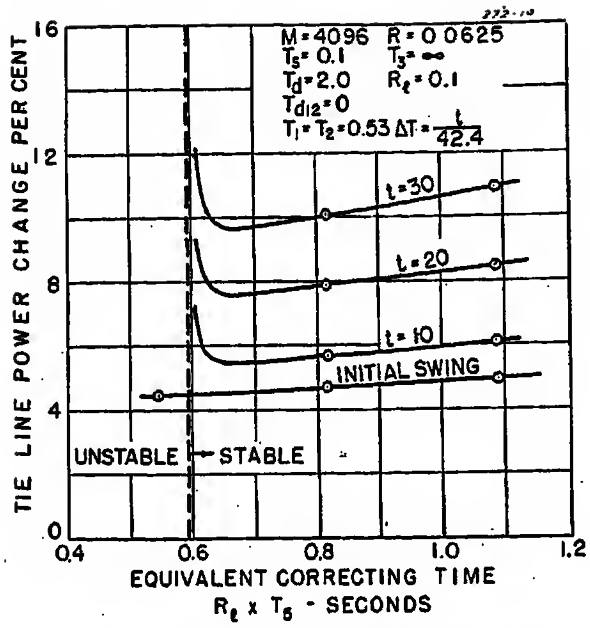

Figure 19. Summary of Figure 18 in terms of the equivalent controller correcting time ($R_t \times T_5$)

ample, the effects of variations of the governor time constant are given on Figure 16 with ΔT applied at the rate of full torque change in 42.4 seconds. The system damping is $T_d=2$, and the governor regulation is $R=0.0625$. The rate of tie-line correction ($R_t'=1.36$) is the approximate optimum value (Figure 11) when the governor and controller time constants are each equal to 1.06 seconds. The curves are of interest in that an increase of governor time constant results in greater tie-line power swings. At a critical governor time lag of 2.04 seconds, the system becomes unstable.

The optimum rate of tie-line correction depends upon the time constants of the control system. In the limiting case of zero controller and governor time lags, Figure 17, the maximum tie-line power change is less with $R_t'=0.68$ than with $R_t'=1.36$, although the natural frequency oscillations are not damped out as rapidly. The smaller R_t' is the one equal to $MR/2\pi f$ seconds correcting time (see section on stability).

2. *Proportional Control.* The curves of Figure 18 include the effects of a proportional tie-line controller having a regulation of $R_t=0.1$ and various amounts of time lag, T_5. The theoretical tie-line regulation is shown by the dashed line. Because of this drift of tie-line power the magnitudes of the initial swing and those at the end of 10, 20, and 30 seconds are summarized on Figure 19 as a function of the equivalent correcting

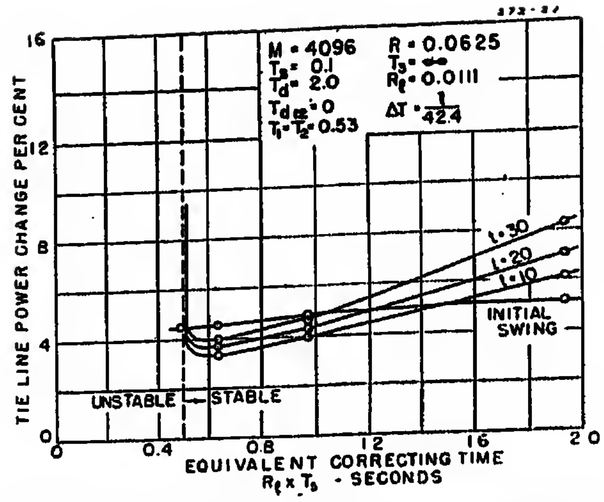

Figure 21. Summary of Figure 20 in terms of the equivalent controller correcting time ($R_t \times T_5$)

time $R \times T_5$. The optimum correcting time is, as before, not much greater than the minimum value required to insure stable operation.

Figures 20 and 21 give similar information for a controller regulation of $R_t=0.0111$. The drift of tie-line power is very much less in this case, and with optimum controller time lag the power deviation at the end of 30 seconds is even less than that of the initial swing. The required controller time lag is much larger, however, being approximately inversely proportional to R_t. The system constants and the rate of load-torque change are the same as those used during the runs of Figure 16 for the floating type of control, and the results are, therefore, directly comparable. With the optimum proportional controller, Figure 21, the maximum tie-line power change is 4.6 per cent as compared to 6.8 per cent for the floating controller, Figure 16, with $R_t'=1.36$ and $T_4=1.06$. This difference would be even smaller if the optimum ($T_4=0$) floating-type controller had been used (see Figure 12 for effect of T_4).

3. *Intermittent Floating Control.* In applying the intermittent adjustments, the tie-line power deviation was read at intervals of 2.12 seconds. Following each reading a corrective indication was ap-

$M=4{,}096$ $T_s=0.1$ $R=0.0625$
$T_d=2$ $T_1=T_2=0.53$ $R_t=0.0111$
$T_{d12}=0$ $T_3=\infty$ $\Delta T=t/42.4$

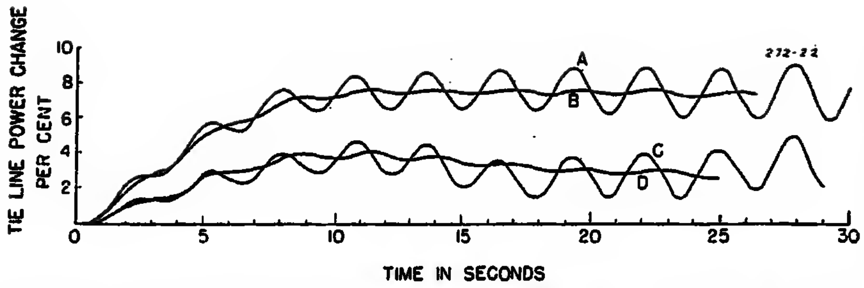

Figure 22. Intermittent control—tie-line power deviation as affected by system damping (T_d) and by the magnitude of load-torque change (ΔT)

Curve A—$T_d=2$, $\Delta T=t/84.8$
Curve B—$T_d=10$, $\Delta T=t/84.8$
Curve C—$T_d=2$, $\Delta T=t/169.6$
Curve D—$T_d=10$, $\Delta T=t/169.6$

$M=4{,}096$ $T_1=T_2=0.53$ $\Delta P_m=0.064$
$T_{d12}=0$ $T_3=\infty$ $k_1=1/42.4$
$T_s=0.1$ $T_4=1.06$ $R_t'(\text{eq.})=5.44$
$R=0.0625$

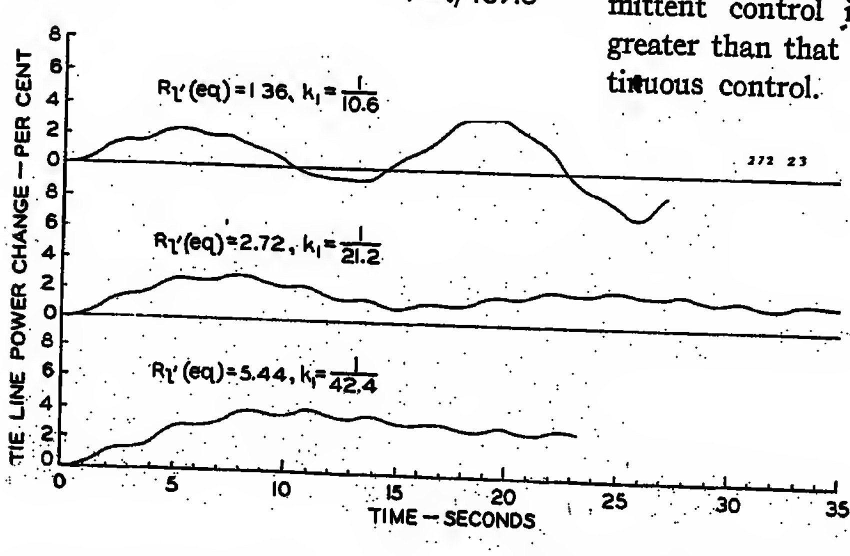
plied for a length of time proportional to the deviation ΔP at the beginning of the interval, and at a constant rate equivalent to k_1 per unit prime-mover torque change per second. The maximum duration of the impulse was limited to 1.06 seconds (half the period) for a power change equal to or greater than ΔP_m. For this controller there is an equivalent R_t' as given by (see appendix):

$$R_t'(\text{eq.})=\frac{2\Delta P_m}{k_1}$$

The tie-line power swings of Figure 22 were obtained with a controller having $T_4=1.06$, $\Delta P_m=0.064$ per unit, $k_1=1/42.4$, and $R_t'(\text{eq.})=5.44$ seconds. Curve A is compared with the curve $T_1=T_2=0.53$, Figure 16, for the continuous controller having the constants $R_t'=1.36$ and $T_4=1.06$. It is observed that the intermittent controller causes system instability, although its equivalent correcting rate is only one-fourth that of the continuous controller. For a system having a larger damping factor $T_d=10$, curve B of Figure 22, the results are satisfactory. Curves C and D give similar results with the load torque applied at one-half the rate. The magnitudes of the tie-line power swings are not proportional to the rate of load-torque change, because of the maximum correction rate imposed by this controller.

Figure 23. Intermittent control—effect of varying the equivalent controller correcting time by changing k, with ΔP_m constant

$M=4{,}096$ $T_s=0.1$ $R=0.0625$
$T_d=10$ $T_1=T_2=0.53$ $\Delta P_m=0.064$
$T_{d12}=0$ $T_3=\infty$ $T_4=1.06$
$\Delta T=t/169.6$



With $\Delta P_m=0.064$ and a large system damping, $T_d=10$, the effects of variations of the constant k_1 are shown on Figure 23. Likewise, Figure 24 gives the effects of variations of ΔP_m with $k_1=1/42.4$. The maximum power swings are summarized on Figure 25 as a function of the equivalent correcting time, R_t' (eq.). The optimum correcting time is of the order of 2.72 seconds under these conditions, that is, it is approximately twice that of the continuous controller. Furthermore, the effectiveness of a controller having the constants $\Delta P_m=0.032$ and $k_1=1/42.4$ is about the same as one with $\Delta P_m=0.064$ and $k_1=1/21.2$ since their equivalent correcting times are both equal to 2.72 seconds.

The power swings of Figures 23 and 24 for $R_t'(\text{eq.})=2.72$ are compared with that of Figure 15, $R=0.0625$, for the optimum continuous controller. After allowance has been made for the fact that the rates of applied load-torque change are different by a factor of four to one in the two cases, it appears that the tie-line power deviation obtained with the intermittent control is about 75 per cent greater than that obtained with the continuous control.

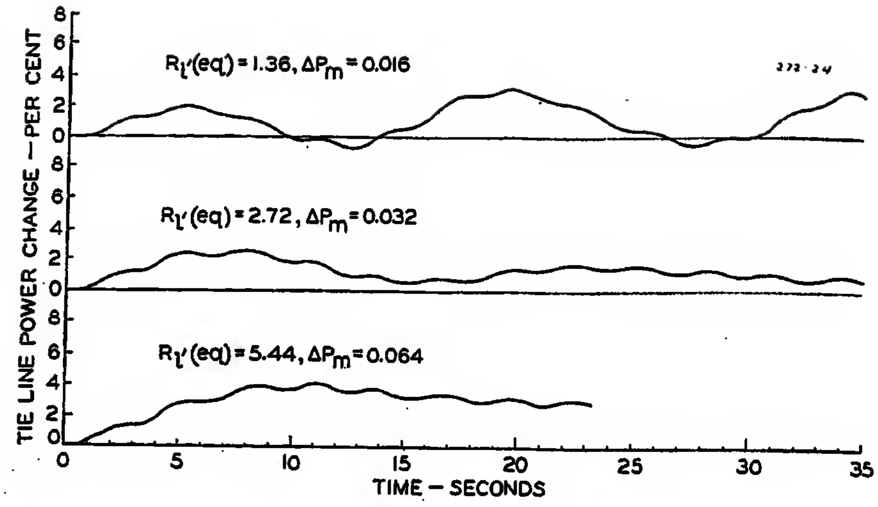


Figure 24. Intermittent control—effect of varying the equivalent controller correcting time by changing ΔP_m with k, constant

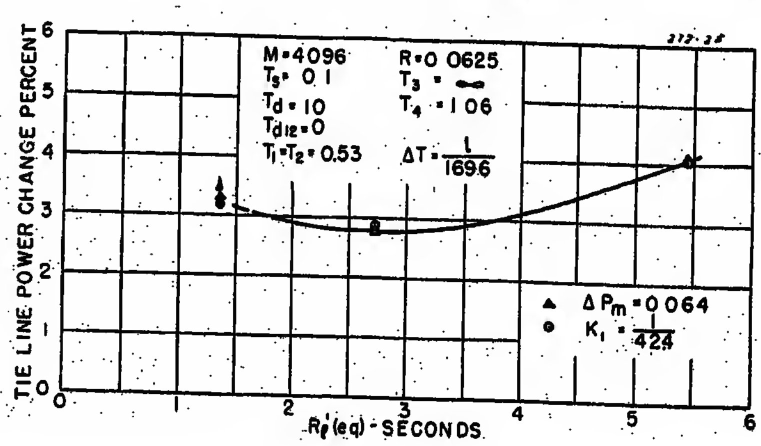
$M=4{,}096$ $T_s=0.1$ $R=0.0625$
$T_d=10$ $T_1=T_2=0.53$ $k_1=1/42.4$
$T_{d12}=0$ $T_3=\infty$ $T_4=1.06$
$\Delta T=t/169.6$

4. *Summary.* The control systems have been compared with respect to their effects upon the prime-mover governor response and tie-line power deviation, when the system is subjected to smooth variable loads. The recorded data also give a measure of the power deviation for the particular load cycles and system constants considered. It is to be expected, however, that the magnitude of the swings depends upon the period as well as the magnitude of the variable load, particularly if the period is very short. The shape of the load cycle may also be of considerable importance. Instantaneous load changes initiate natural-frequency power oscillations. As an example of the extreme condition, successive build up of tie-line power swings can occur if instantaneous load changes are applied at regular time intervals equal to the period of the natural-frequency oscillations.

Conclusions

1. (*a*) Introduction of tie-line power control of the floating type results in system instability, regardless of the value of system

Figure 25. Summary of Figures 23 and 24—tie-line power deviation as affected by the equivalent correcting time of the intermittent controller



damping, if the controller correcting time (R_t') is less than about one fourth of the governor time lag (Figures 1–4). The inherent instability ($T_1+T_2>4R_t'$) is not appreciably affected by variations of the tie-line synchronizing power coefficient T_s or the governor regulation R, but it does appear at an even smaller value of governor time lag if there is time lag (T_4) in the tie-line controller.

(*b*) Instability may also occur in the range of small governor time lags as a result of a large rate of tie-line correction (small R_t'). The appearance of this unstable region is a function of governor regulation, that is, it appears when R_t' is less than $MR/2\pi f$ seconds correcting time (Figure 4). In general, therefore, the minimum allowable R_t', as regards system stability, is a function of the governor time lag and is also a function of governor regulation if the governor time lag is small (Figure 5). Accordingly, there is an optimum governor regulation dependent upon the governor time lag, the system damping factor, and the rate of tie-line correction.

(*c*) With respect to the maximum effectiveness of the floating control in reducing the magnitude of tie-line power swings, the optimum correcting time is not much greater than the minimum allowable value required to insure stable operation (Figure 11). The controller time lag should be reduced to a minimum (Figure 12).

2. The use of a proportional tie-line controller having small regulation and zero time lag will cause instability unless the system damping is very large. Stability is obtained by introducing controller time lag T_5. With small regulation (R_t) and large time lag (T_5), the controller response is primarily a function of the factor $R_t\times T_5$ and is not much different from that of floating control since the above factor is similar to the R_t' type of regulation. On the basis of simplicity, the floating control may be preferable for use with most governors.

3. The impulses of an intermittent control having about two second period and a fast rate of response may result in system instability, if the operation is near the limit of stability without tie-line control. Otherwise, satisfactory results can be obtained, and the optimum equivalent correcting time [R_t'(eq.)] is of the order of two times the optimum R_t' of the continuous controller.

4. The optimum rates of response of tie-line controllers for maximum effectiveness are very much higher than those ordinarily used in power-system control.

5. The optimum continuously acting controllers limit the tie-line power deviation to approximately 15 per cent of the total load variation if the tie-line synchronizing power coefficient is small ($T_s=0.1$), and if the load variation occurs in smooth cycles of about one minute period. With an intermittent controller of the type considered, the tie-line power deviation may be limited to approximately 25 per cent of the load variation.

6. Previous considerations[1,2] have indicated that a turbine-governor regulation of the order of six per cent may be desirable. Although the optimum value depends to some extent upon the governor time lag, system damping, rate of tie-line correction, and so on, the present analysis has shown that six per cent regulation is satisfactory (Figures 11 and 15) when automatic tie-line control is also used. A smaller steady-state regulation is obtained without appreciable change in the degree of system stability by adding a droop-compensation mechanism having a relatively large time constant, but the tie-line power swings are not reduced in magnitude (Figures 1 and 11).

Appendix. Equations and Definitions of Terms

The approximate torque equations for two interconnected power systems were given in reference 2. If it is assumed that one system is infinitely large the equation for the smaller system is,

$$[Mp^2+(T_d+T_{d12})p+T_s]\delta+T_g=\Delta T \qquad (1)$$

where,

$M=4\pi fH$ is the effective inertia of the system and is equal to the time in electrical radians required to reach full rated speed from standstill with rated torque applied to the rotor.

T_d is the system damping factor equal to the slope of the net prime mover plus load torque versus speed curve with fixed prime-mover input valve.

T_{d12} is the tie-line damping-torque coefficient, or the change in torque per unit change in relative system speeds.

T_s is the synchronizing-torque coefficient, or the change in torque per electrical radian change in relative system angles.

T_g equals the change in prime-mover torque resulting from the movement of the input valves.

ΔT is that part of the load-torque change applied to this system.

All of the above quantities are in per unit on a kilovolt-ampere base equal to the system capacity.

δ is the effective system angle in radians with respect to the normal-frequency reference; or in this case with respect to the angle of the infinite system.

$p\delta=d\delta/dt$ is a measure of speed or frequency change.

t equals time in electrical radians; 377 radians = one second for a 60-cycle system.

The governor control mechanism has been represented as a two-stage amplifier having time lags T_1 and T_2.[2] The hydraulic-relay system of an actual governor might be considered as the first stage and the steam-storage capacity as the second. Speed response indications and tie-line control adjustments at the governor head

$$A=p\delta+D \qquad (2)$$

are transmitted to the first stage through a set of levers. The effective leverage of this connection may vary because of the action of a droop-compensation mechanism, and if the variation is at an exponential rate defined by the time constant, T_3, the motion transmitted to the first stage is

$$F=\frac{(T_3p+1)}{\left(T_3p+\dfrac{r}{R}\right)}A \qquad (3)$$

At the first instant ($p=\infty$) following a change at the governor head, the indications are directly impressed upon the governor control system, but in the steady-state condition following droop correction ($p=0$) they are amplified by a factor equal to the ratio (R/r) of the transient to steady-state governor regulations.

In passing through the governor control system this correcting force is modified by the time lags T_1 and T_2 and is amplified by a factor inversely equal to the transient regulation of the governor. Thus the outputs of the first and second stages are, respectively:

$$\left.\begin{aligned} Q&=\frac{1}{(T_1p+1)}F\\ T_g&=\frac{1}{R(T_2p+1)}Q \end{aligned}\right\} \qquad (4)$$

The complete expression for the change in prime-mover torque is, therefore,

$$T_g=\frac{1}{(T_2p+1)(T_1p+1)}\frac{(T_3p+1)}{\left(T_3p+\dfrac{r}{R}\right)}\times\left(\frac{p\delta}{R}+\frac{D}{R}\right) \qquad (5)$$

For a governor without a droop-correction mechanism, $T_3=\infty$ and R is the regulation. Otherwise, R and r are the transient and the steady-state governor regulations, respectively. T_3 is the time constant of the droop-compensation mechanism.

As used in equation 5, the terms $p\delta/R$ and D/R are a measure of the turbine speed response and tie-line control adjustments, respectively, expressed as the equivalent prime-mover torque changes that would result if there were no governor time lag ($T_1=T_2=0$) and if the adjustments were amplified only according to the transient governor regulation $R(T_3=\infty)$. The characteristics of the tie-line control system are interpreted in this paper by evaluating the equivalent response D/R in this manner. For instance, the response of one type of controller has been expressed as

$$\frac{D}{R}=\frac{\Delta P}{R_t'p(T_4p+1)} \qquad (6)$$

where

$\Delta P=(T_s+pT_{d12})\delta$ is the tie-line power change, and

T_4 is the time lag of the controller.

With zero controller time lag ($T_4=0$) the first derivative of this equation

$$p\left(\frac{D}{R}\right)=\frac{\Delta P}{R_t'} \qquad (7)$$

shows that the equivalent correction is applied at a rate inversely proportional to the constant R_t'.

A D-C Telemeter or D-C Selsyn for Aircraft

R. G. JEWELL
ASSOCIATE AIEE

H. T. FAUS
MEMBER AIEE

Synopsis: This paper describes a d-c telemeter which is particularly adapted for transmitting to the instrument board indications of pressure, temperature, liquid level and of the position of the various controlling members of the airplane. The description comprises the principle, variations, characteristics, and application of this telemetering system. Although the applications described are primarily in connection with aircraft, the versatile nature of this device makes it suitable for many other applications.

The large number of indications which must be transmitted accurately to the instrument board of an airplane has created a demand for a telemetering system of small size and light weight. For many years the a-c Selsyn telemetering system has given excellent service in marine applications. Variations of this system are used successfully on aircraft. A search for a simpler and lighter system which will operate on direct current has led to the development of the d-c Selsyn telemetering system.

Paper 42-7, recommended by the AIEE committee on air transportation, for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted October 10, 1941; made available for printing November 3, 1941.

R. G. Jewell and H. T. Faus are development engineers in the West Lynn Works of General Electric Company, Lynn, Mass.

Principle

A SIMPLIFIED concept of the operation of the d-c Selsyn may be obtained by referring to Figure 1 which shows a coil wound on a toroidal iron core. This is a continuous single layer winding with two brushes supplying direct current at diametrically opposite points. It is evident that a magnetic pole will be set up in the core under each of the brushes, and that the magnetic field inside the core will be as shown. This field will follow the brushes as they are rotated. If a polarized permanent magnet rotor is placed inside the core, it will revolve so as to keep its direction of magnetization in line with the brushes.

The next step in the development is shown in Figure 2. The circular rheostat transmitter is tapped at intervals of 120 degrees and these taps are connected to similarly spaced taps on the receiver. This gives a result similar to that obtained in Figure 1 so that, within the accuracy limits to be defined later, the permanent magnet rotor will turn to a position having the same relation to the taps on the receiver winding as the brushes have to the corresponding taps on the transmitter winding. The windings shown are similar to delta connected three-phase windings. Connections similar to other polyphase windings may also be used and the windings may be concentrated in coils rather than being uniformly distributed on the core.

The use of a permanent magnet of high coercive force in combination with a copper damping shell fixed in the air gap between the rotor and the stator gives effective damping combined with high torque. Damping by a permanent magnet used in this manner involves no power loss as would be the case if an alternating field were used. The torque is a function of the product of the rotor and stator fluxes. Since the rotor field is of much higher magnetomotive force than the stator field, and since its excitation involves no electrical losses, it is evident that the inherent torque producing effectiveness is high. The high ratio of torque to weight obtainable with this system is one of its outstanding advantages. This makes it possible to use a comparatively light moving element which requires neither ball bearings nor jewel bearings, since the frictional errors are inappreciable with steel and bronze bearings. Since these bear-

---

For another type of controller response

$$\frac{D}{R}=\frac{\Delta P}{R_l(T_5p+1)} \qquad (8)$$

the equivalent correction is directly proportional to the tie-line power change, but it is delayed by the time lag T_5.

The effects of an intermittent controller are introduced as follows. The tie-line power change, ΔP, is read at regular time intervals. Within the period Δt following each reading a corrective indication is applied at a constant rate k_1 and for a length of time proportional to ΔP. This rate of correction is again expressed as an equivalent prime-mover torque change per unit of time. If the correction is applied through the synchronizing motor then k_1 is also a measure of the synchronizing-motor speed.

It is assumed that the impulse starts after an elapsed time t_1 dependent upon the value of ΔP at the beginning of the interval, and ends after a fixed time t_e. If the reading of tie-line power deviation is equal to or greater than ΔP_m, the full correction is applied, that is, t_1 is equal to some fixed time t_m. Then for any smaller power deviation ΔP the impulse is applied at the time t_1 given by

$$\frac{t_e-t_1}{t_e-t_m}=\frac{\Delta P}{\Delta P_m} \qquad (9)$$

The correcting adjustment applied at the governor head is of the form

$$\frac{D}{R}=\frac{kt}{(T_4p+1)} \qquad (10)$$

where (with t_0 = time at beginning of interval Δt, and $t_e < t_0+\Delta t$)

$k=0$ for $t_1>t>t_0$
$k=k_1$ for $t_e>t>t_1$
T_4 = time lag of the controller

At a fixed power deviation equal to ΔP_m, and neglecting the controller time lag ($T_4=0$), there is an average correcting rate over the entire interval equal to

$$p\left(\frac{D}{R}\right)=\frac{k_1(t_e-t_m)}{\Delta t} \qquad (11)$$

This average rate can be defined by an equivalent R_l' similar to that of equation 7:

$$p\left(\frac{D}{R}\right)=\frac{\Delta P_m}{R_l'(\text{eq.})} \qquad (12)$$

or from the above two equations:

$$R_l'(\text{eq.})=\frac{\Delta P_m\,\Delta t}{k_1(t_e-t_m)} \qquad (13)$$

The effects of variations of the constants k_1 and ΔP_m were obtained from the differential analyzer solutions. The following time intervals were used:

$\Delta t = 2.12$ seconds
$t_m = 0.265$ second
$t_e = 1.325$ seconds

All time constants and the factors R_l' and $1/k_1$ are given in units of electrical radians in the above equations but in other parts of the paper they are given in seconds for a 60-cycle system. Otherwise the notation is consistent throughout.

ings are lightly loaded they withstand severe vibration very well.

The use of sliding contacts has been cited as an objection to this type of telemeter. By using brushes of precious metal alloys operating at carefully determined pressures, a reliable contact is obtained with very little friction. Life tests have shown these brushes to be capable of operating for over 40,000,000 complete revolutions of the transmitter.

Variations

In the transmitter shown in Figure 2, the output voltage passes through 360 electrical degrees for each revolution so that the ratio of angular motions of the transmitter and indicator is unity. By making the number of evenly spaced taps equal to $3n$, where n is the number of indicator revolutions per transmitter revolution, it is possible to obtain a ratio equal to any whole number. Brushes of opposite polarity must be 180 electrical degrees $(360/(2n))$ angular degrees) apart. In order to utilize the full capacity of the winding, $2n$ brushes must be used, but the transmitter is operable with only two brushes. Figure 3 shows a transmitter designed for a ratio of 3.

The transmitter shown in Figure 4 is designed to transmit linear motion without converting it to circular motion by mechanical means. Motion of the brushes for the complete length of this transmitter gives one revolution of the indicator. A multi-revolution modification of this circuit is shown in Figure 5 which gives three revolutions of the indicator. This scheme can obviously be modified to give any number of revolutions of the indicator for a given linear motion of the brushes. Figure 6 is a modification of this circuit which will give fractional ratios with a circular transmitter. Obviously with this circuit, the motion is limited to less than one revolution of the transmitter.

Two or more indicators may be operated in parallel in connection with any of these transmitters. The only effect on their operation is to lower the torque in proportion to the reduction in current through each indicator.

Since there is no torque acting on the indicator when the power is disconnected, the pointer will remain unchanged in position. For applications where an indication of power failure is desired, the indicator is provided with a small fixed permanent magnet which attracts the rotor magnet to a position at which the pointer is off the calibrated part of the scale. Due to the high torque of the instrument, it is possible to use a fixed magnet strong enough to provide a reliable indication of power failure without having any significant effect on the accuracy.

Characteristics

Each indicator element weighs 25 grams and can be mounted in a $1^1/_4$-inch-diameter circle.

The power required by the transmitter and indicator combination is 1.8 watts. With two indicators connected to one transmitter, the power required is 2.2 watts.

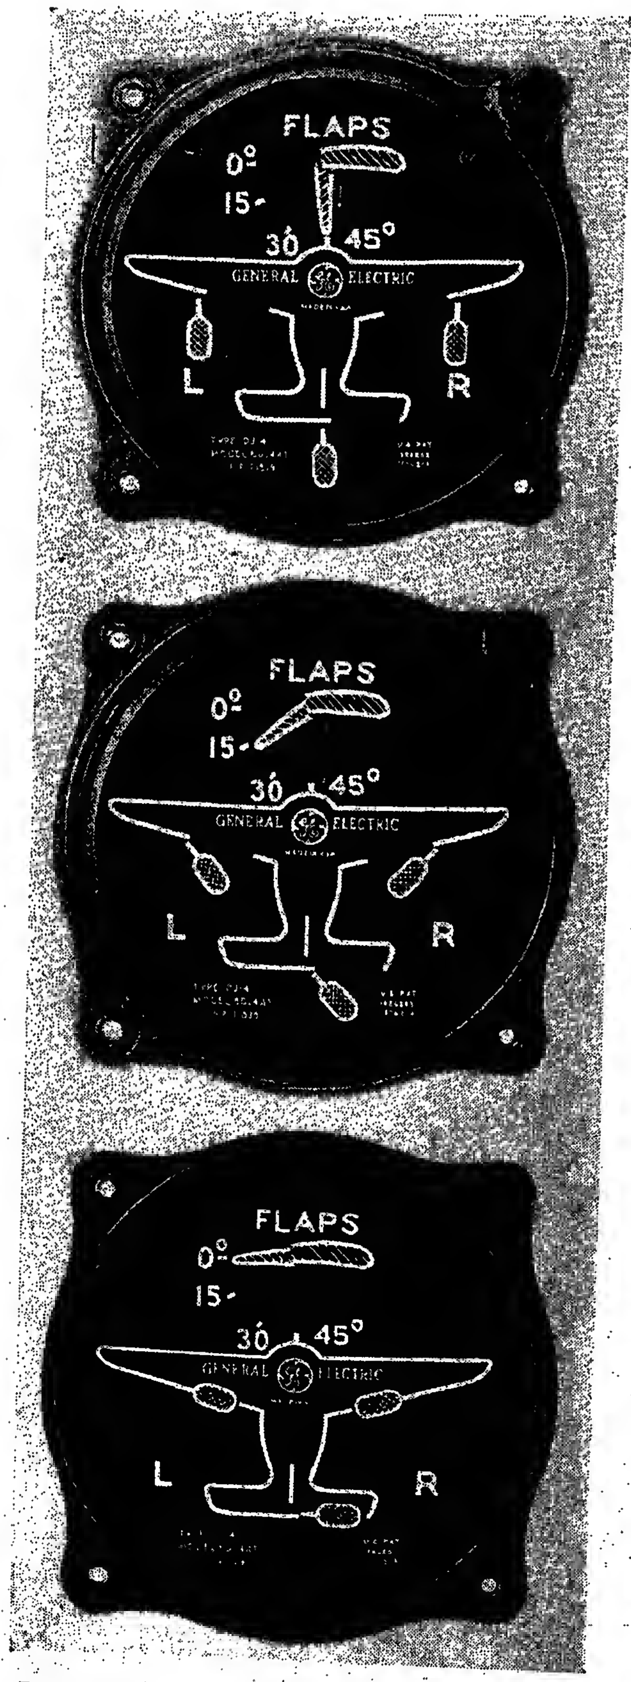

Figure 11. D-c Selsyn position indicators, showing three positions of flaps and landing gear

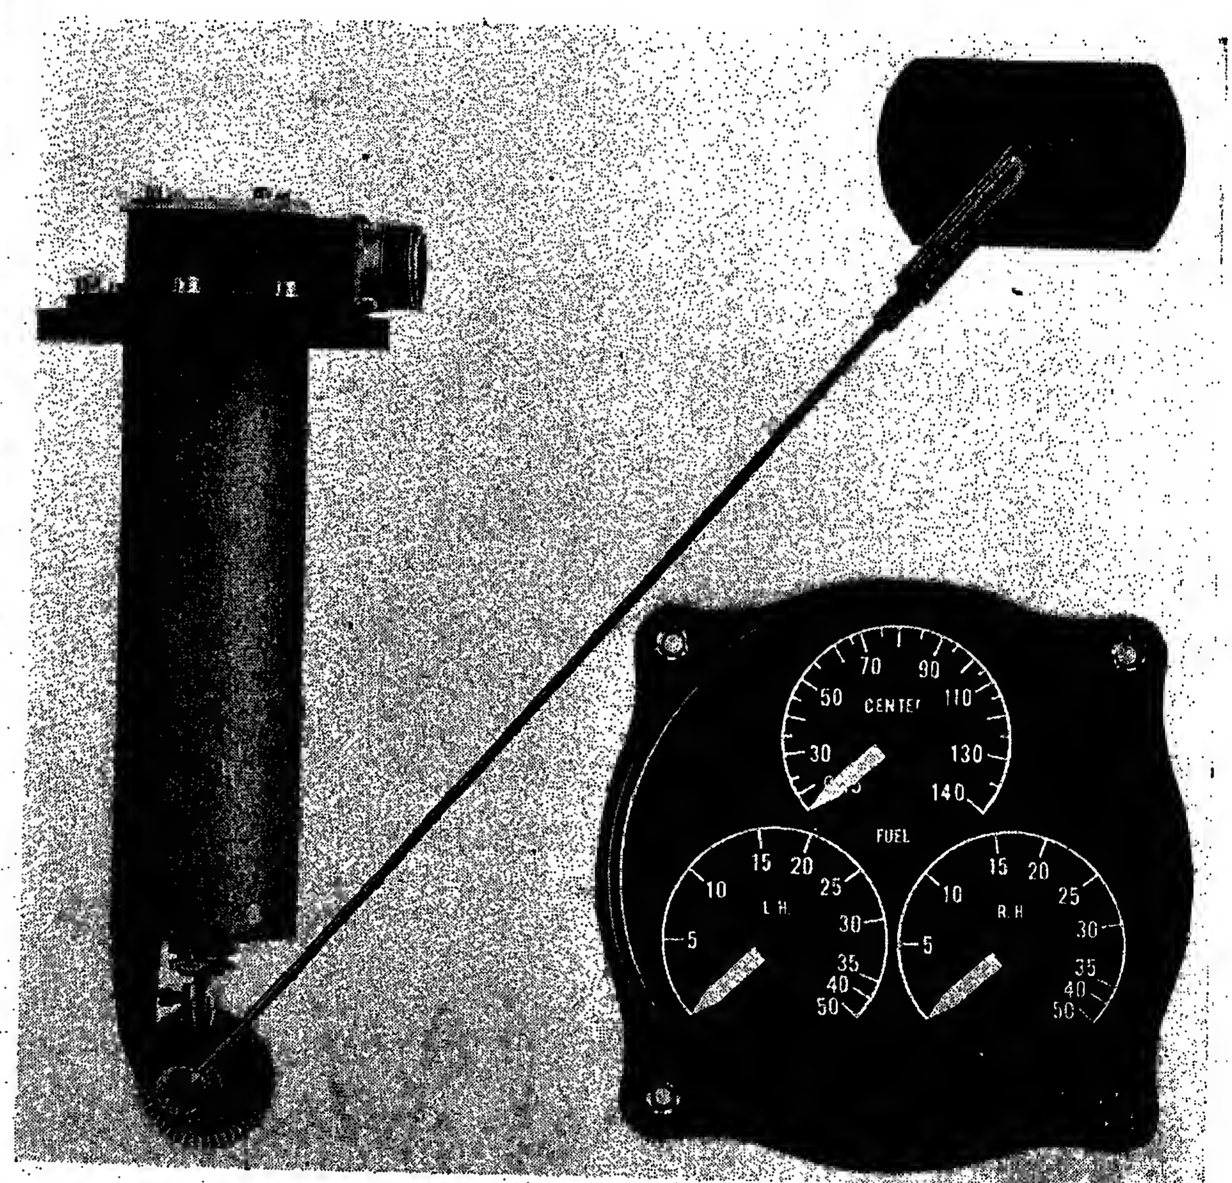

Figure 12. Typical liquid-level transmitter

Figure 13. Typical three-element liquid-level indicator

Varying the voltage of the supply does not affect the indication provided no power failure indicator is used. With the power failure indicator a variation of ten per cent in the voltage will cause a maximum error of one degree.

The torque obtained is shown by the curves in Figure 7. The slope of the torque curve at zero is important since a steep slope at this point gives less frictional error. The torque curves show that the steepest part is at zero.

Temperature effect on indications is negligible because of the symmetry of the circuit.

The wave form of the voltage between taps in the transmitter is shown in Figure 8. At no load the form is triangular with the tops cut off flat. With load, the sides and tops of the form bend inward. The change in the form is of such nature that at any given point the ratio of voltage between one pair of taps to that between another pair of taps does not change with load so that an indicator connected to the transmitter will not change its calibration when another indicator is placed in parallel with it.

The peculiar shape of the voltage wave does prevent the indicator from following the transmitter linearly. This inherent deviation has been determined to have a maximum peak of 1.3 degrees. The peaks occur at six points above the axis, and six points below the axis. Figure 9 shows a typical distribution curve *A* which consists of the 1.3 degree deviation and additional deviation due to manufacturing tolerances. Curve *B* of the same figure shows how the distribution curve is changed by the power failure indicator.

Applications

One of the first applications of the d-c Selsyn was for the remote indication of the positions of the landing gear and wing flaps on an airplane. For this purpose four elements were mounted in a single case, one element being used for each of the three landing wheels and one for the flaps.

The remote indication of oil and fuel pressure is accomplished by connecting a bellows to the oil or fuel pressure line and utilizing the motion of the bellows to rotate the transmitter brushes.

The temperature transmitter has a bimetal helix which rotates the transmitter brushes as the temperature changes.

The manifold pressure transmitter has a partially evacuated sealed bellows in a pressure tight compartment and the manifold pressure is applied to the outside of the bellows. Motion of the bellows is transmitted mechanically through a flexible wall to the d-c Selsyn transmitter. Temperature compensation is obtained by having the right amount of air in the sealed bellows.

The differential fuel pressure transmitter is similar to the manifold pressure except the bellows is not evacuated. The fuel pressure is connected to the inside of the bellows while the surrounding chamber is connected to the manifold. The bellows deflection is then proportional to the differential pressure.

The liquid level measurement utilizes the motion of a float to actuate the transmitter brushes. Magnetic coupling is used between the transmitter outside the tank and the float mechanism inside the tank so as to provide a positive gasoline seal.

Conclusions

The d-c Selsyn has been shown to be particularly suited to applications requiring high accuracy, light weight, and rapid and stable indications. These qualities make it particularly suitable for aircraft use. The fact that it can be operated on any source of low-voltage direct current without auxiliary equipment is an advantage, not only for aircraft use but for other applications where special power sources are not available.

Design of Long-Scale Indicating Instruments

I. Introduction

FROM the viewpoint of utility, the scale length of an indicating instrument bears somewhat the same relationship to its dimensions as does the output of a motor to its frame size. The end product of an instrument is quantitative information. The longer and more legible the scale, the more definite the resulting scale readings, through reduction of observational errors both in the initial calibration and in subsequent use. Thus, instrument designers have endeavored to produce maximum scale lengths within a given space, examples of which are 5-inch scales of 6-inch rectangular switchboard instruments, and the $3^1/_2$-inch scales of 4-inch rectangular instruments. In general, however, the movements of such instruments have been restricted to an angular deflection of about 90 degrees, with consequent limitation in scale lengths as compared to the scale lengths of nonelectrical instruments such as steam and pressure gauges. A study of these fundamentals leads the authors, who attacked the problem of designing a new line of switchboard instruments, to the conclusion that a definite contribution to measurement technique could best be made by designing such instruments for long-range indication, and the smallest practicable panel space.

A study of prior art[1,6] showed that the importance of scale length had been appreciated, although no complete and co-ordinated group of instruments had resulted. Among the long-scale instruments produced were wattmeters, voltmeters, and ammeters operating on the induction disk principle, also permanent-magnet moving-coil voltmeters and ammeters. The induction instruments, while perhaps satisfactory for restricted operating conditions, hardly met modern performance requirements as to frequency range, wave-form variation, and other conditions. There is very little published information on these instruments, and their manufacture appears to have been discontinued, at least in America. It was therefore concluded that no complete group of long-scale instruments, meeting modern installation and performance requirements, was available.

A distinguishing feature of switchboard instruments which cannot be overemphasized is the variety of measurements which must be accomplished in devices having uniform appearance and outline dimensions. These include the measurement of d-c volts, d-c amperes, a-c volts, a-c amperes, watts, vars, power factor, cycles, synchronism, and such nonelectrical quantities as temperature and speed. It is impractical to satisfactorily measure all these quantities with one design of instrument mechanism, a minimum of four being required as shown in Table A.

Table A

Group	Kind of Mechanism	Quantities Measured
A	Permanent-magnet moving-coil	D-c amperes, D-c volts, Temperature, Speed
B	Repulsion - attraction with fixed and moving vanes	A-c amperes, A-c volts
C	Iron-cored electrodynamic	A-c watts, A-c vars, A-c cycles
D	Electromagnet with rotating vane	Power factor, Synchronism

In the following sections, the method of attack in designing long-scale elements for each of these groups will be outlined. A panel dimension of $4^1/_4$ inches square was required, and a scale length of 6.8 inches representing 240 angular degrees was selected. The problem in each case was to obtain (*a*) mechanical freedom of the movement and (*b*) satisfactory torque characteristics, both with respect to magnitude and gradient, over this scale angle. After determining each basic design, much analytical work was necessary to reduce it to practice, but, with one or two exceptions, design details will be omitted in the interest of brevity.

Paper 42-70, recommended by the AIEE committee on instruments and measurements for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted November 27, 1941; made available for printing January 2, 1942.

A. J. CORSON, R. M. ROWELL and S. C. HOARE are engineers of the instrument engineering department, General Electric Company, West Lynn, Mass.

II. The Permanent-Magnet Moving-Coil Instrument for Measurement of D-C Potential and Current

The design of the permanent-magnet moving-coil instrument was definitely simplified by using Alnico as a magnet material. The high coercive force of this material adapted it to short lengths of large cross section, as illustrated in Figure 1. The sector-shaped magnet was cast integrally with a soft-iron pole face for uniform distribution of the field in the air gap, and the magnet was arranged immediately adjacent to the gap to minimize leakage fluxes. The moving coil was pivoted about one of its sides and thus only one of the coil sides was effective in production of torque. The use of two coil sides appeared to involve mechanical complications such as to be thoroughly impracticable. It was found that satisfactory results could be obtained by full utilization of the magnetic material as described above and by using a minimum of weight and inertia in the moving element. The millivoltmeter moving coil was designed for a power input of 0.34 milliwatt, since the instrument will be used with 50-millivolt shunts. This construction also has the advantages of shelf-shielding, mechanical simplicity, and reproducibility. Damping was obtained by adding a short-circuited winding to the moving coil, the wire size and number of turns being determined by the required damping constant of the instrument involved. A uniform scale distribution is obtained as shown in Figure 2. The characteristics are shown in Table II.

Since instruments for the measurement of the temperatures of electrical machinery are required for modern switch-

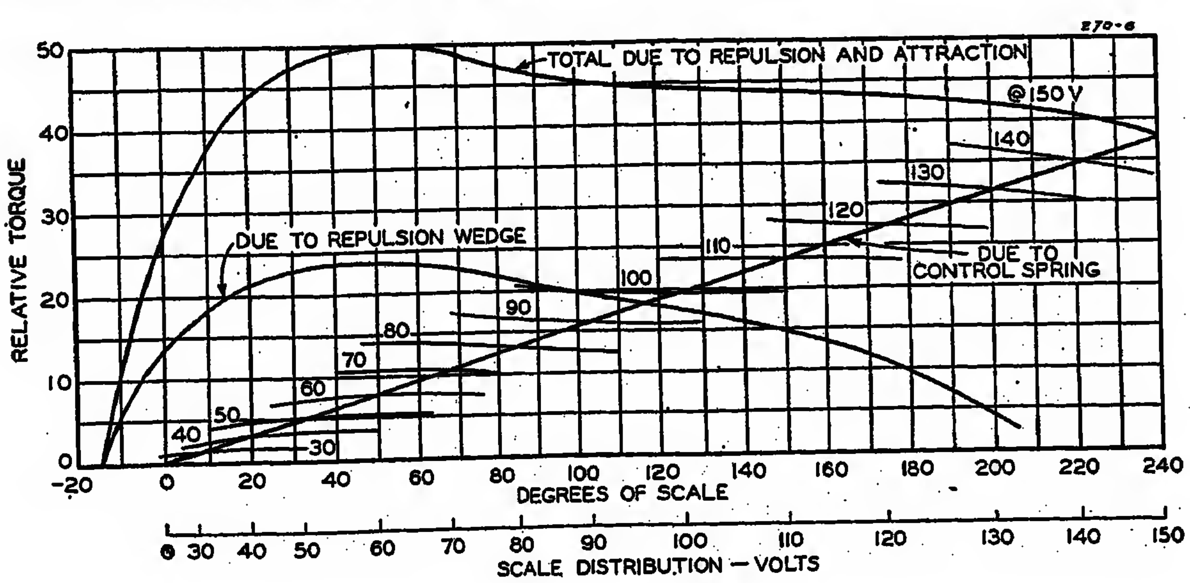
Figure 6 (below). Repulsion–attraction instrument torque characteristics along the scale



boards, such instruments have been included in this group. A circuit, illustrated in Figure 3, was thus designed to adapt the d-c milliammeter to temperature measurement using standard 10-ohm resistance temperature detectors. This circuit is essentially a Wheatstone bridge, energized by a constant potential of 6 volts direct current through a saturating transformer and rectifier designed for use on a standard 115-volt, 60-cycle circuit. The characteristics are given in Table II, and the scale distribution is shown in Figure 23.

III. The Repulsion–Attraction Instrument for Measurement of A-C Potential and Current

In their usual forms, the soft-iron torque-producing mechanisms are inherently limited to angular deflections of about 100 degrees of arc. Serious difficulties arise in matters of scale constriction and increased power consumption if the scales of these simple instruments are extended beyond their natural limits.

In the new element, these limitations are removed by utilizing dual forces of electromagnetic repulsion and attraction which act on a single movable vane as shown in Figures 4 and 5. The main repulsion mechanism is essentially similar to wedge-repulsion mechanisms now in use, in which a rapidly decreasing torque–displacement curve is obtained beyond the usual 0–90 degree scale range. The auxiliary irons exert a force of attraction which increases progressively as the repulsion force decreases. With suitable shapes and spacings for the soft-iron members, the two forces are well blended, resulting in a smooth open scale. In addition to the increase of scale angle, the element possesses a higher "torque-per-watt" effectiveness than any known soft-iron or even electrodynamic instrument mechanism, as illustrated in Table I.

The middle repulsion wedge is moulded integrally with the coil form. The attraction irons are mounted in magnetic contact with soft-iron cups which can be rotated manually through small angles. The rotatable cups serve as a means of instrument adjustment and also as a partial return path for the magnetic circuit. The cups are slotted radially to eliminate induced circulatory currents. Figure 4 is a sectional view of the assembly.

The rotatable cups (and attraction irons) permit of a rather wide range of control in scale distribution. The preferred scales are shown in Figure 9, where the voltmeter scale is expanded over the

normal 110–120-volt interval. The ammeter scale is essentially uniform over the working range.

The Coil

In proportion, an air coil of the greatest electromagnetic effectiveness (that is, maximum flux per watt input) will have a square cross section and a mean diameter equal to three times a side of the square as shown in the curves of Figure 7. The authors' curve of proportions is in agreement with Shawcross and Wells'.[2] The variance with Maxwell's classic proportions[3] of $d = 3.7c$ is due, no doubt, to neglect of higher order terms of the calculations. The two criteria are, however, high up on the curves so the variation is more of academic than practical interest.

The magnetic circuit of a repulsion–attraction mechanism of this kind permitted of little more than a rough mathematical treatment which served as a guide to methodical experimentation in determining the best shapes and spacings for the soft-iron members. From computations and from actual torque curves for

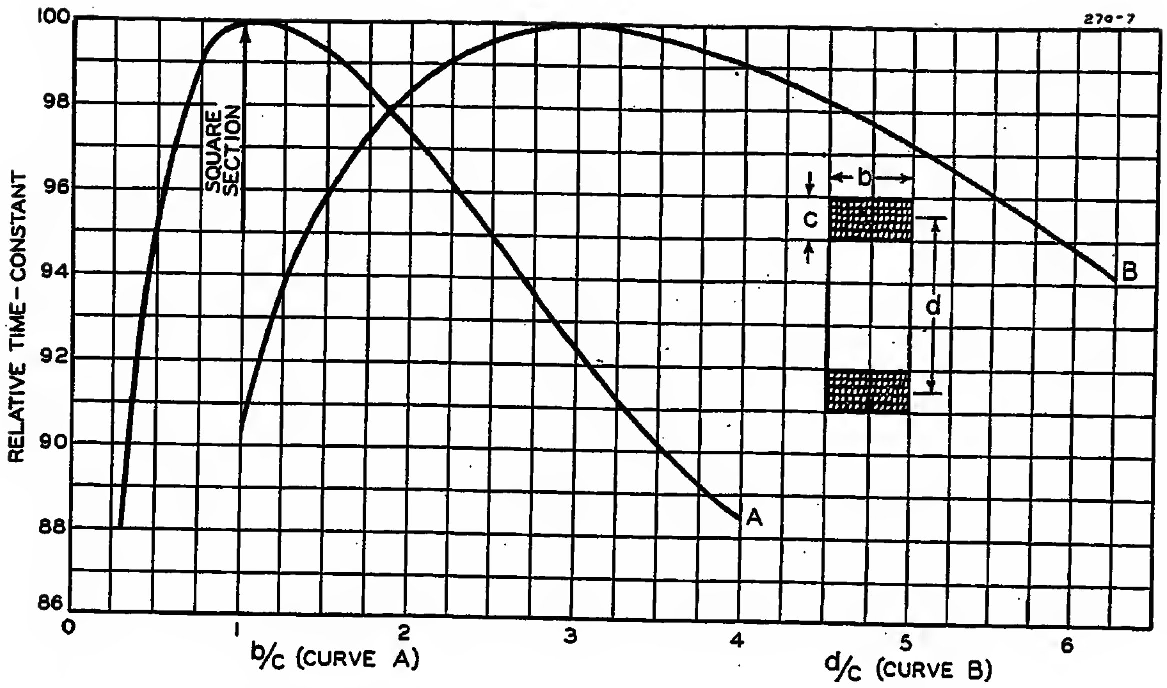

Figure 7. Field-coil proportions as a function of reactance/resistance

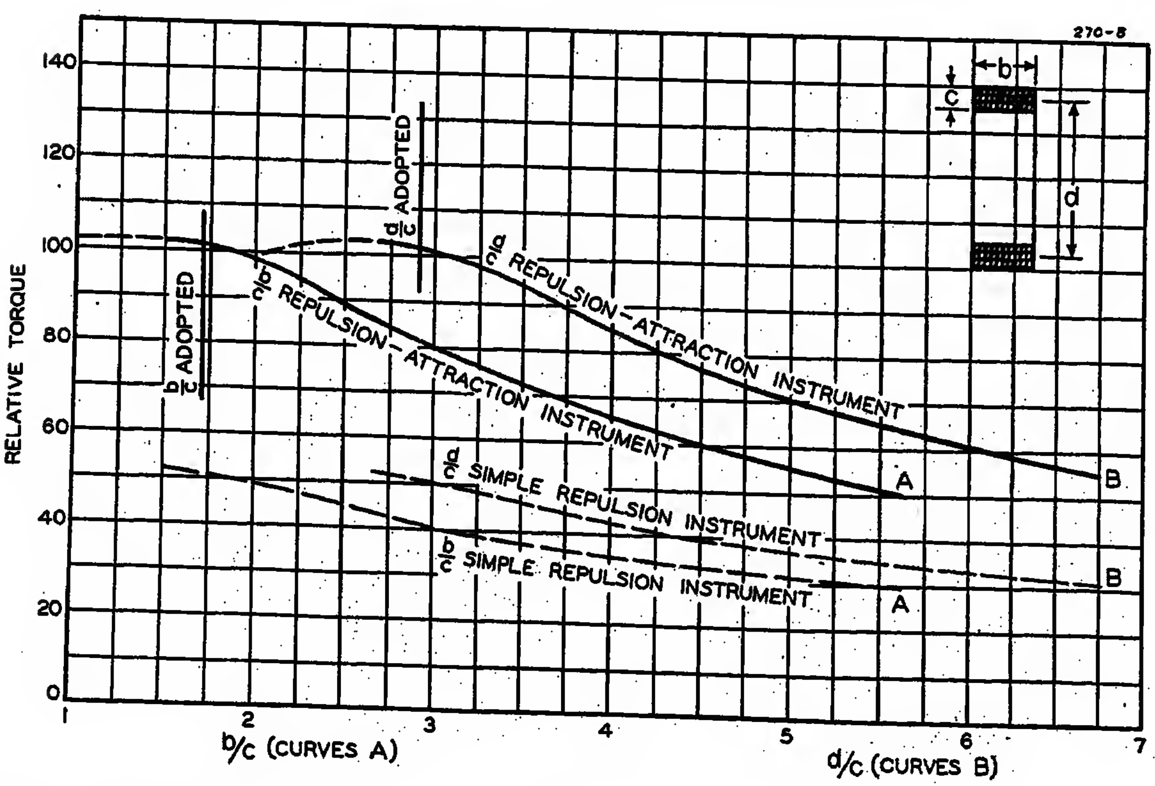
basic iron shapes, one could predict, quite closely, the ultimate results of iron shapes when used in combination. The best fixed repelling wedge to operate in conjunction with the ideal vane was one that best met the three criteria of steep initial torque-gradient, large angular deflection, and maximum torque. The initial steep gradient was especially desirable in ammeters for improved readability with low values of current. The wedge of Figure 5 met the requirements—the curved edges giving the steep gradient; the developed length, the long-scale angle; and the over-all dimensions, the maximum of torque.

The final and most important design problem was the selection of suitable attraction irons to extend the scale angle without increased power consumption.

Figure 8. Field-coil proportions with addition of iron members



It was also necessary to avoid close spacings of adjacent magnetic parts, with their resulting manufacturing hazard. For adjustment purposes, the attraction irons permit of small rotational movements and are provided with means for securely locking them in the final position. The shape and slope of the irons result in a smoothly distributed scale, open to the end of pointer travel. The short curved lengths at the upscale ends of the attraction irons provide a greater degree of scale control. The curves (Figure 8) indicate that the coil system with irons, in its final form, has proportions differing very little from the requirements of ideal air coils.

Torque Characteristics

The torque values of the complete system over the scale, and for comparison, the torque of simple repulsion, is shown in Figure 6. The completely drawn, uppermost curve gives the torque at various angular scale positions with a constant application of full-scale voltage

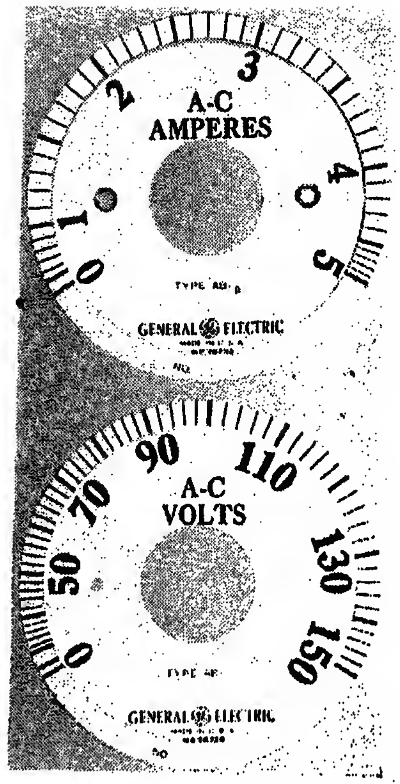


Figure 9. A-c ammeter- and voltmeter-scale distributions

(150 volts). The negative angle of −15 degrees corresponds to the assigned unstable position of the pointer—selected for security of operation. Intersecting the torque curve of the control spring are sectional lengths of torque curves of intermediate voltages. From the intersectional points the actual scale distribution is obtained by projection. The projected scale at the lower edge of the figure is identical with the voltmeter scale of Figure 9.

The torque curve for repulsion alone is for the same 150-volt constant value. It illustrates the limitations of simple repulsion in regard to torque and operating angle.

Damping System

The instruments are equipped with an eddy-current damper of unique construction as shown in Figure 10. It consists of a series of ten uniformly spaced, bipolar magnets of Alnico steel, embedded in two

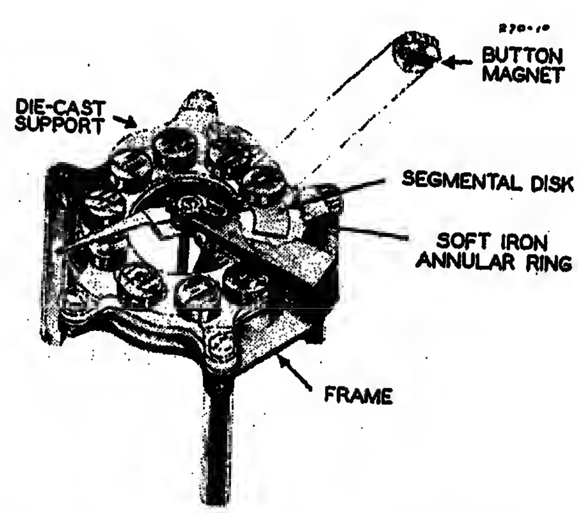

Figure 10. Damping system for a-c instruments

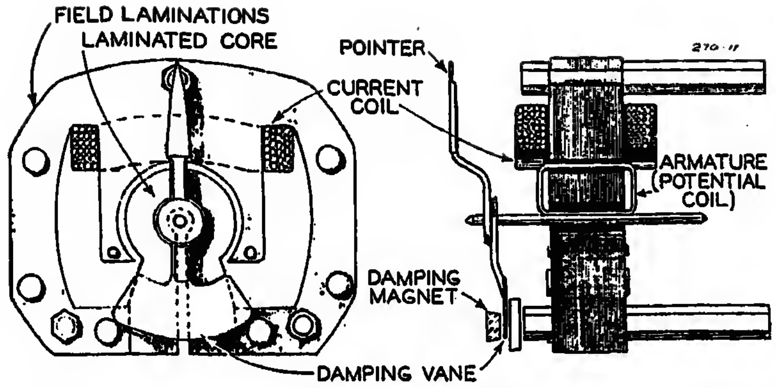

Figure 11. Wattmeter and varmeter mechanism

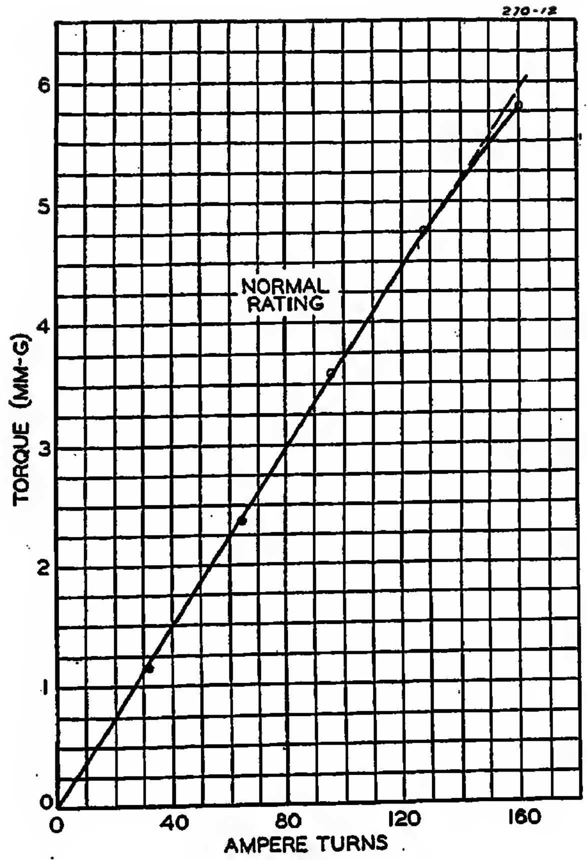

Figure 12 (left). Saturation curve of wattmeter field

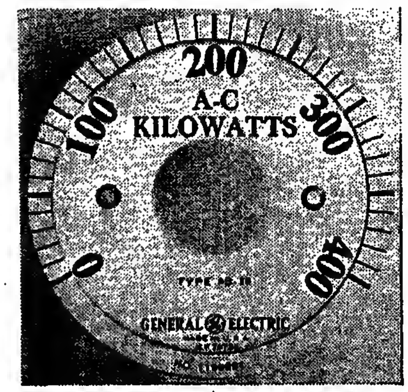

Figure 14. Wattmeter-scale distribution

die-cast half-ring supporting members. The two half-ring groups are assembled on the instrument in a circular arrangement directly over a small segmental aluminum disk, which is carried by the moving element. The magnetic circuit is completed through the disk to a soft-iron split annular-shaped ring mounted directly beneath the disk. The soft-iron ring serves also to shield the actuating element from the field projected by the damper magnets. This system provides an adequate and uniform damping torque throughout 360 degrees of disk movement. It is used on all a-c instruments.

Performance Characteristics

The characteristics of the a-c voltmeters and ammeters are shown in Table II. The efficient iron-clad mechanism has a high reactance-resistance ratio which is reflected in the instrument when constructed as a voltmeter. The effect of this reactance-resistance ratio on frequency influence was, however, overcome by capacitance compensation.

IV. The Iron-Cored Electrodynamic Instrument for the Measurement of Power

The long-scale instruments previously described deal with measurements of single quantities. Since there are important electrical measurements that involve the product or ratio of two electrical quantities, instruments must be provided for performing these mathematical operations. The measurement of the product of two electrical quantities suggested the use of the electrodynamic construction.

Since the conventional type of electrodynamometer instrument mechanism may be used for only a comparatively short-scale range, a modified construction was required for obtaining a scale length of 240 degrees. In order to obtain coordination of design and appearance, the general construction used in the permanent-magnet moving-coil instrument was adopted. In this instrument, however, the permanent magnet was replaced by a magnetic core shaped to permit insertion of a field winding and was designed for a uniform air gap between its pole face and the inner core, as illustrated in Figure 11. Since the magnetic field produced by the coil on the outer field structure is proportional to the current in that coil, the total torque produced by the instrument is proportional to the product of the ampere turns in the field and armature windings. The instrument is magnetically damped in the same manner as described for the iron-vane instruments.

The design of this mechanism presented several problems, particularly with respect to the magnetic circuit:

1. To produce a long scale, the use of magnetic material with attendant iron losses was required to obtain a long air gap.
2. The field circuit had to be designed for a linear flux-current relationship, requiring operations at densities well below the knee of the saturation curve at all possible operating currents.
3. The phase angle between the current and potential fluxes required adjustment to agree with the phase angle between the current and the voltage.
4. Losses in the instrument had to be kept low and voltage errors reduced to a minimum.

Several nickel-iron alloys were considered and tested for this application, and the best combination for low hysteresis and a high saturation density was obtained by the use of an alloy having 49 per cent nickel. The complete field structure, including the central core, was made of thin insulated laminations to reduce eddy currents to a minimum. Figure 12 shows the field density to be well below the saturation value for normal operating ranges.

The use of iron in the magnetic circuit naturally causes the current in the potential coil to lag slightly behind the applied voltage. This is more than canceled by the effect of the iron losses which cause the field flux to lag the line current by a still greater amount. Therefore, the

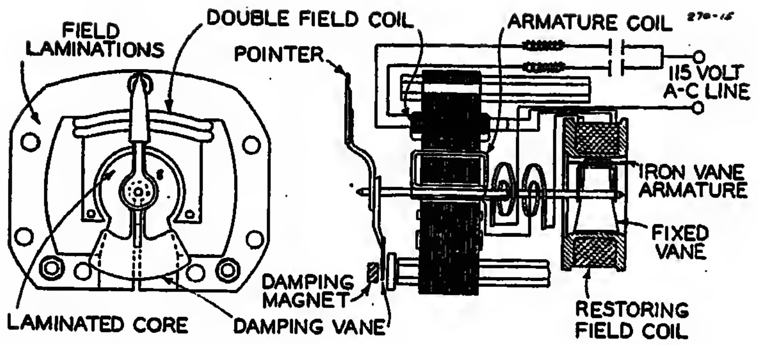

Figure 15 (above). Frequency - meter construction

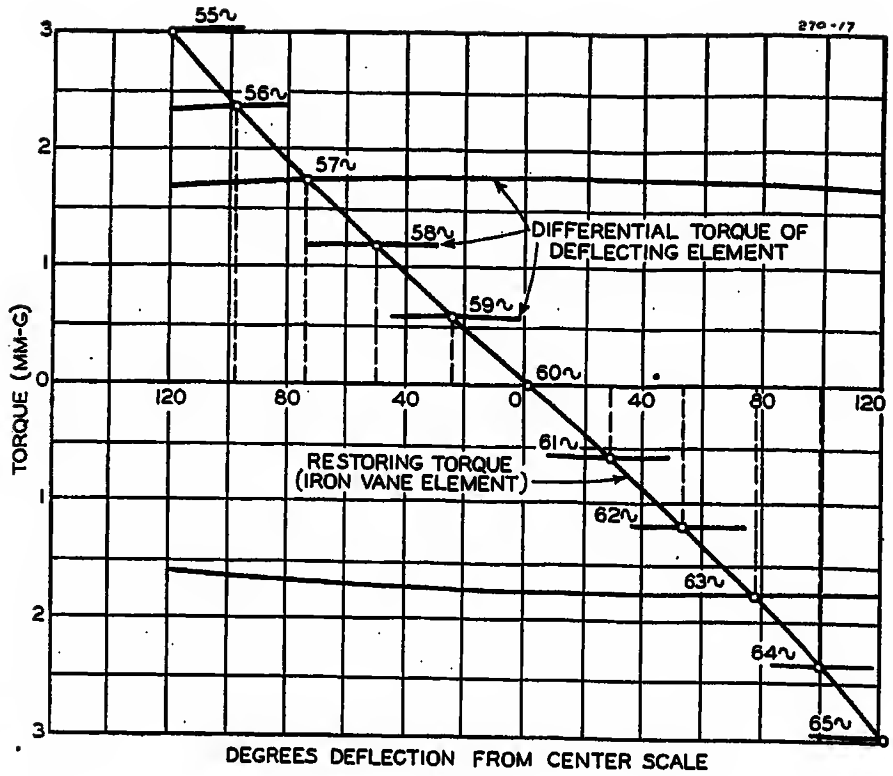

Figure 17 (right). Frequency - meter torque characteristics

potential-circuit current and the field flux are separated by a greater angle than the phase angle of the circuit, and, if uncompensated, would cause the instrument to read low on lagging power factors.

The instantaneous field flux then becomes proportional to

$$I_m \sin(\omega t-\theta-\alpha_2)$$

where α_2 is the angle by which the field flux lags the line current due to iron losses, and θ, the phase angle between current and voltage. The instantaneous armature current is proportional to

$$E_m \sin(\omega t-\alpha_1)$$

where α_1 is the phase angle by which the armature current lags the applied voltage. Without compensation, therefore, the torque would be—

$$T=KEI\cos(\theta-\alpha_1+\alpha_2)$$

Therefore, a capacitor is shunted across the armature and a portion of the series resistor, providing sufficient compensation to make the angle α_1 equal to angle α_2 giving correct indication at any power factor. Figure 13 shows curves taken at leading and lagging power factors indicating the effect of capacitance on compensation for power-factor errors. The curves show that the selection of a value of capacitance corresponding to the point where the two curves intersect, provides sufficient compensation to make the instrument operate with satisfactory accuracy over a wide range of power factors.

It has been mentioned that potential flux was reduced to a minimum to prevent voltage errors. With a high value of potential flux, the moving coil tends to deflect upon the application of potential alone, due to extraneous flux through the field iron and back across the air gap. While this potential creep can be calibrated out and become of little consequence, if maintained at low value, it would result in voltage errors if the extraneous torque so produced became an appreciable part of the total torque of the instrument. To minimize such errors, the armature turns were kept low, and high resistance was used to secure a minimum armature current consistent with high operating torque. The magnetic flux path is also broken by two gaps, the ratio of which determines the magnetic balance of the circuit and consequently the potential-circuit errors. They are, therefore, set to give the best overall performance.

Because of the uniform gap the scale distribution is nearly linear as shown by Figure 14.

The same type of mechanism is used for polyphase wattmeters, two elements being rigidly fastened together to the supporting base. In the polyphase instrument it is possible to still further increase the potential-circuit resistance in order to decrease voltage errors as the torque to weight ratio of the single-phase construction can be maintained without doubling the total instrument torque. Compensation for power-factor errors is made in the same manner as previously described using a double capacitor for this purpose.

When used for the measurement of vars (reactive volt-amperes), the instruments are provided with external phase-shifting auto transformers or are cross-phased to obtain the proper phase angle in the manner used on conventional switchboard instruments. Single-phase varmeters require an external impedance

network to lag the current in the potential circuit by 90 degrees.

Measurement of Frequency

The iron-cored electrodynamic instrument mechanism was applied to the measurement of frequency by using a differential field coil,[4] each side of which was connected in a resonant circuit, one resonant at a frequency below the scale range, and the other, at a frequency above scale range. Since these two field coils are connected in opposition, an auxiliary element is added to provide restoring torque. The deflecting element has a uniform air gap and provides substantially uniform torque over its operating range. Thus the restoring element must

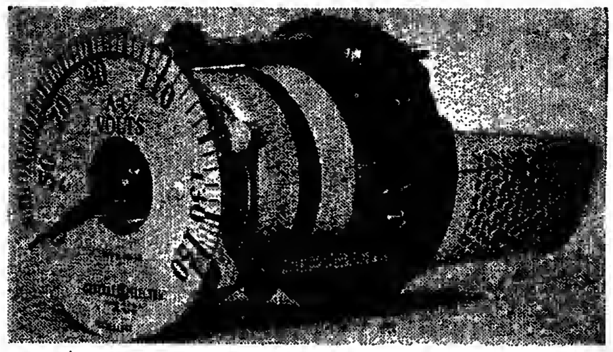

Figure 22. Interior view of a-c voltmeter

also produce approximately uniform torque to obtain a scale as uniform as possible. Obviously with a 240-degree scale, a unidirectional and linear value of torque must be provided for 120 degrees each side of the center-scale position. Since it is evident that such a torque cannot be furnished by a simple dynamometer system, or any of the conventional iron-vane systems, a restoring torque has been provided by utilizing a long-range iron-vane repulsion mechanism similar to that used in the a-c ammeter and voltmeter. The construction is shown in Figure 15. It will be noted that the deflecting element is identical in construction with that used in the wattmeter, and that the restoring element is provided with a fixed iron vane which is wide at scale ends and narrow at center scale.

The connection diagram, Figure 16, shows the two resonant circuits and the differential connection of the deflecting and restoring fields, the resultant current passing through the armature coil.

Variations of these connections are possible. For example, the connection of the restoring field coil with additive polarity, which somewhat changes the shape of the restoring torque curve, provides a scale which is expanded in the center and constricted toward the ends. With the subtractive polarity used, one circuit is resonant at about 34 cycles, while the other is resonant at about 97 cycles, both points being far outside the normal scale range of 55–65 cycles.

The curve in Figure 17 shows that approximately uniform restoring torque has been provided, its intersection with the differential torque curves at cardinal points indicating the angular displacement at these points.

It was necessary to give careful attention to several important points of construction. In the first place, the deflecting and restoring torque curves, extended beyond the scale ends, must be of such shape that the instrument will be stable at both ends of the scale with any condition of normal mechanical variation or changes in the resonant circuits. On a normal 60-cycle frequency meter with a scale of 55–65 cycles, stable operation is provided for about three times the normal frequency range above and below scale ends. The mechanical construction of the restoring field coil is likewise important in maintaining a scale which is essentially uniform and symmetrical. The spacing between the fixed and moving vanes is uniform, and the field winding is

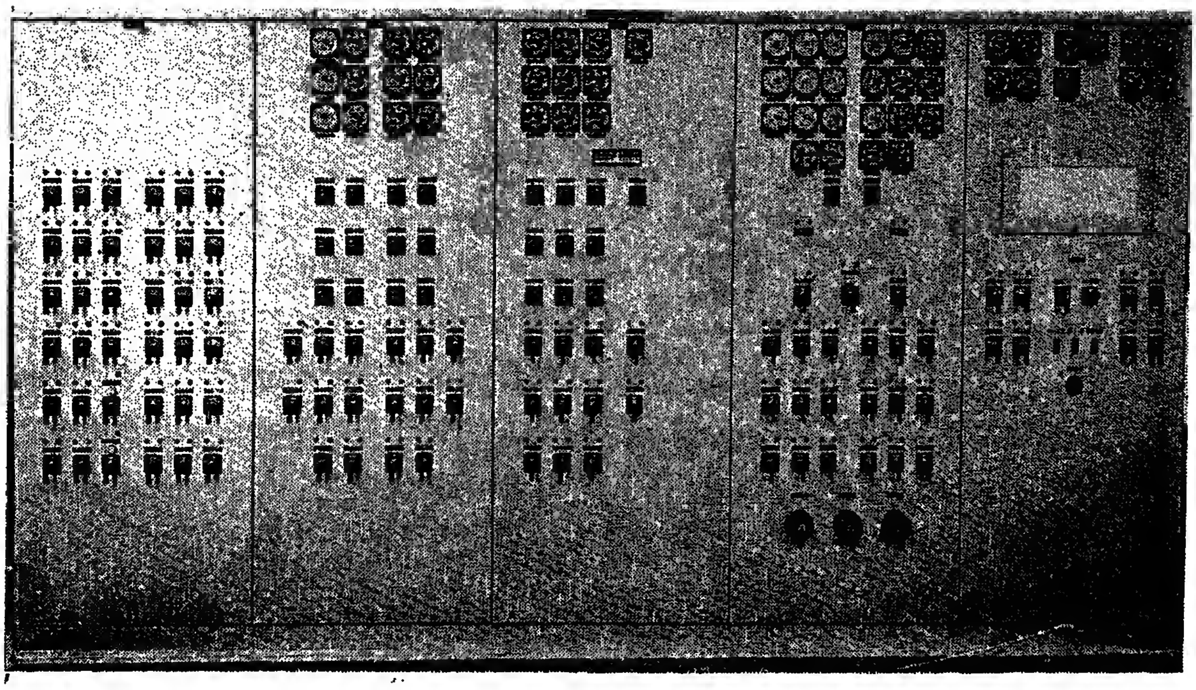

Figure 24. Typical installation of long-scale instruments

concentric with the stationary vane. Greater accuracy is obtained by winding the two coils at the same time, using two insulated wires in multiple.

In the frequency meter, the chief consideration was to make the instrument responsive to frequency changes without being influenced by any ordinary voltage fluctuations and with negligible disturbance from such operating variations as temperature and wave-form changes. It may be shown that the torque of both the deflecting and restoring elements is proportional to the square of the voltage and the deflection dependent on the ratio of currents in the two branches.

$$\text{Angle of deflection } \alpha = \kappa \frac{1-r^2}{1+r^2-2r\cos\theta}$$

(where r = the ratio of the currents in the two resonant branches and θ = the phase angle between them). The instrument indication is thus essentially independent of changes in the operating voltage.

The admittance of the resonant circuits to currents of the third or higher harmonics is very low, resulting in very small accuracy variations when used on distorted wave forms.

Figure 18 shows a standard 60-cycle scale with a range of 55–65 cycles. Other scale ranges are obtained by selecting impedance networks to provide the same current ratios over the required frequency range.

V. Instruments With Rotating Magnetic Field and Polarized Moving Vanes for Measurement of Power Factor

The power-factor meter has a field winding consisting of a motor-type stator with a laminated field structure and a distributed winding. This provides a rotating field when connected to a polyphase circuit. The armature is of the moving-vane type, the vanes of which are magnetically connected by a nickel-iron sleeve and polarized by an axially mounted stationary coil inside the stator. The construction is clearly shown in Figure 19. This system is not new, having been in use for a number of years in other forms,[5] but refinements in mechanical construction and improvements in operation make the instrument worthy of description.

When used to measure power factor, the field winding (stator) is connected through a high resistance to a polyphase line, while the vane is polarized by a stationary coil energized by the current in the circuit.

An analysis of this system will show that the instrument measures directly the phase angle between the current and the voltage and may be calibrated either in terms of power factor or phase angle. Hysteretic drag usually common to this construction has been reduced to a minimum by the use of carefully annealed nickel-iron alloys which produce very little rotational torque, and thus provide accurate readings over a wide range of current.

The movement is free to rotate throughout 360 degrees, and scales of either 180 degrees or 360 degrees can be provided, the latter where operation with reversed current is necessary. Figure 20 shows the scale ranges which may be obtained.

Indication of Synchronism

When designed for use as a synchroscope, the physical construction of the instrument is the same as the power-factor meter since the instrument actually measures the phase difference between the potentials of the bus and the incoming generator. The polarizing coil, however, is wound for potential instead of current and is connected directly across the line.

Since most synchroscopes are designed for single-phase operation, the stator circuit (connected to the incoming machine) was provided with a phase-splitting arrangement. This consists of an external impedor box containing a resistance and an adjustable reactance coil. The stator is of two-phase construction, one phase being connected in the resistance circuit and the other in series with the reactance. (See Figure 21.) The resistance of the A circuit and the inductance in the D circuit will produce a phase angle somewhat less than 90 degrees. The quadrature phase relation and a symmetrical rotating field is obtained by shunting a noninductive resistance R_c across the stator coil in the reactive circuit A. This produces a voltage drop V_A in phase with the lagging current I_{LA} through the reactor. The resistance R_c is of such a value that the inherent inductance in the stator causes the current through it (I_A) to lag the voltage drop V_A by an angle giving a 90-degree angle between I_A and I_D, the currents through the two stator branches. Final adjustment is made by a magnetic shunt on the reactance coil L_A.

Both "incoming" and "running" circuits were designed for low-power consumption, and the instrument, therefore, may be used for remote indication of synchronism. Uniform speed of rotation was obtained by the use of steel flux distributor rings as shown in Figure 19. These practically eliminated the slot effect of the stator and prevented spasmodic movement of the pointer at speeds approaching synchronism.

Since the armature vanes are polarized, the instrument becomes, in effect, a synchronous motor. If the polarizing coil were excited by direct current, synchronous operation would be obtained at a speed

$$S = \frac{120f}{P} \text{ (rpm)}$$

where f is the frequency and P the number of poles. The application of alternating current excitation of a different frequency, however, produces rotation at a speed proportional to the difference of these frequencies or

$$S = \frac{120(f_i - f_r)}{P}$$

where f_i = the incoming frequency and f_r the frequency of the running machine.

Since the stator is of two-pole construction

$S = 60(f_i - f_r)$ or 60 rpm for every cycle difference in frequency

Formulas for the Magnetic-Field Strength Near a Cylindrical Coil

HERBERT B. DWIGHT
FELLOW AIEE

THE magnetic-field strength at any given point near a circular cylindrical coil or solenoid in a nonmagnetic medium requires various formulas for its determination, depending on the shape of the solenoid and the position of the point. Formulas are required for the axial component of the magnetic field, called H_x in this paper, and other formulas are needed for the radial component, H_r.

A number of the formulas were given in "Absolute Measurements in Electricity and Magnetism,"[1] by Andrew Gray, editions of 1893 and 1921. Others have been published in other articles, as indicated in the footnotes and references of this paper. A collection of formulas for this problem was published by the writer in "The Magnetic Field of a Circular Cylindrical Coil,"[2] *Philosophical Magazine*, volume 11, April 1931, page 948.

In this paper, an additional group of formulas is presented, suitable particularly for points close to the coil section and for short coils. A device is also given (see paragraphs following equation 3) by which formulas for the flux density in the end plane only of a solenoid are listed, and this greatly increases the range in which the flux density of solenoids under all conditions can be precisely and quickly calculated. It is shown in Figure 5 that the formulas listed in this paper cover the entire field of a solenoid.

All of the published series formulas for solenoids of which the writer is aware, have been rearranged in this form and are given in this paper. Thus this paper contains the complete equipment for computing the magnetic field of a solenoid of any shape and at any point, far or near, including points within the cross section of the winding. The effect of insulation space between conductors, however, is not considered, but the rectangular cross section of the solenoid is assumed to have uniform current distribution.

One application of the formulas and methods listed in this paper is in finding the mutual inductance of a solenoid and a comparatively small coil, particularly when the latter is irregular in its shape or position. In many cases the mutual inductance is equal to the magnetic field of the solenoid at the center of the small coil, multiplied by the projected area of the small coil, crossing the field. This is of use in problems of electromagnetic interference and shielding.

Paper 42-27, recommended by the AIEE committee on basic sciences for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted October 8, 1941; made available for printing November 28, 1941.

HERBERT B. DWIGHT is professor of electrical machinery, Massachusetts Institute of Technology, Cambridge, Mass.

The author acknowledges the work of the following students, done under his supervision in connection with theses written at the Massachusetts Institute of Technology:

Mason F. Miller, work on the derivation of equation 36 and other formulas, derivation of the first few terms of equation 8 by expansion of equation 13 in series, and comparison of calculated values of field strength with laboratory measurements of solenoids.

A. C. Louie, work on the derivation of equation 9, on the determination of boundaries of ranges in Figure 5 and comparisons with laboratory measurements.

A. L. Carpentier, work on properties of the formulas and determinations of boundaries of ranges in Figure 5.

Logarithmic Formulas

The group of logarithmic formulas for points close to the coil section may be derived from a mutual-inductance formula for two circles which was published by T. H. Havelock[3] in 1908 and was extended by E. B. Rosa and F. W. Grover in equation 16, reference 4. It is given in equation 16A, reference 5.

If we let a circle of radius $y=a+c$ on the same axis as the circle of radius a, pass through P, Figure 1, then by differentiating equation 16A, reference 5, for the mutual inductance of the two circles, with respect to y or c, the change in mutual inductance for an increase in y is found. This is the change in flux passing through the circle of radius y when y is increased, caused by a continuous current in the circle of radius a. The increment in flux passes through the ring of width ∂y and circumference $2\pi y$.

If a certain amount of flux φ, for 1 centimeter perpendicular to the paper, passes through an area of width ∂y, at an angle θ to the normal to ∂y, as in Figure 2, then the flux density, or force on a unit magnetic pole is $\varphi/(\partial y \cos\theta)$. The horizontal component of the flux density is obtained by multiplying by $\cos\theta$, and is $\varphi/\partial y$.

Therefore, in the case of Figure 1, the axial component of flux density at radius y, or at P, is

$$\frac{1}{2\pi y}\frac{\partial M}{\partial y} \tag{1}$$

Thus, the instrument will make one complete revolution for each cycle difference in frequency, the direction of rotation determining whether the incoming generator is slow or fast. Synchronism is indicated when the pointer reaches a vertical position.

VI. Conclusion

These instruments have been designed to meet existing American Standards Association standards of performance, as shown in Table II, and, in general, the characteristics are equivalent to those of 6-inch rectangular instruments. An accuracy rating of 1 per cent of the full-scale reading has been applied. The mechanical durability as evaluated by shipping, vibration, and impact tests is also fully equal to the standards established by present practice. The application of these instruments to a typical switchgear unit is shown in Figure 24. The group represents a potential panel-space saving of 42 per cent with an average weight saving of 16 per cent and an increased scale length of 33 per cent as compared to 6-inch rectangular instruments. It is concluded, therefore, that 90-degree scale angles need no longer be regarded as an inherent limitation of electrical indicating instruments, and instruments having long scales with satisfactory accuracy may be produced.

Putting $2a=d$ and $2y=D$, as in Figure 1, in order to make the numerical coefficients smaller, the following expression is obtained for the axial component of flux density at P due to a current of I amperes in a circular coil of N turns and of diameter d, assuming that the dimensions of the cross section of the coil are so small that they may be neglected:

$$H_{x(\text{circle})}=\frac{NI}{10}\times\frac{1}{2\pi y}\frac{\partial M}{\partial y}$$
$$=\frac{NI}{10}\frac{\sqrt{d}}{D\sqrt{D}}\left[\left\{\text{logn}\frac{16Dd}{u^2}\right\}\times\left\{1-\frac{3}{4}\frac{u^2}{Dd}+\frac{45}{64}\frac{u^4}{D^2d^2}\cdots+\frac{c}{d}\left(\frac{3}{2}-\frac{15}{16}\frac{u^2}{Dd}\cdots\right)\right\}-\frac{2CD}{u^2}-\left(2-2\frac{u^2}{Dd}+\frac{123}{64}\frac{u^4}{D^2d^2}\cdots\right)+\frac{c}{d}\left(\frac{5}{2}-\frac{77}{32}\frac{u^2}{Dd}\cdots\right)\right]$$

lines per square centimeter (2)

where $u^2=x^2+c^2$ and where logn denotes natural logarithm.

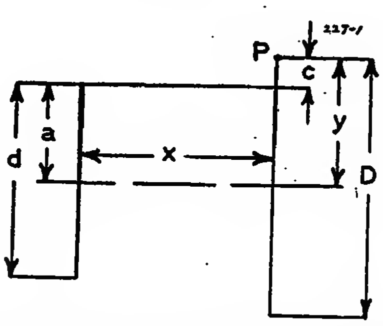

Figure 1. Magnetic field at P near a circle of radius a

Dimensions throughout this paper are in centimeters and electromagnetic centimeter-gram-second units are used, except where otherwise stated.

The current is assumed to be in such a direction around the circle that the flux density at the center of the circle is to the right. If the flux density given by equation 2 is a minus quantity, as it usually is when y is greater than a in Figure 1, that indicates that the direction of the flux at P is to the left. If y is less than a in Figure 1, the flux density is given by equation 2 but c has a negative numerical value.

Equation 2 and practically all the formulas of this paper, are infinite series, and they should be used for a given case only if the last term used in each series is almost negligibly small and is smaller than the preceding term. Otherwise, the succeeding terms which are neglected are probably of importance and the formula should not be used for such a case.

To obtain the axial component of flux density at P due to an infinitely thin solenoid, multiply expression 2 by $n\,dx/N$ and integrate from x_1 to x_2, taking these lengths to be positive values. See Figure 3. The quantity n is the number of turns per centimeter of axial length of the solenoid. The expression is 0 when x is 0, and so by putting $x_1=0$ and $x_2=x$ there is obtained the following formula 3 for the axial field at a point P in the end plane of a solenoid of length x, which is the only type of formula that needs to be listed for solenoids whose length is given:

$$H_{x(s)}=\frac{nI}{10}\left[\left\{\text{logn}\frac{32yd}{x^2+c^2}\right\}\times\left\{\frac{x}{d}\left(1-\frac{3}{2}\frac{c}{d}+\frac{9}{4}\frac{c^2}{d^2}-\frac{55}{16}\frac{c^3}{d^3}+\frac{345}{64}\frac{c^4}{d^4}\cdots\right)-\frac{x^3}{d^3}\left(\frac{1}{4}-\frac{15}{16}\frac{c}{d}+\frac{75}{32}\frac{c^2}{d^2}\cdots\right)+\frac{9}{64}\frac{x^5}{d^5}\cdots\right\}-2\tan^{-1}\frac{x}{c}+\frac{x}{d}\left(\frac{1}{2}\frac{c}{d}-\frac{1}{2}\frac{c^2}{d^2}-\frac{3}{32}\frac{c^3}{d^3}+\frac{115}{64}\frac{c^4}{d^4}\cdots\right)+\frac{x^3}{d^3}\left(\frac{1}{2}-\frac{61}{32}\frac{c}{d}+\frac{151}{32}\frac{c^2}{d^2}\cdots\right)-\frac{21}{64}\frac{x^5}{d^5}\cdots\right]$$

lines per square centimeter (3)

The letter s in $H_{x(s)}$ denotes an infinitely thin solenoid or current sheet. This formula has been shortened somewhat by expressing D in terms of d, the mean diameter of the coil.

It is evident from Figure 3 that the magnetic flux density at P due to the actual solenoid of length (x_2-x_1) is equal to the difference between the field densities of two solenoids of lengths x_2 and x_1, respectively, of the same thickness, for both of which P is in the end plane. A physical meaning is thus given to the value of expression 3 for x_1 and x_2 separately, when integration is carried between these limits for the case shown in Figure 3.

It is, therefore, possible to calculate the value for x_1 by one formula, suitable for short coils, and that for x_2 by another formula if desired, suitable for long coils. The use of this device greatly increases the capability of calculating the flux density due to a solenoid under various conditions, with ease and precision.

A similar device for mutual inductance of solenoids was given in reference 5 (see paragraphs following equation 9 of that paper) and it produced a corresponding increase in the capacity to calculate the mutual inductance of coils of various shapes, in various positions.

A correction for the thickness, t, of the coil is desirable. Following Maxwell, Electricity and Magnetism,[6] paragraph 700, and noting that the differential of d is twice the differential of a radical distance

$$H_{(\text{coil})}=H_{(s)}+\frac{t^2}{3!}\frac{\partial^2 H_{(s)}}{\partial d^2}+\frac{t^4}{5!}\frac{\partial^4 H_{(s)}}{\partial d^4}\cdots \quad (4)$$

where $H_{(s)}$ is the magnetic-field density, either axial or radial, at a given point P in the end plane due to the infinitely thin central solenoid whose diameter is d (see Figure 3).

Expressing equation 3 in terms of $D=2y$ instead of d, so that c is the only variable, and differentiating, we obtain the term in t^2 of equation 4.

$$H_{x(\text{coil})}=H_{x(s)}+\Delta H_x$$

where

$$\Delta H_x=\frac{nI}{10}\frac{t^2}{D^2}\left[\left\{\text{logn}\frac{16D^2}{x^2+c^2}\right\}\times\left\{\frac{x}{D}\left(\frac{1}{12}+\frac{1}{16}\frac{c}{D}-\frac{7}{32}\frac{c^2}{D^2}\cdots\right)-\frac{9}{32}\frac{x^3}{D^3}\cdots\right\}-\frac{xD}{(x^2+c^2)}\left\{\frac{1}{3}+\frac{1}{2}\frac{c}{D}+\frac{5}{12}\frac{c^2}{D^2}+\frac{7}{48}\frac{c^3}{D^3}-\frac{21}{64}\frac{c^4}{D^4}\cdots-\frac{x^2}{D^2}\left(\frac{1}{12}+\frac{9}{16}\frac{c}{D}+\frac{45}{32}\frac{c^2}{D^2}\cdots\right)+\frac{3}{64}\frac{x^4}{D^4}\cdots\right\}-\frac{xcD^2}{(x^2+c^2)^2}\left\{\frac{2}{3}-\frac{2}{3}\frac{c}{D}-\frac{1}{3}\frac{c^2}{D^2}-\frac{1}{6}\frac{c^3}{D^3}-\frac{1}{24}\frac{c^4}{D^4}+\frac{7}{96}\frac{c^5}{D^5}\cdots+\frac{x^2c}{D^3}\left(\frac{1}{6}+\frac{3}{8}\frac{c}{D}+\frac{9}{16}\frac{c^2}{D^2}\cdots\right)-\frac{3}{32}\frac{x^4c}{D^5}\cdots\right\}-\frac{x}{D}\left(\frac{1}{2}+\frac{121}{96}\frac{c}{D}+\frac{175}{96}\frac{c^2}{D^2}\cdots\right)+\frac{33}{32}\frac{x^3}{D^3}\cdots\right] \quad (5)$$

Equation 5 should be used only for thin solenoids where t is small and where the correction ΔH_x is a small percentage. For somewhat thicker coils, the following formula may be used, obtained by putting equation 3 in terms of $D=2y$ and then integrating over the cross section of the coil:

$$H_{x(\text{coil})}=\frac{nI}{10}\left[\left\{\frac{c}{t}\,\text{logn}\frac{16D^2}{x^2+c^2}\right\}\times\left\{\frac{x}{D}\left(1+\frac{1}{4}\frac{c}{D}+\frac{1}{12}\frac{c^2}{D^2}+\frac{1}{64}\frac{c^3}{D^3}-\frac{7}{320}\frac{c^4}{D^4}\cdots\right)-\frac{x^3}{D^3}\left(\frac{1}{4}+\frac{9}{32}\frac{c}{D}+\frac{9}{32}\frac{c^2}{D^2}\cdots\right)+\frac{9}{64}\frac{x^5}{D^5}\cdots\right\}-\left\{\frac{x}{t}\,\text{logn}\frac{x^2+c^2}{D^2}\right\}\left\{1+\frac{1}{4}\frac{x^2}{D^2}-\frac{19}{64}\frac{x^4}{D^4}\cdots\right\}+\left\{\tan^{-1}\frac{c}{x}\right\}\left\{\frac{2c}{t}-\frac{x}{t}\left(2\frac{x}{D}-\frac{2}{3}\frac{x^3}{D^3}+\frac{4}{5}\frac{x^5}{D^5}\cdots\right)\right\}-\frac{c}{t}\left\{\pi-\frac{x}{D}\left(2-\frac{1}{2}\frac{c}{D}-\frac{4}{9}\frac{c^2}{D^2}-\frac{59}{192}\frac{c^3}{D^3}-\frac{917}{4{,}800}\frac{c^4}{D^4}\cdots\right)-\frac{x^3}{D^3}\left(\frac{1}{6}-\frac{1}{6}\frac{c}{D}-\frac{103}{120}\frac{c^2}{D^2}\cdots\right)+\frac{151}{320}\frac{x^5}{D^5}\right\}\right]_{c=c_1}^{c_2}$$

lines per square centimeter (6)

If y is less than a_1, then c_1 and c_2 are negative. If y lies in value between a_1 and a_2, then c_1 is negative and c_2 is positive.

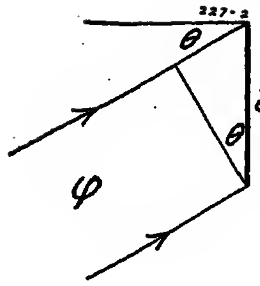

Figure 2. Flux passing through an area of width ∂y

Corresponding formulas are required for the radial component of magnetic field. Using equation 16, reference 4, for the mutual inductance of two circles, the radial field at P, Figure 1, due to a circle or coil of N turns of very small cross section, is

$$-\frac{NI}{10}\times\frac{1}{2\pi y}\frac{\partial M}{\partial x} \tag{7}$$

$$=H_{r(\text{circle})}=\frac{NI}{10D}\frac{\sqrt{d}}{D\sqrt{D}}\left[\frac{2xD}{u^2}+\frac{x}{d}\left(\frac{5}{2}-\frac{77}{32}\frac{u^2}{Dd}+\frac{141}{64}\frac{u^4}{D^2d^2}-\frac{17{,}165}{8{,}192}\frac{u^6}{D^3d^3}\cdots\right)-\left\{\text{logn}\ \frac{16Dd}{u^2}\right\}\left\{\frac{3}{2}\frac{x}{d}\left(1-\frac{5}{8}\frac{u^2}{Dd}+\frac{35}{64}\frac{u^4}{D^2d^2}-\frac{525}{1{,}024}\frac{u^6}{D^3d^3}\cdots\right)\right\}\right]$$

lines per square centimeter (8)

where $u^2=x^2+c^2$.

In equation 8, the dimension D, which is twice the radial distance to the point P, Figure 1, may be either larger or smaller than d, the diameter of the circle. Only even powers of the quantity c are involved.

The minus sign occurs in equation 7 since the mutual inductance of the two circles in Figure 1 decreases as x increases.

For the radial field at a point P in the end plane of an infinitely thin solenoid of diameter d, multiply equation 8 by ndx/N and integrate from 0 to x, where n is the number of turns per centimeter of axial length.

$$H_{r(s)}=\frac{nI\sqrt{d}}{10\sqrt{D}}\left[\left\{\text{logn}\ \frac{16Dd}{c^2}\right\}\times\left\{1+\frac{3}{4}\frac{c^2}{Dd}-\frac{15}{64}\frac{c^4}{D^2d^2}+\frac{35}{256}\frac{c^6}{D^3d^3}-\frac{1{,}575}{128^2}\frac{c^8}{D^4d^4}\cdots\right\}-\left\{\text{logn}\ \frac{16Dd}{u^2}\right\}\times\left\{1+\frac{3}{4}\frac{u^2}{Dd}-\frac{15}{64}\frac{u^4}{D^2d^2}+\frac{35}{256}\frac{u^6}{D^3d^3}-\frac{1{,}575}{128^2}\frac{u^8}{D^4d^4}\cdots\right\}+\frac{u^2-c^2}{2Dd}-\frac{31}{64}\frac{u^4-c^4}{D^2d^2}+\frac{247}{768}\frac{u^6-c^6}{D^3d^3}-\frac{7{,}795}{128\times256}\frac{u^8-c^8}{D^4d^4}\cdots\right] \tag{9}$$

where $u^2=x^2+c^2$. Here also, $D=2y$ may be greater or less than d.

Note that the radial field close to the end of an infinitely thin solenoid becomes infinitely great, because c approaches 0 and logn c is involved.

By equation 4

$$H_{r(\text{coil})}=H_{r(s)}+\Delta H_r$$

where

$$\Delta H_r=\frac{nI}{10}\left[\frac{t^2}{D^2}\left\{\text{logn}\ \frac{x^2+c^2}{c^2}\right\}\times\left\{\frac{1}{12}+\frac{1}{4}\frac{c}{D}+\frac{17}{32}\frac{c^2}{D^2}+\frac{95}{96}\frac{c^3}{D^3}\cdots\right\}-\frac{t^2}{D^2}\left\{\text{logn}\ \frac{16D^2}{x^2+c^2}\right\}\left\{\frac{x^2}{D^2}\left(\frac{7}{32}+\frac{15}{32}\frac{c}{D}\cdots\right)\right\}+\frac{t^2}{x^2+c^2}\left\{\frac{1}{3}-\frac{c}{D}+\frac{5}{12}\frac{c^2}{D^2}+\frac{7}{12}\frac{c^3}{D^3}+\frac{51}{64}\frac{c^4}{D^4}+\frac{247}{96}\frac{c^5}{D^5}\cdots+\frac{x^2}{D^2}\left(\frac{1}{4}+\frac{3}{4}\frac{c}{D}+\frac{35}{32}\frac{c^2}{D^2}+\frac{35}{32}\frac{c^3}{D^3}\cdots\right)-\frac{x^4}{D^4}\left(\frac{5}{64}+\frac{45}{64}\frac{c}{D}\cdots\right)\right\}-\frac{t^2c^2}{(x^2+c^2)^2}\left\{\frac{2}{3}-\frac{2}{3}\frac{c}{D}+\frac{1}{6}\frac{c^2}{D^2}+\frac{1}{6}\frac{c^3}{D^3}+\frac{17}{96}\frac{c^4}{D^4}+\frac{19}{96}\frac{c^5}{D^5}\cdots+\frac{x^2}{D^2}\left(\frac{1}{2}+\frac{1}{2}\frac{c}{D}+\frac{7}{16}\frac{c^2}{D^2}+\frac{5}{16}\frac{c^3}{D^3}\cdots\right)-\frac{x^4}{D^4}\left(\frac{5}{32}+\frac{15}{32}\frac{c}{D}\cdots\right)\right\}+\frac{t^2}{c^2}\left\{\frac{1}{3}+\frac{1}{3}\frac{c}{D}-\frac{1}{4}\frac{c^2}{D^2}-\frac{5}{12}\frac{c^3}{D^3}-\frac{119}{192}\frac{c^4}{D^4}-\frac{57}{64}\frac{c^5}{D^5}\cdots+\frac{x^2}{D^2}\left(\frac{89}{96}\frac{c^2}{D^2}+\frac{101}{32}\frac{c^3}{D^3}\cdots\right)\right\}\right] \tag{10}$$

Since equation 10 is applicable only to thin solenoids with a small value of t^2/c^2 because terms in t^4 and higher powers of t have been omitted, the following formula, obtained by integration of equation 9 after it was expressed in terms of D, is given for use with thicker coils:

$$H_{r(\text{coil})}=\frac{nI}{10}\left[\frac{x^2}{Dt}\left\{\text{logn}\ \frac{16D^2}{x^2+c^2}\right\}\times\left\{\frac{1}{2}-\frac{3}{4}\frac{c}{D}-\frac{3}{8}\frac{c^2}{D^2}-\frac{7}{32}\frac{c^3}{D^3}-\frac{15}{128}\frac{c^4}{D^4}\cdots-\frac{x^2}{D^2}\left(\frac{5}{16}-\frac{15}{64}\frac{c}{D}-\frac{45}{128}\frac{c^2}{D^2}\cdots\right)+\frac{161}{384}\frac{x^4}{D^4}\cdots\right\}+\frac{c}{t}\left\{\text{logn}\ \frac{x^2+c^2}{c^2}\right\}\left\{1-\frac{1}{2}\frac{c}{D}+\frac{1}{12}\frac{c^2}{D^2}+\frac{1}{16}\frac{c^3}{D^3}+\frac{17}{320}\frac{c^4}{D^4}+\frac{19}{384}\frac{c^5}{D^5}\cdots\right\}+\frac{2x}{t}\left(\tan^{-1}\frac{c}{x}\right)\times\left(1+\frac{2}{3}\frac{x^2}{D^2}-\frac{2}{5}\frac{x^4}{D^4}\cdots\right)-\frac{c}{t}\frac{x^2}{D^2}\left(\frac{5}{6}-\frac{11}{16}\frac{c}{D}-\frac{49}{60}\frac{c^2}{D^2}-\frac{145}{192}\frac{c^3}{D^3}\cdots\right)+\frac{c}{t}\frac{x^4}{D^4}\times\left(\frac{101}{320}-\frac{13}{24}\frac{c}{D}\cdots\right)\right]_{c=c_1}^{c_2}$$

lines per square centimeter (11)

If y is less than a_1, then c_1 and c_2 are negative. If y lies in value between a_1 and a_2, then c_1 is negative and c_2 is positive.

Note that if the current is assumed to flow in a mathematically exact rectangular cross section, the radial field is not infinite at the corners or elsewhere. The limit of c logn c is 0 when c approaches 0. See reference 9, numbers 72 and 605.

Elliptic Integral Formulas for Circles

The following general formulas for the flux density in any position whatever, relative to a circle which carries a current, have been published by Alexander Russell[7] and give the same results as equations 2 and 8:

$$H_{x(\text{circle})}=\frac{2NI}{10r_1}\left\{\frac{2a(a-y)}{r_2^2}E+(K-E)\right\} \tag{12}$$

$$H_{r(\text{circle})}=\frac{2NI}{10r_1}\left\{\frac{2ax}{r_2^2}E-\frac{x}{y}(K-E)\right\} \tag{13}$$

where the dimensions are as in Figure 1 and where

$$r_1^2=(a+y)^2+x^2 \tag{14}$$

$$r_2^2=(a-y)^2+x^2=c^2+x^2 \tag{15}$$

K and E are complete elliptic integrals of the first and second kinds of modulus k, where

$$k^2=1-r_2^2/r_1^2 \tag{16}$$

Values of K and E may be taken from tables, as for instance, reference 8, pages 199 and 204.

It is seen from Figure 1 that r_2 is the distance from P to the nearest part of the circumference of the circle carrying current. If this distance is very small, k^2 approaches 1 and the value of the elliptic integral K approaches infinity. When this occurs, the values in any table become far apart so that interpolated values cannot be obtained with precision and it becomes better to use a series involving logarithms than to use a table of values. That, however, is equivalent to using formulas 2 and 8, which involve logarithms. It is always possible to find the precise value of the logarithm of any given number, however large or small, one way being to find first the logarithm to base 10.

Since equations 2 and 8 are power series in r_2^2/ay, they have greater precision, the closer the point P approaches to the circumference of the circle and the greater becomes the difficulty of obtaining the value of K from a table.

Zonal Harmonic Formulas for Circles

Other formulas will now be listed. The formulas for solenoids are put in the more useful and usually more concise form giving the flux density at a point in the end plane of the solenoid.

For points near the center of the circle,

$$H_{x(\text{circle})}=\frac{2\pi NI}{10a}\left[1-\frac{3}{2}\frac{r^2}{a^2}P_2\left(\frac{x}{r}\right)+\frac{3\times5}{2\times4}\frac{r^4}{a^4}P_4\left(\frac{x}{r}\right)-\dots\right]\qquad(17)$$

where

$$r^2=x^2+y^2\qquad(18)$$

$P_2(x/r)$, $P_4(x/r)$ and so on, are surface zonal harmonics which may be defined by

$$P_n(\mu)=\frac{1}{2^n n!}\frac{\partial^n}{\partial\mu^n}(\mu^2-1)^n$$

Values are tabulated in reference 8, page 188, reference 10, and elsewhere, or they may be calculated from series (see reference 9, page 169 and equation 46 of this paper).

$$H_{r(\text{circle})}=\frac{\pi NI}{10}\frac{yr}{a^3}\left[P_2'\left(\frac{x}{r}\right)-\frac{3}{4}\frac{r^2}{a^2}P_4'\left(\frac{x}{r}\right)+\frac{3\times5}{4\times6}\frac{r^4}{a^4}P_6'\left(\frac{x}{r}\right)-\dots\right]\qquad(19)$$

where $P_n'(\mu)=\dfrac{\partial}{\partial\mu}P_n(\mu)$

Values are tabulated in reference 10 or reference 8, page 196, or they may be calculated from series, as above.

For points at a considerable distance from the center of the circle,

$$H_{x(\text{circle})}=\frac{2\pi NI}{10r}\left[\frac{a^2}{r^2}P_2\left(\frac{x}{r}\right)-\frac{3}{2}\frac{a^4}{r^4}P_4\left(\frac{x}{r}\right)+\frac{3\times5}{2\times4}\frac{a^6}{r^6}P_6\left(\frac{x}{r}\right)-\dots\right]\qquad(20)$$

$$H_{r(\text{circle})}=\frac{\pi NIy}{10r^2}\left[\frac{a^2}{r^2}P_2'\left(\frac{x}{r}\right)-\frac{3}{4}\frac{a^4}{r^4}P_4'\left(\frac{x}{r}\right)+\frac{3\times5}{4\times6}\frac{a^6}{r^6}P_6'\left(\frac{x}{r}\right)-\dots\right]\qquad(21)$$

See reference 11, equations 3 and 4.

For points not far from the axis of the circle

$$H_{x(\text{circle})}=\frac{2\pi NIa^2}{10\rho^3}\left[P_1'\left(\frac{x}{\rho}\right)-\frac{1}{2}\frac{y^2}{\rho^2}P_3'\left(\frac{x}{\rho}\right)+\frac{1\times3}{2\times4}\frac{y^4}{\rho^4}P_5'\left(\frac{x}{\rho}\right)-\dots\right]\qquad(22)$$

$$H_{r(\text{circle})}=\frac{2\pi NIa^2y}{10\rho^4}\left[\frac{1}{2}P_2'\left(\frac{x}{\rho}\right)-\frac{1\times3}{2\times4}\frac{y^2}{\rho^2}P_4'\left(\frac{x}{\rho}\right)+\frac{1\times3\times5}{2\times4\times6}\frac{y^4}{\rho^4}P_6'\left(\frac{x}{\rho}\right)-\dots\right]\qquad(23)$$

where

$$\rho^2=x^2+a^2\qquad(24)$$

Equations 22 and 23 are equivalent to equations 9 and 10, reference 1, page 248, volume 2, edition of 1893 and page 212, edition of 1921, changing $1{,}680x^4$ to $1{,}680a^2x^4$.

Formulas for Short Coils

All these formulas for circles can be integrated, though not always by one direct step, to give expressions for the flux density at a point in the end plane of a solenoid, each applicable to a certain range, as approximately indicated in Figure 5. Each formula may be used in an area in Figure 5 in which its number, such as equation 25, occurs, and up to the boundary marked by an arrow leading from that number. The areas are seen to overlap. Satisfactory convergence may be found beyond the boundaries marked, and, on the other hand, the rapidity of convergence may be very poor for the thickness correction formulas near the boundaries. Figure 5 is a preliminary guide, and the criterion for use of a certain formula in any given case is the rapidity of convergence of the series. If the convergence is not suitably rapid, the formula should not be used in that particular case.

By integrating equations 17 and 19 from 0 to x, for values of $r=\sqrt{x^2+y^2}$ less than approximately $0.7a$ (see Figures 3 and 5),

$$\begin{aligned}H_{x(\text{coil})}=\frac{2\pi nI}{10}\Bigg[&\frac{r}{a}P_1\left(\frac{x}{r}\right)\left\{1+\frac{t^2}{12a^2}+\frac{t^4}{80a^4}+\frac{t^6}{448a^6}+\dots\right\}-\frac{1}{2}\frac{r^3}{a^3}P_3\left(\frac{x}{r}\right)\times\\&\left\{1+\frac{t^2}{2a^2}+\frac{3}{16}\frac{t^4}{a^4}+\frac{1}{16}\frac{t^6}{a^6}+\dots\right\}+\\&\frac{1\times3}{2\times4}\frac{r^5}{a^5}P_5\left(\frac{x}{r}\right)\left\{1+\frac{5}{4}\frac{t^2}{a^2}+\frac{7}{8}\frac{t^4}{a^4}+\frac{15}{32}\frac{t^6}{a^6}+\dots\right\}-\frac{1\times3\times5}{2\times4\times6}\frac{r^7}{a^7}P_7\left(\frac{x}{r}\right)\times\\&\left\{1+\frac{7}{3}\frac{t^2}{a^2}+\frac{21}{8}\frac{t^4}{a^4}+\frac{33}{16}\frac{t^6}{a^6}+\dots\right\}\dots\Bigg]\end{aligned}$$

lines per square centimeter (25)

where n = turns per centimeter of axial length of the coil. For dimensions see Figure 3.

$$\begin{aligned}H_{r(\text{coil})}=\frac{3\pi nIy}{20a}\Bigg[&\frac{x^2}{a^2}\left\{1+\frac{t^2}{2a^2}+\frac{3}{16}\frac{t^4}{a^4}+\frac{1}{16}\frac{t^6}{a^6}+\dots\right\}-\frac{5}{4}\left(\frac{x^4}{a^4}-\frac{3x^2y^2}{2a^4}\right)\left\{1+\frac{5}{4}\frac{t^2}{a^2}+\right.\\&\left.\frac{7}{8}\frac{t^4}{a^4}+\frac{15}{32}\frac{t^6}{a^6}+\dots\right\}+\frac{35}{24}\left(\frac{x^6}{a^6}-\frac{15}{4}\frac{x^4y^2}{a^6}+\right.\\&\left.\frac{15}{8}\frac{x^2y^4}{a^6}\right)\left\{1+\frac{7}{3}\frac{t^2}{a^2}+\frac{21}{4}\frac{t^4}{a^4}+\frac{33}{16}\frac{t^6}{a^6}+\dots\right\}\Bigg]\end{aligned}\qquad(26)$$

Formulas for $H_{x(s)}$ and $H_{r(s)}$ are obtained by putting $t=0$. For thick coils, the brackets containing power series in t/a may be replaced by the complete expression

$$\frac{a}{mt}\left\{\left(1-\frac{t}{2a}\right)^{-m}-\left(1+\frac{t}{2a}\right)^{-m}\right\}\qquad(27)$$

where m is 0 or an even number. The values of m are 0, 2, 4, 6, in equation 25 and 2, 4, 6, in equation 26. For $m=0$, the binomials may be expanded and m cancelled out before m is put $=0$, thus giving a/t logn a_2/a_1 which may be obtained also by integration of $1/a$. The complete expressions may be used also for extending the formulas.

Formulas for Infinitely Long Coils

It is not permissible to integrate expressions 20 or 21 from the limit $x=0$, or past that point, for small values of y, because a/r would be greater than 1 and the series would be divergent. But the series and their integrals become 0 when x becomes infinitely great, and so it is possible to integrate from x to ∞ and obtain the field density at P due to a coil extending from x to ∞. By subtracting this from the field at P due to a coil extending from 0 to ∞, which may be called $H_{x\infty}$ and $H_{r\infty}$ respectively, one obtains the field due to a coil from 0 to x, at a point in the end plane, the same as for all the other formulas for solenoids listed in this paper.

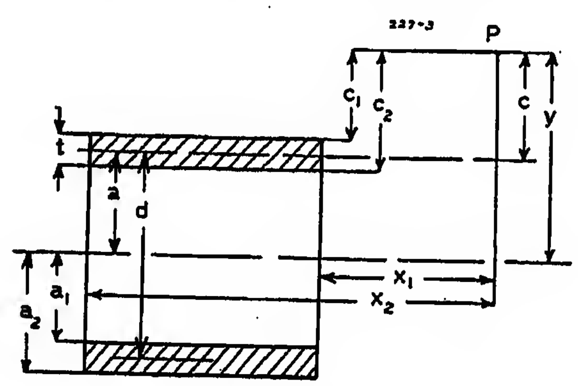

Figure 3. Magnetic field at point P near a solenoid

The axial component of field at a point P outside a solenoid which extends to an infinite distance in both directions from P is 0, as is well known. Such a coil is the limiting condition of a toroidal coil of very large coil diameter compared to the section diameter. The parts of the solenoid to the right and left of the radial plane through P give equal axial fields, which are therefore 0. Thus

$$H_{x\infty}=0\qquad(28)$$

for points outside the solenoid.

The axial field inside a coil extending to infinity in both directions is also well known to be $4\pi nI/10$, a constant. By taking a radial plane through P, the axial field due to the half coil to the left of P is by symmetry equal to

$$H_{x\infty}=\frac{2\pi nI}{10}\qquad(29)$$

For values of y which lie between a_1 and a_2, Figure 3, the value of $H_{x\infty}$ is that due to the turns lying outside of y. In such a case

$$H_{x\infty}=\frac{a_2-y}{a_2-a_1}\times\frac{2\pi nI}{10} \tag{30}$$

The value of $H_{r\infty}$ requires more computation, for various values of y. First, for large values of y, the integration of equation 21 from $x=0$ to ∞ is permissible, and gives

$$H_{r\infty}=\frac{\pi nI}{10}\left[\frac{a^2}{y^2}\left(1+\frac{t^2}{12a^2}\right)+\frac{1\times3}{4\times2}\frac{a^4}{y^4}\left(1+\frac{t^2}{2a^2}+\frac{t^4}{80a^4}\right)+\frac{1\times3}{4\times6}\times\frac{3\times5}{2\times4}\frac{a^6}{y^6}\left(1+\frac{5}{4}\frac{t^2}{a^2}+\frac{3}{16}\frac{t^4}{a^4}+\frac{t^6}{448a^6}\right)+\frac{1\times3\times5}{4\times6\times8}\times\frac{3\times5\times7}{2\times4\times6}\frac{a^8}{y^8}\left(1+\frac{7}{3}\frac{t^2}{a^2}+\frac{7}{8}\frac{t^4}{a^4}+\frac{t^6}{16a^6}+\frac{t^8}{2{,}304a^8}\right)+\ldots\right] \tag{31}$$

See equation 40. The series in t/a are not infinite series, but are complete. The general expression is given in equation 41.

For convenience in computation, the numerical coefficients of powers of a/y in equation 31 are 1, $^3/_8$, $^{15}/_{64}$ and $^{175}/_{1024}$.

For small values of y, integration of equation 23 from $x=0$ to ∞ gives

$$H_{r\infty}=\frac{\pi nIy}{10a}\left[1+\frac{3}{8}\frac{y^2}{a^2}+\frac{15}{64}\frac{y^4}{a^4}+\frac{175}{1{,}024}\frac{y^6}{a^6}+\ldots+\frac{t^2}{a^2}\left(\frac{1}{12}+\frac{3}{16}\frac{y^2}{a^2}+\frac{75}{256}\frac{y^4}{a^4}+\frac{1{,}225}{3{,}072}\frac{y^6}{a^6}+\ldots\right)+\frac{t^4}{a^4}\left(\frac{1}{80}+\frac{9}{128}\frac{y^2}{a^2}+\frac{105}{512}\frac{y^4}{a^4}+\frac{3{,}675}{8{,}192}\frac{y^6}{a^6}+\ldots\right)+\text{terms in } t^6/a^6 \text{ and so on}\right] \tag{32}$$

For thicker coils

$$H_{r\infty}=\frac{\pi nIy}{10t}\left[\log n\,\frac{a_2}{a_1}+\frac{3}{16}y^2\left(\frac{1}{a_1^2}-\frac{1}{a_2^2}\right)+\frac{15}{256}y^4\left(\frac{1}{a_1^4}-\frac{1}{a_2^4}\right)+\frac{175}{6{,}144}y^6\times\left(\frac{1}{a_1^6}-\frac{1}{a_2^6}\right)+\ldots\right] \tag{33}$$

For values of y not very different from a, consider the mutual inductance of two infinitely thin coaxial solenoids of lengths b_1 and b_2 and with a distance between their adjacent end planes equal to w, as in Figure 4. The mutual inductance is given by equation 1, reference 5, as follows:

$$\frac{M}{nn'}=F(x1)-F(x2)-F(x3)+F(x4) \tag{34}$$

where, in the notation used in Figure 4

$x_1=b_1+b_2+w$
$x_2=b_1+w$
$x_3=b_2+w$
$x_4=w$

and where n and n' are the turns per centimeter of the two coils.

Assume that w is a small quantity, and that b_2 is smaller still, so that the right-hand coil is equivalent to a turn of very fine wire. Then $F_{(x1)}$ and $F_{(x2)}$ are to be computed by equation 7 and $F_{(x3)}$ and $F_{(x4)}$ by equation 6 of reference 5. Allow w to increase a small amount. Then, as in equation 7 of this paper, the radial flux density at the circumference of the right-hand coil is

$$-\frac{1}{\pi Dn'b_2}\frac{\partial M}{\partial w} \tag{35}$$

Differentiating $F_{(x1)}-F_{(x2)}$ with respect to w or x, and expanding the first few terms in powers of $1/b_1$, it is found that the result is 0 when b_1 becomes infinite. Differentiating

$$\frac{F_{(x3)}-F_{(x4)}}{\pi Dn'b_2}$$

and discarding higher powers of b_2 and w, the result, excepting the terms in c^8, is

$$H_{r(s)\infty}=\frac{nI}{10}\frac{\sqrt{d}}{\sqrt{D}}\left[\left(\log n\,\frac{16Dd}{c^2}\right)\left(1+\frac{3}{4}\frac{c^2}{Dd}-\frac{15}{64}\frac{c^4}{D^2d^2}+\frac{35}{256}\frac{c^6}{D^3d^3}-\frac{1{,}575}{128^2}\frac{c^8}{D^4d^4}\ldots\right)-4-\frac{1}{2}\frac{c^2}{Dd}+\frac{31}{64}\frac{c^4}{D^2d^2}-\frac{247}{768}\frac{c^6}{D^3d^3}+\frac{7{,}795}{128\times256}\frac{c^8}{D^4d^4}\ldots\right] \tag{36}$$

The process of taking the same function of w and $w+b_2$, subtracting and dividing by the small quantity b_2 is equivalent to differentiating with respect to w. Expression 36 is therefore the result of differentiating $F_{(x)}$ twice. But $F_{(x)}$ was the result of integrating equation 16, reference 4, twice. Equation 36 should therefore correspond to equation 16, reference 4, which it does, and so the two terms in c^8 can be added from the earlier publication.

The following correction for thickness may be added to equation 36:

$$\Delta H_{r\infty}=\frac{nI}{10}\left[\left(\log n\,\frac{16D^2}{c^2}\right)\frac{t^2}{D^2}\left(\frac{1}{12}+\frac{1}{4}\frac{c}{D}+\frac{17}{32}\frac{c^2}{D^2}+\frac{95}{96}\frac{c^3}{D^3}\ldots\right)+\frac{t^2}{c^2}\left(\frac{1}{3}+\frac{1}{3}\frac{c}{D}+\frac{1}{4}\frac{c^2}{D^2}-\frac{1}{12}\frac{c^3}{D^3}-\frac{157}{192}\frac{c^4}{D^4}-\frac{1{,}271}{576}\frac{c^5}{D^5}\ldots\right)\right] \tag{37}$$

Since terms in t^4 and higher powers of t are omitted in equation 37, the following formula for thick coils may be used instead of 36 and 37:

$$H_{r\infty}=\frac{nIc}{10t}\left[\left(\log n\,\frac{16D^2}{c^2}\right)\left(1-\frac{1}{2}\frac{c}{D}+\frac{1}{12}\frac{c^2}{D^2}+\frac{1}{16}\frac{c^3}{D^3}+\frac{17}{320}\frac{c^4}{D^4}+\frac{19}{384}\frac{c^5}{D^5}\ldots\right)-2+\frac{1}{2}\frac{c}{D}+\frac{5}{9}\frac{c^2}{D^2}+\frac{11}{96}\frac{c^3}{D^3}+\frac{7}{4{,}800}\frac{c^4}{D^4}-\frac{71}{1{,}440}\frac{c^5}{D^5}\ldots\right]_{c=c_1}^{c_2} \tag{38}$$

If y is less than a_1, Figure 3, then c_1 and c_2 are negative. If y has a value between that of a_1 and a_2, then c_1 is negative and c_2 is positive.

Formulas for Long Coils

By an integration of equation 20 from $x=x$ to ∞, there is obtained the following formula for the axial flux density at a point P in the end plane of a solenoid of length x, for cases in which $r=\sqrt{(x^2+y^2)}$ is greater than about $1.25a$ (see Figures 3 and 5):

$$H_{x(\text{coil})}=H_{x\infty}-\frac{\pi nI}{10}\left[\frac{a^2}{r^2}P_1\left(\frac{x}{r}\right)\left\{1+\frac{t^2}{12a^2}\right\}-\frac{3}{4}\frac{a^4}{r^4}P_3\left(\frac{x}{r}\right)\left\{1+\frac{t^2}{2a^2}+\frac{t^4}{80a^4}\right\}+\frac{3\times5}{4\times6}\frac{a^6}{r^6}P_5\left(\frac{x}{r}\right)\left\{1+\frac{5}{4}\frac{t^2}{a^2}+\frac{3}{16}\frac{t^4}{a^4}+\frac{t^6}{448a^6}\right\}-\frac{3\times5\times7}{4\times6\times8}\frac{a^8}{r^8}P_7\left(\frac{x}{r}\right)\left\{1+\frac{7}{3}\frac{t^2}{a^2}+\frac{7}{8}\frac{t^4}{a^4}+\frac{t^6}{16a^6}+\frac{t^8}{2{,}304a^8}\right\}\ldots\right] \tag{39}$$

See reference 12. The value of $H_{x\infty}$ is given by equations 28, 29, or 30, depending on the value of y.

By integrating equation 21 from $x=x$ to ∞, the corresponding formula for radial flux density is obtained:

$$H_{r(\text{coil})}=H_{r\infty}-\frac{\pi nIy}{10a}\left[\frac{a^3}{r^3}P_1'\left(\frac{x}{r}\right)\times\left\{1+\frac{t^2}{12a^2}\right\}-\frac{1}{4}\frac{a^5}{r^5}P_3'\left(\frac{x}{r}\right)\left\{1+\frac{t^2}{2a^2}+\frac{t^4}{80a^4}\right\}+\frac{1\times3}{4\times6}\frac{a^7}{r^7}P_5'\left(\frac{x}{r}\right)\left\{1+\frac{5}{4}\frac{t^2}{a^2}+\frac{3}{16}\frac{t^4}{a^4}+\frac{t^6}{448a^6}\right\}-\frac{1\times3\times5}{4\times6\times8}\frac{a^9}{r^9}P_7'\left(\frac{x}{r}\right)\left\{1+\frac{7}{3}\frac{t^2}{a^2}+\frac{7}{8}\frac{t^4}{a^4}+\frac{t^6}{16a^6}+\frac{t^8}{2{,}304a^8}\right\}\ldots\right] \tag{40}$$

where $r^2=x^2+y^2$. See reference 11, equation 5.

The value of $H_{r\infty}$ is given by equations 31–38 and sometimes two of these formulas can be used to check each other. If in Figure 3, $x_1^2+y^2$ and $x_2^2+y^2$ are so large that equation 40 is used for both, then it is evident that in the subtraction of the two results $H_{r\infty}$ cancels out and so does not need to be computed.

The general expression for the brackets in t is

$$\frac{a}{mt}\left\{\left(1+\frac{t}{2a}\right)^m-\left(1-\frac{t}{2a}\right)^m\right\} \qquad (41)$$

where $m=3$, 5, 7, and 9 for equations 39 and 40 as far as shown. They are not infinite series, but are complete.

From equations 22 and 23

$$H_{x(\text{coil})}=H_{x\infty}-\frac{2\pi nI}{10}\left[1-\frac{x}{\rho}-\frac{a^2}{\rho^2}\times\left\{\frac{1}{2\times2}\frac{y^2}{\rho^2}P_2'\left(\frac{x}{\rho}\right)-\frac{1\times3}{2\times4\times4}\frac{y^4}{\rho^4}P_4'\left(\frac{x}{\rho}\right)+\frac{1\times3\times5}{2\times4\times6\times6}\frac{y^6}{\rho^6}P_6'\left(\frac{x}{\rho}\right)\ldots\right\}+\frac{t^2x}{\rho^3}\times\left\{\frac{1}{24}\frac{x^2}{\rho^2}-\frac{1}{12}\frac{a^2}{\rho^2}-\frac{y^2}{\rho^2}\left(\frac{1}{16}\frac{x^4}{\rho_4}-\frac{21}{32}\frac{x^2a^2}{\rho^4}+\frac{3}{8}\frac{a^4}{\rho^4}\right)\ldots\right\}\right] \qquad (42)$$

$$H_{r\,(\text{coil})}=H_{r\infty}-\frac{\pi nIa^2}{10\rho^2}\left[\frac{y}{\rho}P_1'\left(\frac{x}{\rho}\right)-\frac{1}{4}\frac{y^3}{\rho^3}P_3'\left(\frac{x}{\rho}\right)+\frac{1\times3}{4\times6}\frac{y^5}{\rho^5}P_5'\left(\frac{x}{\rho}\right)-\frac{1\times3\times5}{4\times6\times8}\frac{y^7}{\rho^7}P_7'\left(\frac{x}{\rho}\right)+\ldots+\frac{t^2y}{a^2\rho}\left(\frac{1}{12}\frac{x^4}{\rho^4}-\frac{11}{24}\frac{x^2a^2}{\rho^4}+\frac{1}{12}\frac{a^4}{\rho^4}\right)-\frac{t^2y^3}{a^2\rho^3}\left(\frac{1}{8}\frac{x^6}{\rho^6}-\frac{17}{8}\frac{x^4a^2}{\rho^6}+\frac{159}{64}\frac{x^2a^4}{\rho^6}-\frac{3}{16}\frac{a^6}{\rho^6}\right)\ldots\right] \qquad (43)$$

where $\rho^2=x^2+a^2$

Since terms in t^4 and higher powers of t have been omitted from equations 42 and 43, the following equations may be used for thick coils:

$$H_{x(\text{coil})}=H_{x\infty}-\frac{2\pi nI}{10}\left[1-\frac{x}{t}\left\{\operatorname{logn}\frac{a_2+\rho_2}{a_1+\rho_1}+\left(\frac{1}{4}\frac{y^2}{x^2}-\frac{5}{16}\frac{y^4}{x^4}\right)\left(\frac{a_2^3}{\rho_2^3}-\frac{a_1^3}{\rho_1^3}\right)+\frac{33}{64}\frac{y^4}{x^4}\left(\frac{a_2^5}{\rho_2^5}-\frac{a_1^5}{\rho_1^5}\right)-\frac{15}{64}\frac{y^4}{x^4}\left(\frac{a_2^7}{\rho_2^7}-\frac{a_1^7}{\rho_1^7}\right)+\text{terms in higher powers of } y\right\}\right] \qquad (44)$$

$$H_{r(\text{coil})}=H_{r\infty}-\frac{\pi nIy}{10t}\left[\operatorname{logn}\frac{a_2+\rho_2}{a_1+\rho_1}-\frac{a_2}{\rho_2}+\frac{a_1}{\rho_1}-\left(\frac{1}{2}\frac{y^2}{x^2}-\frac{5}{8}\frac{y^4}{x^4}\right)\left(\frac{a_2^3}{\rho_2^3}-\frac{a_1^3}{\rho_1^3}\right)+\left(\frac{3}{8}\frac{y^2}{x^2}-\frac{27}{16}\frac{y^4}{x^4}\right)\left(\frac{a_2^5}{\rho_2^5}-\frac{a_1^5}{\rho_1^5}\right)+\frac{105}{64}\frac{y^4}{x^4}\times\left(\frac{a_2^7}{\rho_2^7}-\frac{a_1^7}{\rho_1^7}\right)-\frac{35}{64}\frac{y^4}{x^4}\left(\frac{a_2^9}{\rho_2^9}-\frac{a_1^9}{\rho_1}\right)+\text{terms in higher powers of } y\right] \qquad (45)$$

where $\rho_1^2=x^2+a_1^2$ and $\rho_2^2=x^2+a_2^2$.

See also reference 1, edition of 1921, equation 28, page 222 (change $5a$ to $5a^2$) and equation 31, page 225. Note that $r_1^2=a^2+(x+b/2)^2$ and $r_2^2=a^2+(x-b/2)^2$ where b is the length of the solenoid.

The following are useful formulas for zonal harmonics:

$$P_0(\mu)=1;\quad P_1(\mu)=\mu;$$
$$P_2(\mu)=\frac{1}{2}(3\mu^2-1);$$
$$P_3(\mu)=\frac{1}{2}(5\mu^3-3\mu);$$
$$P_4(\mu)=\frac{1}{2\times4}(5\times7\mu^4-2\times3\times5\mu^2+1\times3);$$
$$P_5(\mu)=\frac{1}{2\times4}(7\times9\mu^5-2\times5\times7\mu^3+3\times5\mu);$$
$$P_0'(\mu)=0;\quad P_1'(\mu)=1;$$
$$P_2'(\mu)=3\mu;\quad P_3'(\mu)={}^1/_2(3\times5\mu^2-1\times3);$$
$$P_4'(\mu)=\frac{1}{2}(5\times7\mu^3-3\times5\mu) \qquad (46)$$

It is to be noticed that in the formulas, ratios of dimensions occur almost entirely and in such ratios, dimensions in inches may be used throughout instead of dimensions in centimeters, since powers of 2.54, the conversion factor, would occur equally in the numerator and denominator of a ratio and would cancel out. However, the letter n means turns per centimeter and not turns per inch. The letter N means turns per coil.

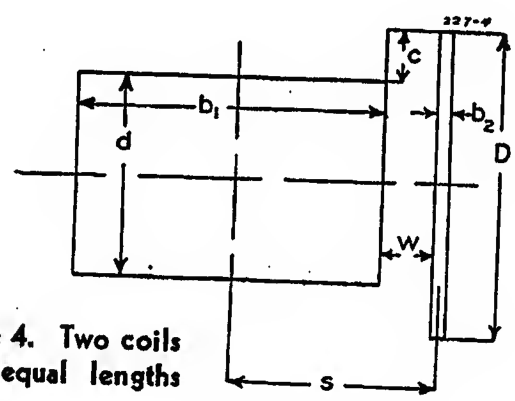

Figure 4. Two coils of unequal lengths

The laboratory measurements which were made agreed with calculated values within a very few per cent.

Example I. The following case, near to the meeting-point of three boundaries, enables one formula to be checked by the others: Find the radial component of field in the end plane of a solenoid where

$x/a=0.9$, $y/a=0.95$, $t/a=0$
$c/a=-0.05$

By equation 9, $H_{r(s)}=5.36\dfrac{nI}{10}$

By equation 36, $H_{r(s)\infty}=6.26\dfrac{nI}{10}$

By equation 40, $H_{r(s)}=6.26-\pi\times0.95(0.446-0.133-0.033+0.020+0.007\ldots)\dfrac{nI}{10}=5.35\dfrac{nI}{10}$

By equation 43, $H_{r(s)}=6.26-\dfrac{\pi}{1.81}\times(0.706-0.164-0.044+0.020+0.007\ldots)\times\dfrac{nI}{10}=5.35\dfrac{nI}{10}$

Example II. The following problem also can be computed by three different formulas. Find the horizontal component of the field in the end plane of the following solenoid:

$x/a=0.4$, $y/a=0.6$, $t/a=0$
$c/a=-0.4$

By equation 3, $H_{x(s)}=2.90\dfrac{nI}{10}$

By equation 25, $H_{x(s)}=2\pi\dfrac{nI}{10}0.721\,(0.555+0.105-0.004-0.013-0.004)=2.90\dfrac{nI}{10}$

By equation 29, $H_{x(s)\infty}=2\pi\dfrac{nI}{10}$

By equation 42, $H_{x(s)}=\left[2\pi-2\pi\times\left\{1-0.3712-\dfrac{1}{1.16}(0.0864+0.0171+0.0023-0.0001)\right\}\right]\dfrac{nI}{10}=2.90\dfrac{nI}{10}$

Example III. A solenoid consists of a single layer of fine wire, $a=0.971$ inch;

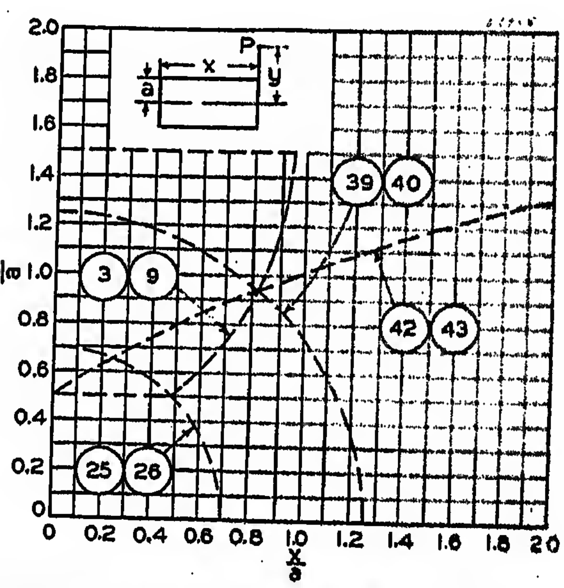

Figure 5. Approximate ranges of application of formulas for magnetic field in end plane of a solenoid

$x=18.25$ inches; $y=0$. The search coil is in the calibrating position, at the center of the solenoid. By equations 29 and 42

$$H_{x(s)}=\frac{2\pi nI}{10}\left[1-1+\left(1+\frac{a^2}{x^2}\right)^{-1/2}\right]=\frac{2\pi nI}{10}\left[1-\frac{1}{2}\frac{a^2}{x^2}\ldots\right]=\frac{2\pi nI}{10}[1-0.0014]$$

due to the half coil, which is 0.14 per cent less than the nominal value for a very long solenoid.

It is evident that, for accurate work, the calibration of search coils, or other measurements depending on the magnetic field in the middle of a long solenoid, should include a correction according to the formulas in this paper of the nominal field $4\pi nI/10$ in the middle of the solenoid.

Example IV. Find the radial component of the field in the end plane of the

solenoid of example III, at eight inches from the axis.

In this problem, x is equal to the full length of the solenoid, 36.5 inches.

By equation 31, $H_{r(s)\infty} = \frac{\pi n I}{10} \times 0.01482$

By equation 43, $H_{r(s)} =$

$$\frac{\pi n I}{10}(0.01482 - 0.00014)$$

Only a very few terms in each series are needed. The turns per centimeter are 7.57 and the current in the test was 1.70 amperes, giving $H_{r(s)}$ by equation 43 $=0.0593$ lines per square centimeter. Test value $=0.0589$ (measurement by M. F. Miller).

MEMBER AIEE

Synopsis: In the electrical system on aircraft, the voltage regulator and reverse-current cutout are key pieces of equipment which, in addition to having requirements of utmost dependability, must be small, light in weight, and of a design adaptable to manufacture on a quantity production basis. The conception and simplification of the prime requirements and their attainment by careful analytical designing is described in this paper in such a way as to show not only the steps in design but also the pertinent application features.

REQUIRED: A voltage regulator which weighs less than one-fifth its nearest relative in the industrial field, and a reverse-current cutout weighing less than one-sixth an industrial contactor of equivalent current rating. Such were some general requirements of the generator voltage regulator and cutout whose design and development are described in this paper. This development involved a careful combination of electrical and mechanical engineering principles and necessitated continuous attention being paid to the application requirements. The magnitude of the design problem involved is emphasized by stating that in addition to all those problems normally encountered there are the problems created by the prime requirements of low weight and small size, as well as those created by atmospheric conditions. In this paper the voltage-regulator is taken up first, and this is followed by the reverse-current cutout.

Mr. T. B. Holliday in the paper "Application of Electric Power in Aircraft" (Electrical Engineering, volume 60, May 1941, pages 218–25) gave a very comprehensive picture of the problems and requirements of electric equipment for aircraft, as seen by a member of the materiel division, Wright Field, United States Army Air Corps. A review of that paper provides an excellent foundation for appreciation of specific design problems such as treated in this present paper.

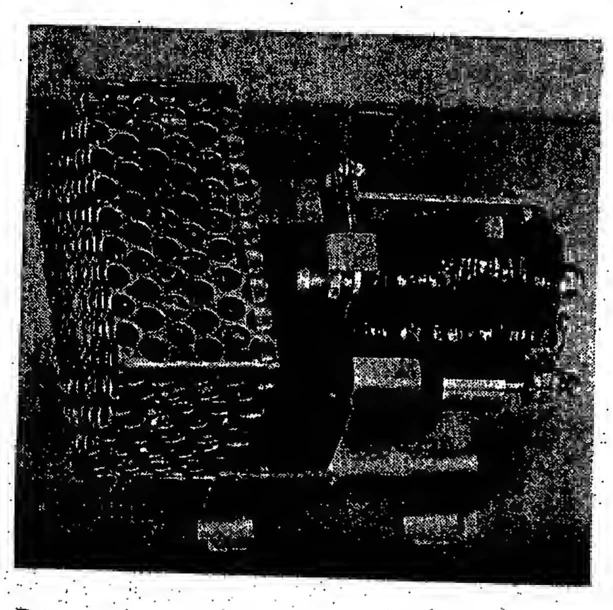

Figure 1. View of voltage regulator showing resistors on left and operating magnet on right

Voltage Regulator

The aircraft voltage regulator described in this paper is shown in Figure 1 and is suitable for operating with any approved 28.5-volt d-c self-excited generator whose maximum field current (at full load and minimum speed) is not more than eight amperes, and whose minimum field current (at no load and maximum speed) is 0.5 ampere. A schematic diagram is shown in Figure 2. Additional specific requirements are:

1. Hold voltage within ±2 per cent of 28.5 volts. This must be maintained over the range from no-load to full-load generator current, while the generator speed may vary from 2,500 to 4,500 rpm.
2. Radio interference must be held to a minimum.
3. Satisfactory operation with air conditions varying over a range of: −40 degrees centigrade to +60 degrees centigrade in temperature, sea level to 35,000 feet in altitude 10 to 90 per cent in relative humidity.
4. Must fit on a standard quick-mounting base which includes all electrical connections.
5. Dimensions including base must not exceed $6^1/_2$-inch length, 4-inch width, and $3^7/_8$-inch depth, and of this a total space of $2^1/_2$ inches by 4 inches by 1 inch must be kept free for mounting base terminal studs and cables.
6. Weight must not exceed 2.5 pounds.
7. Current-carrying capacity of contacts = 15 amperes continuous.
8. Regulator to vary the field resistor between 0.25 ohm and 75 ohms in such a way that generator-voltage surges do not exceed three volts.
9. Regulator must operate satisfactorily with as many as five generators and regulators connected in parallel and provide equal division of load. Maximum deviation from the average value of load must not exceed 10 per cent of generator full-load rating.

Paper 42-48, recommended by the AIEE committee on air transportation for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 17, 1941; made available for printing January 22, 1942.

R. C. Jones is transportation control engineer, D. W. Exner small motor division engineer, and Sherwin H. Wright new products division engineer, all with Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

The above requirements call for a rather unusual piece of equipment involving major development. It might well be added that neither the attaining of such requirements nor their prior recognition as key characteristics are matters that could be or were settled in a moment or by superficial analysis or study. Rather, the setting down of the requirements and their practical attainment were the result of the engineers of the materiel division keeping a step ahead of the best efforts of the manufacturer's design engineers, thus leading to the final result in a minimum of time.

The voltage-regulator is conveniently divided into four parts in this discussion:

1. Contact device.
2. Operating magnet.
3. Resistor.
4. Base.

These four parts will be treated separately and in that order.

Contact Device

A multicontact type of regulator was chosen as being best fitted to meet the requirements. The Silverstat unit illustrated in Figure 3 is an industrial type of multicontact device which has proven itself by years of service on innumerable applications. It consists essentially of a number of spring bronze leaves with built-in silver contacts at the movable end of each leaf. At the stationary or clamp end of the assembly short strips are used between each leaf to both insulate and space them from each other. The movable ends of the leaves lie against an insulation block whose face is cut at an angle such that, in the free position, all contacts are open and equally spaced. The opening force on each contact is dependent upon the

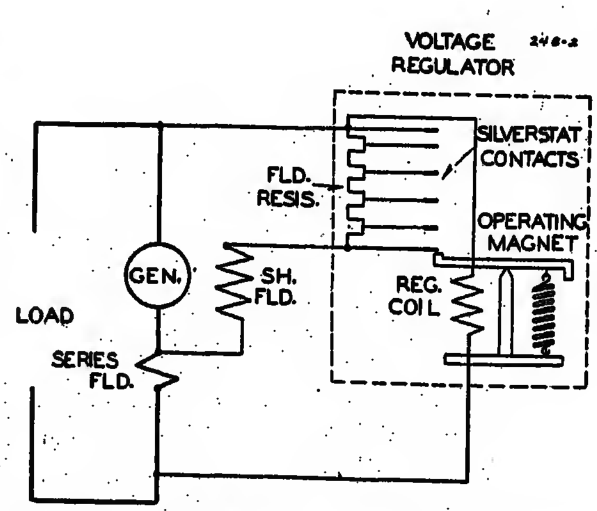

Figure 2. Schematic diagram of voltage regulator

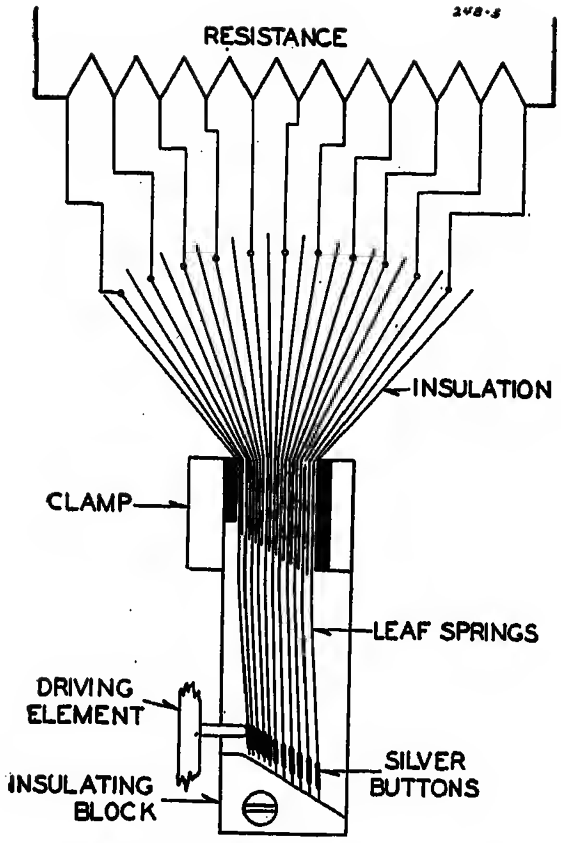

Figure 3. Industrial-type Silverstat unit

tension in its own leaf. Since the leaves are spaced approximately $^1/_{64}$ inch apart, and since accurate response to small changes in voltage is necessary, the leaf material must be straight and must have very consistent spring characteristics. On the standard Silverstat assembly, which has been in production for industrial applications for some years, it has been found necessary to maintain a very careful control of the leaf material in order to insure proper leaf characteristics. The standard leaf material, however, was impractical for the aircraft regulator, as markedly higher conductivity and shorter lengths of leaves operating in a wider range of ambient temperatures were required. In view of this, the successful quest for a new material was a metallurgical achievement of no small moment to the designer.

Other factors and problems entering into the design of the contact unit were those connected with the generator itself. In the first place the generators to be regulated were themselves in the development stage. Calculated generator characteristics had to be checked, and the designs changed to be suitable for operation in a regulated voltage system. Changes were being made in the generator specifications giving new field-current limitations. Initially, consideration was given to limiting the total field current to 12.5 amperes and allowing the use of two field circuits both on the generator and the regulator. Final specifications limited the field current to eight amperes and required that the regulator use only one circuit which would vary the field resistor from 75 ohms to 0.25 ohm in steps that would not produce surges higher than three volts at the generator terminals.

A double-deck construction of the contact assembly is used to obtain the necessary number of contact leaves in minimum space. This also reduces the movement required between the all-open and all-closed position of the contacts to one-half of the standard construction which has all leaves in line. The full number of steps is obtained by alternating the operation of the contact leaves in the upper and lower stacks. The mechanical assembly of this double-decked Silverstat is accomplished by the preassembly of the leaves and insulation in a fixture which establishes the correct relation of parts and cements them together. After being baked to fix the cement, these stacks are placed in the double-deck frame and adjusted to proper relation and spring tension. Each Silverstat assembly is checked in a pressure-measuring device and adjusted to have the same corresponding leaf in each stack operate at the same pressure. This is necessary to obtain consistent results required in quantity production.

Operating Magnet

The operating magnet supplies the activating force for closing or releasing as many leaves and steps as is required to establish a voltage within the chosen limits. It must respond to small changes in voltage, moving only enough to readjust the field circuit resistance to the proper value, and it must be small and of such form as to fit in compactly with the other units. Temperature effects must be compensated for, and residual magnetism kept to a minimum. The moving member must be shockproof.

A clapper or moving-iron type is the form of magnet chosen for this application. See Figure 1 which shows the armature at the left of the coils. Two long slender coils are employed in order to obtain the lowest winding weight. The stationary part of the magnetic circuit is arranged in the form of a *U* with a coil on each leg. The armature which completes the circuit is pivoted parallel to the line of the two coils. To reduce the number of parts and obtain a unit assembly, the pivot support is made by extending the flat section of iron connecting the two cores, parallel to the coils to a point approximately even with the open end of the magnetic circuit, then bending this extension at right angles. To minimize weight, the extended section of frame is cut out, leaving only a skeleton form having sufficient mechanical strength. This is possible since the material is not in the magnetic circuit.

To obtain dependable as well as frictionless pivot action, a leaf spring is used. The armature itself is made of a single flat piece of iron cut out around the pivot for free action and extending beyond the pivot to provide for attachment of the calibrating spring and to act as a counterbalance. An insulation angle is attached to the coil side of the armature to act as the contact operating member. The stationary end of the calibration spring is supported by a strip of bimetal attached to the frame.

Adjustment of the calibration spring is obtained by a novel scheme using a minimum number of parts, and is best described with the aid of Figure 4. A hole is punched in the stationary support to fit a threaded stud with one side machined flat; a small point is lanced out of the support in proper relation to the hole to engage with notches on the circumference of the adjusting nut. With the regulator magnet completely assembled, the tension of the calibrating spring holds the adjusting nut in engagement with the point, locking it securely. To change the adjustment it is necessary to tip the adjusting nut and stud just enough to disengage them from the locking projection, then rotate the adjusting nut. The nut is made from a standard pinion stock rod and the fineness of adjustment is determined by the number of teeth. The final choice of:

1. Thread for the adjusting stud of the calibrating spring.
2. Teeth on the adjusting nut.

resulted in a design giving 0.05 ounce change in adjustment per notch or tooth.

The design of the calibrating spring is complicated by the building up of the contact assembly load when the spring loading decreases, also by the fact that the contact assembly load is high in proportion to the magnet pull.

With the lightweight clapper-type magnet it is impractical to obtain stable regulator operation without some form of damping. To obtain damping, trial was

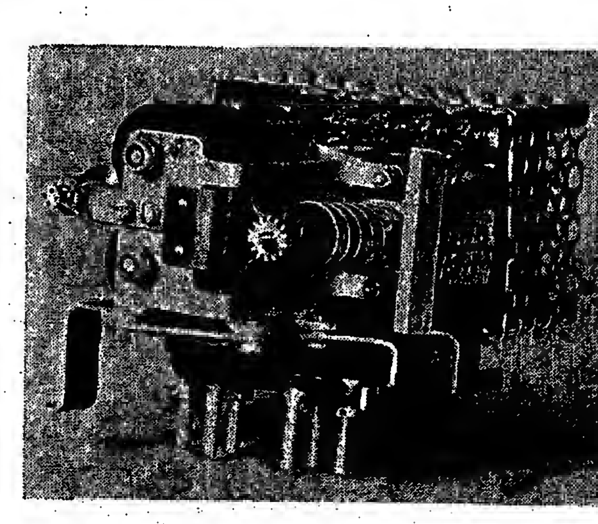

Figure 4. End view of voltage regulator

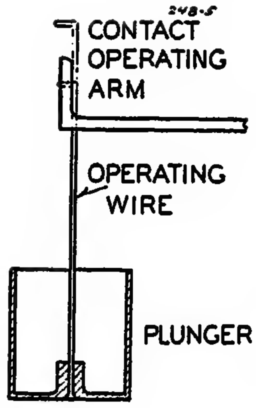

Figure 5 (left). Dashpot attachment

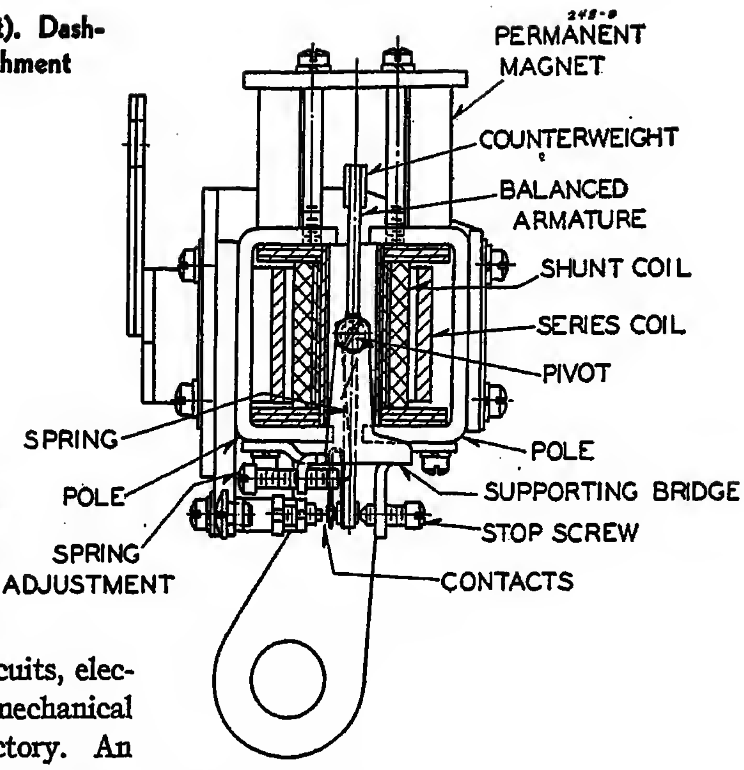

Figure 8 (right). Simplified view of reverse-current relay structure showing balanced armature and location of polarizing magnet

made of electrical damping circuits, electrodynamic dampers, and mechanical dampers, but none was satisfactory. An air dashpot was tried and found to have very desirable characteristics, and it gave excellent results. Both the piston and plunger of this dashpot are made of stainless steel. This minimizes the effects of differential expansion due to temperature, and of corrosion.

Because the end of the armature moves in an arc, and the dashpot plunger in a straight line, it was necessary to provide a connection between them which would not set up a side pressure on the stationary cylinder. Common practice is to include a universal joint in an operating-rod assembly of this type, but such construction is subject to friction and play, both of which are detrimental to accurate regulation. To avoid these faults a long piece of spring wire is employed as a column, one end being soldered in the plunger and the other end slipped through a close-fitting hole in the contact-operating arm. See Figure 5. This same end is bent at a right angle and is sprung to go into another close-fitting hole in the angle of the arm. This results in a tight connection with minimum weight and number of parts.

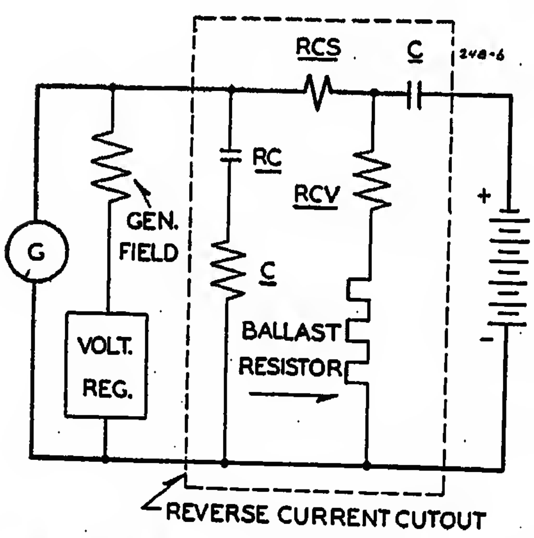

Figure 6. Schematic diagram of reverse-current cutout

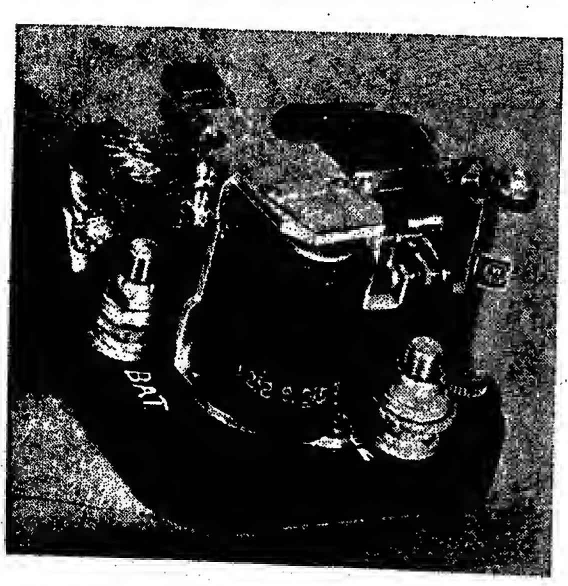

Figure 7. Reverse-current cutout

To allow maximum tolerance on the plunger and cylinder diameters, and thus facilitate manufacture, a needle valve is provided for adjusting the restraining effect of the dashpot. The cylinder is mounted on a stud extension from the main body, and the needle valve located inside this stud, thus adding only one part and no weight. Friction is minimized by putting a mirror-smooth polish on the outside of the plunger and the inside of the cylinder, and by use of a carefully chosen lubricant.

Because of the wide variation in operating temperature encountered by aircraft, considerable thought was given to the best method of compensating for the temperature range produced by both ambient change and coil heating. The temperature effect in this regulator is limited by winding the coils with an alloy wire having a temperature coefficient of approximately one-eighth that of copper and a specific resistance of six times that of copper. This gives heavier coils but eliminates the use of an external resistor. It also eliminates the problems of:

1. Finding a negative temperature coefficient resistor to suit this application.

2. A construction for keeping the temperatures of the two parts together so that there is a minimum time lag in correcting for coil heating and cooling.

To correct for the smaller effect of temperature on the alloy wire, a bimetal strip mounted on the magnet frame is used for the stationary support of the calibrating spring. This is located between the points where the two coil cores attach to the frame. Heat transfer from the coil windings to the cores and frame is improved by winding the coils directly on the cores, thus eliminating the heavy insulating tube and air space required where a separate self-contained coil is used. The bimetal strip reduces the calibrating spring tension with a rise in either coil or ambient temperature. It is necessary to co-ordinate the bimetal support and calibrating-spring design closely to gain the ultimate in compensation. The scheme used provides regulation within the required limits under all operating conditions.

Resistor Design

The field resistor presents two separate problems. The first is to obtain a form that will be light enough, work into a compact unit and have taps which are accessible for wiring. The problem was solved only by the wholehearted co-operation of the resistor manufacturer. The original estimate of the resistor weight for the 200-ampere generator was one pound, leaving $1^1/_2$ pounds for the regulator mechanism and mounting base. The final resistor design weighing one-half pound was reached only after intensive study of operating conditions, and by many tests.

The second problem is that of designing the resistor with the right resistance steps to give even voltage response from the generator without overloading the contacts. This requires the co-ordination of generator characteristics with the regulator response and balancing these against practical voltage and volt-ampere limitations of the contacts. The work on this problem was complicated by the changes in generator design and by the requirement that the regulator be satisfactory for regulating any Air Corps approved generators of the 50-, 100- and 200-ampere capacities, without reconnection of the resistor. The characteristics of the various sizes of generators had to be studied, and the resistor steps changed to the best over-all compromise. The resistor steps were of such low value in the high current zone that a ribbon type of resistor material had to be used. This is corrugated after the fashion of the standard Ribflex round resistor tubes, but

wound on a flat earthenware form and held in place by ceramic glaze.

MOUNTING BASE

The regulator base presents no special problems, since the other parts are designed as individual units, all mounting from the same flat surface. The base is, therefore, flat except for the special lugs for mounting on the standard subbase. It is cut out for weight reduction and for maintenance purposes and carries a special contact assembly needed to complete electrical circuits to the mounting panel. A perforated metal cover is furnished to protect the resistor.

The complete regulator in its final form as shown in Figures 1 and 4, weighs less than 2.0 pounds, is $5^{15}/_{16}$ inches long, 4 inches high, and $3^{3}/_{4}$ inches deep. It has passed all laboratory tests successfully, operated satisfactorily on test flights and is now in quantity production.

Reverse-Current Cutout

The demand for a reverse-current cutout to handle the 100- and 200-ampere 28.5-volt generators arose coincident with the need for a voltage regulator. In June 1940 the materiel division issued a tentative specification for a 100-ampere device weighing less than two pounds and a 200-ampere device with a 2.5-pound limit. For reasons explained later, the 100-ampere rating has since been abandoned.

While the aircraft cutout performs the same function as the well-known automobile cutout, namely to connect the generator to the battery and load when the generator voltage is sufficient to charge the battery, and to disconnect it when the voltage drops below the charging point, conditions peculiar to the aircraft electrical system demand a higher standard of performance. In particular, the storage battery has a much lower ampere-hour capacity in proportion to the generating capacity, making a low reverse-current dropout setting desirable. Because operation of two or more generators in parallel is usual, a pickup voltage as close as possible to the normal regulated voltage of the generators is necessary to prevent excessive chatter in closing. This requirement results in close specification of pickup voltage tolerances.

The tentative specification called for opening at a reverse-current of not more than five per cent of the continuous rating, and set the pickup voltage between 26.8 and 27.2 volts, or an accuracy of plus or minus three quarters of one per cent. It was further specified that the device should be capable of opening a current equal to 150 per cent of its rating. Maximum dimensions were set at four by four by four inches. These cutouts may frequently be mounted close to the main engines where severe vibration is encountered. To ensure sound mechanical construction a ten-hour vibration test is specified, with a total excursion of 0.07 inch and a frequency varying periodically between 10 and 55 cycles per second.

During the course of the development, modifications of the requirements narrowed down the original problems and introduced new ones. The first addition was the requirement that the cutout should not close on application of reversed voltage. The arc-rupturing capacity of the 200-ampere unit was increased to 500 amperes. An over-all millivolt drop was included and finally whittled down to 85 millivolts at rated current, with the further provision that this must not exceed 95 millivolts after 100 operations of the arc-rupturing test. On the basis of preliminary models submitted by manufacturers, the materiel division reduced the weight limit of the 200-ampere cutout to 2.25 pounds.

Past experience made it clear from the beginning of the development that the measuring and circuit-operating functions should not be combined in one structure, but rather that the design should comprise a relay in addition to a contactor. It is impractical to provide high calibration accuracy in a device which also must carry and efficiently rupture high current. In addition to the greater friction and contact wear effects, the calibration change with temperature cannot readily be controlled without an objectionable increase in weight. The necessity for polarization also influenced the decision to use a separate measuring relay. Figure 6 gives schematically the circuit of such a device consisting of a relay having a shunt voltage-measuring coil *RCV*, a series current coil *RCS*, and contacts *RC* energizing the coil of contactor *C*. Figure 7 shows the cutout in final form.

RELAY

The term "polarization" presupposes the existence of a reference factor of constant direction with which to compare the generator voltage. This factor may be voltage from a battery, the unidirectional conduction of a rectifier, or the fixed polarity of a permanent magnet. For the purpose of a reverse-current cutout, the use of battery voltage as a reference is the most direct line of attack and has the definite advantage of preventing circuit closure when either the battery or generator is reversed. It has the disadvantage of draining current from the battery when the generator is idle. Variations in battery voltage have an adverse effect on the accuracy of calibration.

Use of a rectifier as a reference, while satisfactory for many applications, in general involves a weight handicap. Dry-plate rectifiers, in a case of this kind, must be applied with caution because of the wide range of temperatures which may be expected. High ambient temperature, coupled with normal internal losses, may result in failure. The change in rectifier characteristics with temperature may be reflected in calibration errors, especially at sub-zero temperatures where all dry-plate rectifiers show a large increase in forward resistance. The fact that such rectifiers have a negative temperature coefficient can be used to advantage to balance the positive coefficient of copper windings over a moderate temperature range. Over a wide range this is less practical because the rectifier resistance does not change linearly with change in temperature.

Polarization by a permanent magnet overcomes the disadvantages of the other two methods. Proper application of the better magnetic materials which have been developed in recent years provides a reference polarity of stability adequate to meet the requirements. The proportions of the permanent magnet may be selected so that, with a given permeance of the associated magnetic circuit, the desired flux is obtained with minimum weight. It should be so located as to minimize the demagnetizing effect of external fields, particularly the field of the relay series coil.

The high sensitivity of a polarized relay recommends it for this service. The required sensitivity is determined by the specified reverse-current and the turns in the series coil. Minimum weight demands that the relay operate with a single-turn series coil for the highest current rating for which the frame is intended. Multiple-turn coils may then be used for lower ratings. The relay used in this cutout was designed to have a single-turn coil in the 200-ampere rating, so that with the reverse-current specified as 10 amperes, it must drop out on a 10-ampere-turn reversal as a maximum limit. Reasonable manufacturing and testing tolerances require a design value of six or seven ampere-turns.

For positive contact operation a snap action is necessary in opening and closing. This requires that the armature, in closing, move into a denser magnetic field where the force is greater than that required to move it out of its initial position. The reduction in ampere-turns required

to decrease the pull to the drop-out value is produced by the bucking action of the series coil. Experience has shown that a drop-out-to-pickup ratio of 0.8 is near the maximum which will provide satisfactory snap action. If we use this value and a drop-out-to-pickup differential of seven ampere-turns, the correct pickup value will be approximately 35 ampere-turns.

Because of the vibration and shock conditions encountered on aircraft, as well as the high acceleration forces produced by maneuvering and flight in rough air, full static balance is essential on the moving parts of all accurate relays. If the relay structure is not inherently balanced, counterweights must be added even though they mean an objectionable increase in weight. The magnetically polarized relay is easily modified into an inherently balanced mechanical structure by the use of a center-pivoted armature having a working air gap at each end. This requires the addition of sufficient counterweight to balance the weight of the light moving contact only.

Figure 8 shows the details of the relay in its final form. The center-pivoted armature operates between the two *U*-shaped poles which are polarized by the cobalt steel magnet. The armature and poles are made of hydrogen-annealed Hipernik magnetic alloy to minimize hysteresis which would otherwise be objectionable in a low energy relay. To avoid the critical adjustment required in assembling cone pivots without damage or looseness, small diameter polished pin bearings are used. The shaft is 18–8 stainless steel running in bronze bearing screws. A stainless-steel torsion spring with screw adjustment contributes to the shock resistance of the relay and gives latitude of correction for manufacturing variations. A stamped brass bridge supports the armature, spring, and stop screw, so that the whole assembly may be removed after taking out the screws which fasten it to the poles. The combined shunt and series coil spool surrounds the armature and is contained within the poles, the whole assembly being supported from the base by an aluminum mounting frame.

Contactor

The contactor magnetic circuit is of conventional clapper design, but the contact structure is turned around from the usual position in order to place the pivot near the center of gravity. This reduces the armature spring strength required to provide stability under shock, and so somewhat reduces the weight of the magnetic circuit.

When large currents are to be interrupted it is important to remove the arcing from the main contact surfaces to prevent a rise in millivolt drop after repeated operations. Auxiliary arcing tips, opening after the main contacts have separated, are sometimes used for this purpose, but they have several disadvantages. In lightweight devices there is a tendency to make them too weak so as to add as little as possible to the magnet load. They are, therefore, vulnerable to mechanical damage in handling and may not always be effective. Being electrically in parallel to the main contacts they carry a portion of the main current. Gritty dust deposited on the main contacts may cause all of the main current to pass through the arcing tips; a load which they seldom can be designed to carry for more than a short time.

A more satisfactory solution is the conventional rolling contact wherein the final opening always occurs at the tip, leaving the contact heel clean. By varying the kinematic layout, any reasonable value of wipe or scrubbing action may be obtained to keep the contacts clean and break through dust deposits. This is accompanied by a strong toggle action capable of prying apart contacts partially welded by heavy overload. Almost universal use of this construction on industrial contactors indicates its superiority.

The moving contact is an extruded copper shape with a silver-alloy contact face. This part is sufficiently balanced with respect to its pivot so that the spring is able to maintain adequate contact pressure against vibration accelerations in excess of those obtained in the specification test. The flexible copper shunt is brazed directly to the extruded contact by an electrically-controlled spotwelding process using a water spray to prevent annealing or oxidation of the shunt strands. To minimize the bending action as the contactor operates, the point of shunt attachment is located close to the contact pivot.

The silver-alloy-faced stationary contact is carried by a steel extension of the magnet frame, giving a rigid support and making the whole contactor a self-supported unit. The stationary contact structure is so shaped with respect to the moving contact that the current path forms a sharp loop as the contacts separate. This produces a noticeable magnetic blowout action which is particularly useful at currents of 100 amperes and higher.

Instead of using the conventional arrangement with separate armature and contact springs, both functions are performed by one stainless-steel tension spring. Elimination of the extra parts reduces the size and weight and simplifies the assembly. The characteristics of any usual double-spring combination may be essentially duplicated with care in the selection of the factors of spring stiffness, lever arm lengths, and pivot locations. Contact force of one pound is obtained in the sealed position, measured at the contact tip.

Previous to the design of the magnetic circuit, complete magnetic torque data were taken on a somewhat smaller frame having similar proportions. These data were extrapolated to obtain the proportions of a magnet having a torque curve fitting the desired torque curve of the contact and spring system. Tests on a model showed that the first approximation was fairly close, requiring only determination of the best core head and body diameters to obtain the optimum design. The critical portion of the torque-versus-distance curve is the point at which the contacts initially touch. As it is unreliable to depend on kinetic energy to carry the armature over this point, sufficient magnetic torque must be obtained at the minimum design voltage and maximum coil temperature. Best results are obtained with a three-quarter-inch head diameter and a seven-sixteenths-inch core-body diameter. The core end has an integral threaded stud which passes through the frame and is secured by a nut, a construction which eliminates the sharp reduction in core area caused by tapping a fastening screw into the core.

Since it is most economical in weight to limit saturation to the core at the touch point of the torque curve, the frame has a greater cross-sectional area than the core near the junction of the two. The frame area is reduced near the hinge because of the lower leakage flux passing into this portion.

Low reluctance of the unavoidable magnetic gap at the armature hinge is important, since this joint consumes ampere-turns which would otherwise be more usefully employed at the core-head air gap. In addition to minimizing mechanical clearance at this point, an ear is bent down from each side of the armature to utilize the side area of the frame. The magnetic parts are made from low carbon steel and given 925 degrees centigrade annealing in a hydrogen atmosphere to improve the permeability and decrease the residual. The results permit the use of a 0.005-inch-thick residual shim.

With the core diameter and length determined by magnetic considerations, the mean diameter of the coil is determined primarily by the heat dissipation rate. Usual construction methods, involving a coil wound on an insulating tube and slipped loosely over the core, give a high

Analysis of the Application of High-Speed Reclosing Breakers to Transmission Systems

IN recent years many new or improved kinds of apparatus have been made available for increasing the reliability of transmission circuits. These include high-speed relays, high interrupting speed breakers, ground-fault neutralizers, protector tubes, and high-speed reclosing breakers. Though they may be used in combination, ground-fault neutralizers, protector tubes, and high-speed reclosing breakers offer alternate methods for reducing the outages on the transmission circuit. The reliable loading of a transmission circuit may also be increased by introducing intermediate switching stations and by increasing the interrupting speeds of existing breakers.

Considerable technical-application information has been presented to aid in the general understanding and use of most of this equipment. Although many successful applications of high-speed breaker reclosing have been made in recent years, there still appears to be a real need for an analysis of the general possibilities and limitations of high-speed reclosing of both the three-phase and the single-phase types. This paper attempts to present such an analysis.

Paper 42-31, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE winter convention, New York, N. Y., January 26-30, 1942. Manuscript submitted November 12, 1941; made available for printing December 8, 1941.

S. B. CRARY, L. F. KENNEDY, and C. A. WOODROW are all of the central station engineering department, General Electric Company, Schenectady, N. Y.

The authors acknowledge the assistance of their associates, in particular, H. A. Peterson for his discussion of single-phase arc clearing, and C. G. Adams, H. C. Anderson, R. B. Bodine, N. H. Meyers, and J. E. Paul for their work on the network analyzer and for their calculations.

General Considerations for High-Speed Reclosing

High-speed reclosing circuit breakers have been shown by experience and analysis to be capable of improving the reliability of transmission systems.[1,2,3] Where they may be used to best advantage can be fairly well predetermined by stability studies and analysis of test and experience information. Fundamental to the problem are:

1. Maximum permissible time—after the fault has been cleared—for de-energization of the faulted circuit without loss of synchronism.

2. Minimum permissible time for deionization of the fault arc.

The first depends upon the following factors:

a. System arrangement and design.

b. Amount and distribution of generating capacity.

c. Load being carried on faulted circuit and remainder of system.

d. Type, duration, and location of fault.

The second depends upon many factors, among which are:

a. Fault current and its duration.

b. Length of arc.

c. Number of conductors involved.

d. Tower and circuit configuration.

e. Insulator dielectric strength.

f. Weather conditions.

g. Multiple lightning stroke phenomena.

The first fundamental consideration, the maximum time the faulted circuit may be deenergized without loss of synchronism, can be determined by analysis. It is generally recognized that systems sometimes pull back into synchronism even though they may be reclosed together out of synchronism or at

---

thermal drop between the two, and depend, therefore, mainly on heat dissipation from the barrel area. By winding the coil directly on the mica-insulated core and impregnating the whole assembly, an excellent thermal joint is obtained, allowing a large portion of the heat to be conducted into the frame and armature for dissipation. The reduction in coil weight by this construction may be as high as 50 per cent, based on designs having equal values of hot ampere-turns and temperature rise as measured by resistance.

The complete contactor, with a rating of 200 amperes and 29 volts continuously, weighs under 14 ounces and is capable of rupturing in excess of the 500 amperes called for in the specification. With its stainless-steel pivot pins operating in bronze bearings it has undergone a mechanical life test of 3,000,000 operations without measurable wear or broken shunt strands.

The contactor and relay designs were co-ordinated to permit combining them on a four-by-four-inch square base with a direct line of connection between the main generator and battery terminal studs so as to minimize the weight of connectors and the over-all millivolt drop, which is less than 75 millivolts at 200 amperes. The base is molded plastic, ribbed for stiffness and minimum weight, and is recessed to keep the main and control terminal posts from turning under wrench forces. Over-all weight of the complete 200-ampere cutout is less than 1.90 pounds. This is under the weight originally specified for the 100-ampere rating. Furthermore, the weights of models submitted by the several manufacturers showed a uniform difference of only a few ounces between the 100- and 200-ampere ratings. Since the weight advantage was so slight the materiel division wisely decided to eliminate the 100-ampere rating and use the 200-ampere size for both the 100- and 200-ampere generators.

Conclusions

Aircraft electrical equipment, such as voltage regulators and cutouts, must meet most of the requirements found in other industrial applications, and in addition must have certain special characteristics. These special characteristics have to do with weight, size, and atmospheric conditions.

While aircraft-application requirements of electrical equipment differ in certain respects from those of other related industrial applications, it is to be expected that the use of equipment specially developed for aircraft service may well be extended to other fields.

so large an angular displacement that synchronism is temporarily lost. The severity of the consequent disturbance depends upon many factors, but the phenomenon further supports the advisability of quick reclosing. However, operating experience, in general, indicates that it is not desirable even under emergency conditions, to allow for anything but a short interval of nonsynchronous operation.

The time for deionization of an arc is variable and it becomes good practice to allow as much time as possible for the deionization without encroaching too closely upon the stability limits of the system. Information as regards the deionization time is rather meager. The best data are given in a series of papers showing results obtained on the American Gas and Electric Company systems.[1,2,3] These indicate that a time of six to nine cycles for three-phase clearing and 12 cycles for re-energizing results in about 90 per cent successful operation. This gives a datum point of 12 cycles for deionization time at 138 kv, with three-phase clearing and reclosing. Under some conditions the actual time necessary for deionization will be less than 12 cycles, while under severe conditions it may be more. With single-phase switching the arc on the faulted conductors, after the line breakers have opened, tends to be maintained by the capacitive coupling with the sound phase or phases. Longer times are probably required for deionization of the arc path with single-pole switching.[4] See appendix III. It seems evident that the optimum time for de-energization is not necessarily a fixed value but is determined by system conditions. It is hoped and expected that further tests and experience information will be made available by the operating companies.

If the stability margins are small, it may become justifiable to decrease the allowed time for deionization; while if the stability margins are large, it would appear that a longer time could be allowed. An extreme case of a large stability margin (sufficient parallel circuit strength) would require no reclosing at all. Between the two extremes of stability conditions, represented by a single circuit tie and a circuit with many parallel ties, there exist many conditions and cases where high-speed reclosing of some form may be used to advantage. The aim is to obtain improved reliability over transmission circuits for the loads which those circuits are required to carry. This necessitates a proper evaluation of many factors and is an interesting and practical engineering problem for consideration by those responsible for system design and operation.

With the use of generally available a-c network analyzers, calculations are quite readily made to determine the maximum permissible time for de-energization of the faulted circuit. Such a stability study is an important part of the engineering analysis of the feasibility and desired characteristics for reclosing equipments for the particular system under consideration. Fortunately, however, a certain amount of helpful information can also be obtained by analysis of typical system arrangements and conditions. This was done with the use of a network analyzer. The conditions for the cases studied are given in appendixes I and II. Following is a discussion of the results which have been obtained.

Three-Phase Reclosing—Tie Lines and System Interconnections

A series of cases was taken as representative of interconnections or ties between system areas. The systems on either end of the interconnection were assumed to be of equal capacity having fairly low system impedances (five per cent on 2.5(kv)²) corresponding to about 1,000,000 short-circuit kva when the transmission line voltage is 138 kv. The line length was varied from 0 to 300 miles in order to show the effect of change in line length. Both systems at either end of the line were assumed to be solidly grounded. The inertia constants were

*Corresponds to about the surge impedance or unity power-factor loading of the line when $\sqrt{L_1/C_1} \cong$ 400 ohms.

taken to correspond to systems having a connected capacity equal to about four times the unity power-factor loading (equal to 2.5(kv)²) of a single circuit. These represent relatively small systems compared to those which may be found in practice as ties between major system groups. However, the results may be interpreted to correspond to either larger or smaller systems by a corresponding change in the clearing and de-energization times, as explained in appendix I.

Figure 1 shows the maximum permissible de-energization time for stability versus line length for line-to-ground, double-line-to-ground, and three-phase faults at the sending-end terminal for a power transfer at the sending end corresponding to ten per cent above the unity power-factor or surge-impedance loading of the line. At 138 kv this corresponds to $1.1 \times 2.5(138)^2 = 53{,}000$ kw. Fault clearing times were taken as six and nine cycles with simultaneous operation at each end of the line. Under these conditions successful operation can be expected for even three-phase faults for line lengths up to 150 miles and 210 miles for a de-energization time of 12 cycles with nine cycles and six cycles clearing, respectively. Successful operation could be expected up to 250 miles for line-to-ground faults with either six or nine cycles clearing. A decrease in the clearing time from nine to six cycles for three-phase faults allows for an increase in the line length of 60 miles for the same de-energization time. It is of interest to note that the type of fault makes an appreciable difference in the allowable de-energization time. These results indicate the importance of keeping the clearing time to a minimum, as this makes possible a further increase in the stability margin of the circuit or an increase in the permissible de-energization times. This has been pointed out previously.[3]

The curves of Figure 1 were drawn for a loading equal to ten per cent above the unity power-factor loading of the line. This is probably the loading to which lines exceeding 150 miles may be loaded. However, for the shorter lengths of line higher loadings may be desired. Fortunately stability characteristics are such as to allow for an increase in loading for shorter lengths with the same de-energization time.

If the sizes of the terminal systems are increased, the resulting increase in the inertia constants produces more stable performance. Such changes can be estimated from Figure 1. For instance if the inertia constants are about double (2.25 times), the six-cycle clearing curve represents the performance with nine-cycle clearing on the new system if the ordinate scale, representing the maximum permissible de-energized time is multiplied by 1.5. The permissible de-energized time for a 150-mile line following the clearing of a three-phase fault in nine cycles is increased from 12 to 22 cycles. Conversely the same load may be transmitted 300 miles, rather than 150 miles, with the same 12 cycles de-energized time.

To illustrate the effect of change of load, the case of 100 miles was analyzed more in detail, results of which are shown on Figure 2. The power in this case is in terms of receiver-end power. The values of per-unit power equal to 1.04 correspond to the case of sending-end power of 1.1 per unit. Table I gives values of per-unit power for various transmission line voltages to be used in the interpretation of the curves.[5] Figure 2 also shows results for single-phase clearing and reclosing. Of particular interest is the very substantial increase in power limit with decrease in the de-energization time with three-phase switching. For three-phase or double-line-to-ground faults, the curves are such

that, in the region of 12 cycles de-energization time, a decrease of three cycles in the de-energization time is equivalent to about a three-cycle reduction in fault-clearing time. This indicates that a cycle reduction in fault-clearing time is equivalent to a cycle of reduction in de-energization time. There is possibly a further improvement with the quick clearing in that the ionization in the arc path does not involve as great a volume of air, and, therefore, a further reduction in deionization time may be allowed. This is of considerable interest because studies of transient stability limits of systems have indicated that there was not much to be gained by reduction in fault clearing times *without* reclosing below eight or possibly five cycles. Figure 2 indicates that with three-phase reclosing, three cycles reduction in time, either clearing or de-energization is worth about 15 per cent increase in power limit.

If the interconnected systems have greater inertias than those used in determining the curves on Figure 2, a correspondingly greater amount of power can be transferred for the same de-energization time. For example, if the inertia constants of the interconnected systems are 2.25 times those used for Figure 2 (generating capacity equal to about nine times 2.5 $(\text{kv})^2$ or 400,000 kva for a 138-kv transmission line) the transient stability limit is increased from a per-unit receiver power of 1.16 to 1.62 with nine-cycle clearing of three-phase faults and a 12-cycle de-energization time. This indicates that the inertias of the interconnected systems have a considerable effect upon the allowable de-energization time and that, when applying reclosing mechanisms, this effect should be considered. It is evident that when the interconnected areas are of a large capacity compared with the tie-line capacity, three-phase reclosing may be entirely adequate, even for single-circuit ties for loads up to the maximum which the circuit will be required to carry.

Figure 4 gives the results for 100 miles of double-circuit line with no intermediate switching station. It will be noted from the bottom curve on this figure that a load corresponding to two per unit (this corresponds to unit power on each circuit) may be carried with no reclosing, following a three-phase terminal fault which is cleared in nine cycles. A power of 2.4 per unit may be carried with no reclosing if six-cycle clearing is used. As shown by Figure 4, the increase in power limit by the use of reclosing is much less than that for a single line, as shown in Figure 2. With 12 cycles de-energization time and nine cycles clearing for a three-phase fault, the power limit is increased about ten per cent over what it would be with no reclosing. It will be noted that the improvement in stability limit for six cycles clearing of the three-phase fault over nine cycles clearing is 40 per cent greater than the improvement obtained by the use of reclosing. These results indicate that for some types of system, depending upon the load it is desired to transfer, there is very little benefit to be obtained from the use of high-speed reclosing. However, if the systems have relatively large inertias, the increase in power limit can be further improved. This indicates that an appreciably greater gain may be obtained with three-phase reclosing on parallel lines when the inertia constants are large; whereas, if the inertia constants are small, it may be impossible to carry the rated load of the circuit. Additional curves are given in Figures 3 and 5 for 50 and 200 miles of double-circuit line, respectively, with no intermediate switching station. Figure 6 corresponds to a 200-mile double-circuit line bussed together at the center. It will be noted that by bussing, the 200-mile line performance is improved, and the gain due to reclosing is decreased, and may be such that it may not be necessary to use any reclosing. For the 50-mile double-circuit line, Figure 3, the curves are relatively flat indicating very little benefit to be derived from reclosing.

For circuits which are on the same tower, more than one circuit may be involved in the fault, and in such a case successful reclosure of even one of the two circuits may prevent loss of synchronism. Therefore, a benefit greater than that shown in the attached curves for double-circuit lines can be realized when the conductors are supported on the same tower. The performance under these conditions would be somewhat similar to that of single-line performance as shown on Figures 1 and 2. Single-line performance or simultaneous faults on double-circuit line can be adequately taken care of by three-phase reclosing when the interconnected areas have sufficient capacity or

inertia effect. This has been supported by experience as given in reference 3.

Single-Phase Reclosing—Tie Lines and System Interconnections

Single-phase clearing and reclosing of transmission-line circuits has been considered a possibility for a long time but has been put into operation only to a limited extent. With a line-to-ground fault only one-phase wire need be interrupted, the remaining tie over the two sound phases and ground being sufficiently strong to prevent loss of synchronism for a considerable range of load and system conditions obtained in practice. When two-phase wires are involved, however, the remaining tie is so reduced in strength as to result in but little benefit over three-phase reclosing for the same de-energization times. There is, of course, no benefit if all three-phase wires are involved.

Figure 7 shows the maximum permissible de-energization time in cycles for stability of a single circuit tie using single-phase clearing and reclosing. These curves are for a loading corresponding to a sending-end power ten per cent above the unity power-factor loading of the line and with the connected systems having a capacity about four times the transmitted power. As shown by these curves, this power can be transmitted up to 150 miles with three-phase switching, nine-cycle clearing, and a 12-cycle de-energization time, for a three-phase fault. It is also of interest to note that the permissible de-energization time for line-to-ground faults is considerably higher than for three-phase or double-line-to-ground faults. This indicates that for line-to-ground faults single-phase reclosing is a very effective way of preventing loss of stability. However, its greatest advantage occurs when the loading is such that three-phase reclosing is no longer adequate. This condition is more likely to exist when the interconnected systems are relatively small.

Figure 2 shows the results for a single-circuit line 100 miles long. This compares the results using single-phase reclosing with three-phase reclosing. If the loading of the line is increased above unity power-factor loading, and the inertias correspond to those used in the figure, the line-to-ground faults may be switched off by the use of single-phase switching without loss of synchronism up to a loading which is 50 per cent greater than that of a line-to-ground fault with three-phase reclosing based on the same de-energization time of 12 cycles. However, if the deionization time for single-phase reclosing must be 50 per cent longer, which may be necessary for a 100-mile line, the improvement is from a per-unit power of 1.5 to 2.05 or about 35 per cent increase in power limit. Similar comparisons can be made by examining the results shown on Figures 3, 4, 5, and 6.

High-Speed Reclosing—Hydroelectric System

Representative of a type of system where reclosing might be applied is a hydroelectric station located at some distance from a large system to which it delivers power. This case of a typical hydroelectric station was studied for various lengths of line and line loadings. The transmission line constants were assumed to be the same as for the study of interconnections previously discussed. Typical hydroelectric generator constants

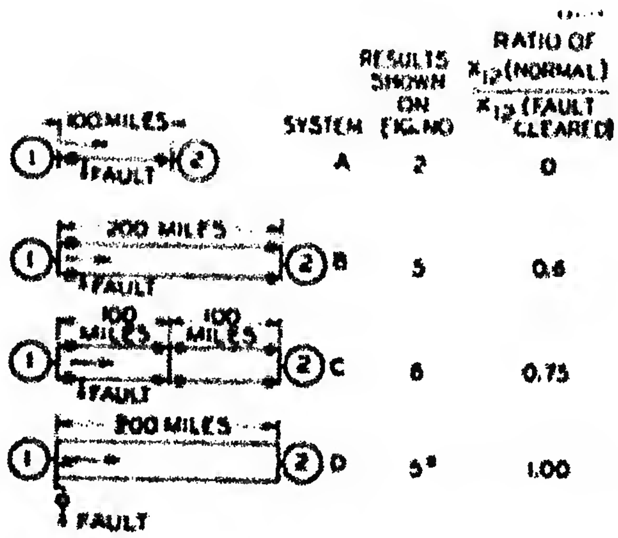

Figure 10. Systems used for interpretation of results in terms of present-day standard breakers shown on Figures 11 and 12

*De-energization times for this case taken to correspond to zero cycles

were used ($x_d'=0.30$, $H=3.0$). The sending- and receiving-end transformer reactances were assumed as ten per cent on the generator rating. The receiving-end system was assumed to have infinite inertia and an equivalent reactance corresponding to ten per cent of the hydroelectric generator rating. See appendix II. Calculations were then made to determine the transient-stability limits with single-line operation and high-speed reclosing. The hydroelectric generators were assumed to have a rated power factor of 0.9 and to be operating at ten per cent above their kilowatt rating, a loading which about corresponds to their kilovolt-ampere rating. The results are therefore on the basis of the total hydroelectric generating capacity being operated at slightly above rated kilowatt load. The results indicate the maximum permissible de-energization times under these conditions.

For this type of system, which has a relatively low inertia constant and which has a transmitted load equal to the total generated capacity at the sending end of the line, three-phase reclosing is impractical unless de-energization times of one to five cycles were possible. Furthermore, single-phase reclosing for anything but line-to-ground faults is impractical, because of the small available time for deionization before stability is lost. However, for line-to-ground faults single-phase reclosing may prove practical. Figures 8 and 9 show the results of calculations for this case with nine- and six-cycle fault clearing, respectively. It will be noted from Figure 8 that a line loading of unity corresponding to 50,000 kw at 138 kv may be transmitted 50 miles, with stability, when nine-cycle clearing and 27-cycle de-energization time are used. From Figure 9, if six-cycle clearing is used, a line loading of unity may be transmitted 55 miles with stability. For heavier line loadings a corresponding reduction in miles to which the power can be successfully transmitted through a line-to-ground fault is obtained.

Calculations were also made to determine the effectiveness of a high-resistance amortisseur winding for increasing the permissible de-energization time when single-phase switching is used. As is well known,[12,13] such a winding will increase the braking torque during a circuit unbalance and may be of advantage under such conditions in reducing the effective accelerating torque. For a 100-mile single-circuit line with a unit loading ($P_0=1.0$), the maximum permissible de-energization time was found to be increased about 35 per cent for line-to-ground faults. Such a winding may, therefore, be effective for a hydroelectric generator connected to its load area by single-circuit line, when it is desired to protect against line-to-ground faults by single-phase switching rather than by a ground-fault neutralizer. If it is necessary to protect against faults involving two or more phases, single-phase switching is not effective, and there is but little benefit to be derived by the use of a high-resistance amortisseur winding.

Summary From Preceding Studies

(*a*). Three-Phase Reclosing on System Ties

1. The benefits to be obtained from reclosing are greatest for single-circuit lines, or simultaneous faults on double-circuit lines.

2. Three-phase reclosing is a very practical means for maintaining the transmission-line loading between interconnected areas when the interconnected areas have generating

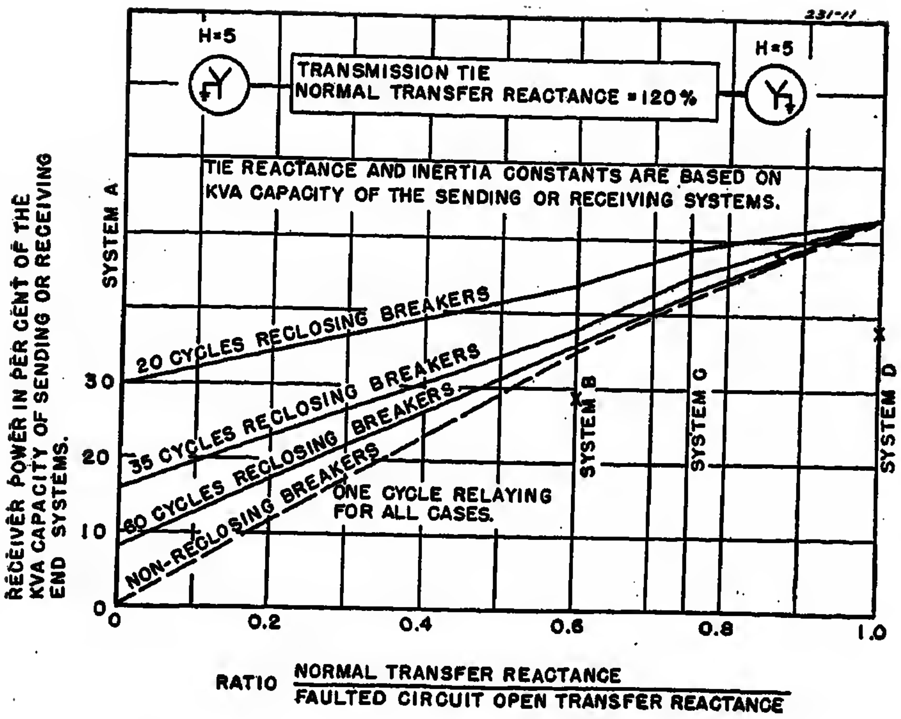

Figure 11. Stability limits for three-phase faults at sending-end line terminal, nine cycles clearing, as a function of reclosing time and ratio of transfer reactances

Refer to Figure 10. The two points marked "x" on the figure show the power limit for unsuccessful reclosure against a three-phase fault on one circuit using 20-cycle reclosing breakers

capacities of the order of at least four times the transmission-line loading.

3. With three-phase reclosing of single-circuit lines a decrease in the clearing time for three-phase faults is as important as a decrease in de-energization time. Therefore, further reductions in the fault-clearing time directly improve the stability.

4. With parallel circuits, the benefits to be realized from reclosing decrease with decrease in line length and with increase in the number of intermediate switching stations.

(*b*). Single-Phase Reclosing on System Ties

1. Single-phase switching provides increases in transient power limits on single-circuit lines for line-to-ground faults which are not possible with three-phase switching; the difference however, may be small if the interconnected areas have high generating capacity relative to the power to be transmitted.

2. The power limits of a single-circuit line are greater with a ground-fault neutralizer for extinction of line-to-ground faults than those which can be obtained with single-phase switching.

3. If the inertia constants of the interconnected systems or the connected capacities are sufficiently great, the practical advantages of single-phase switching may be negligible.

4. For line-to-ground faults, if single-phase switching is used, the time for de-energization is not particularly critical as regards its effect on the stability limits, and, therefore, it is not necessary to strive for low reclosing time as is the case with three-phase reclosing.

5. The advantage of single-phase switching appears to be important only when reclosing is used on single-circuit interconnecting lines and when the generating capacity of one of the interconnected areas is not much greater than the load which must be transmitted.

6. Single-phase switching appears to offer no advantage over three-phase switching for faults involving more than one phase.

(*c*). Single-Phase Switching for a Hydroelectric Station Delivering Power Over a Single-Circuit to a Large System

1. Single-phase reclosing makes possible the maintenance of stability through self-clearing line-to-ground faults for normal line loadings and for short distances.

2. For longer lines and more heavily loaded circuits, other means such as the ground-fault neutralizer may be required in order that the system may ride through line-to-ground faults.

3. This type of system is not stable with either single-phase or three-phase reclosing of faults which involve more than one phase.

Ground-Fault Neutralizers

Ground-fault neutralizers should be compared with the use of single-phase switching, since the advantages of using the latter means are chiefly limited to line-to-ground faults. The ground-fault neutralizer has an advantage over single-phase switching in that there is no reduction in stability limits for line-to-ground faults. For the shorter lines this may be of no particular advantage over single-phase switching, as the circuit loadings may be well below the transient-stability limits with single-phase switching. However, it may be necessary to retain as

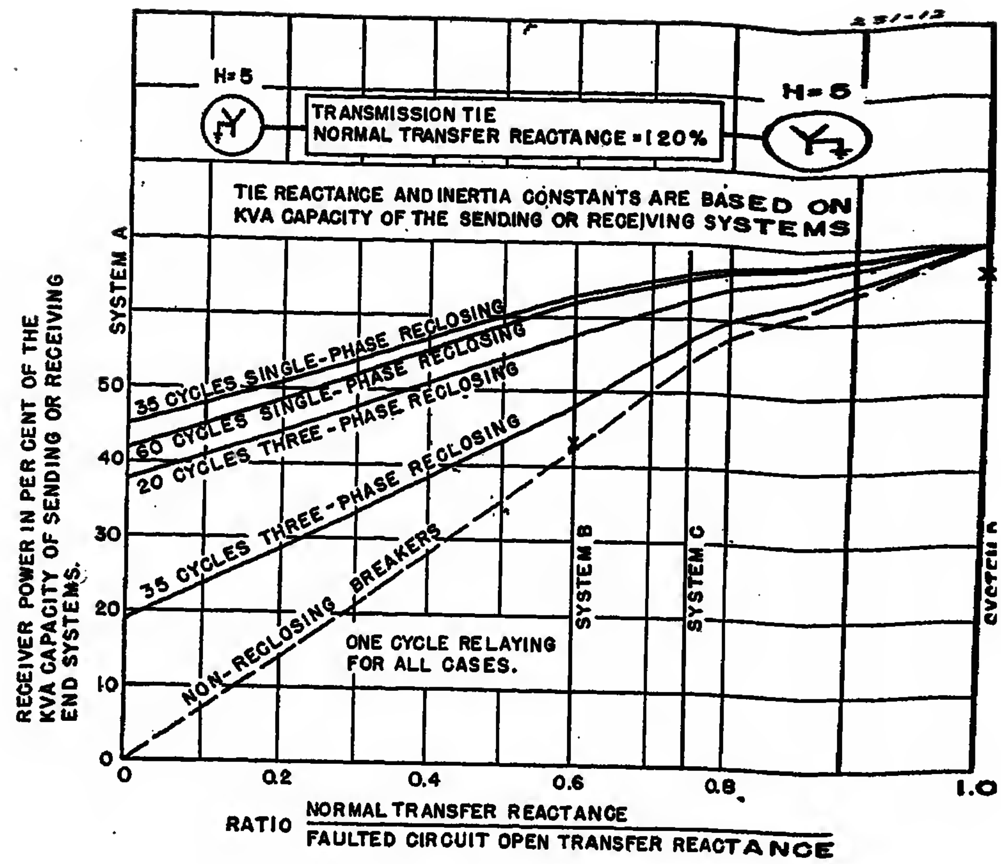

Figure 12. Stability limits for line-to-ground faults at sending-end terminal, nine cycles clearing, as a function of reclosing time and ratio of transfer reactances

Refer to Figure 10. The two points marked "x" on the figure show the power limit for unsuccessful reclosure against a line-to-ground fault on one circuit using 20-cycle three-phase reclosing breakers

much stability margin as possible in order to carry rated circuit loadings on the longer lines. This, therefore, indicates that for long single-circuit lines, ground-fault neutralizers have a distinct advantage over single-phase switching, whereas for the shorter lines and on systems which are necessarily solidly grounded, single-phase switching may have important advantages. When using ground-fault neutralizers on single-circuit lines, one should give attention to the switching and circuit arrangements in order to avoid the possibility of high transient switch voltages. This problem, however, is now well understood,[11] so that the conditions which give rise to such abnormal voltages can be avoided.

Relaying

In general, the use of reclosing on tie circuits requires that the terminal breakers be opened simultaneously in order to obtain the benefit of maximum deionization time to clear the arc path. This essentially requires the use of pilot-wire relays of some form to give the simultaneous tripping at both terminals. For the lines generally considered in this analysis, the line lengths are such that the carrier-current form of pilot relaying would be

used. Successful operation of high-speed reclosing with carrier relaying is already a matter of record.[3]

For single-phase operation, it is only necessary to add to the basic carrier pilot-relay equipment phase-selecting relays to select the proper phase or pole to be opened in case of single-phase faults. Since single-phase operation is feasible only on a solidly grounded neutral system, these phase selecting relays can be simple impedance devices operating from line-to-neutral voltage and line residual current. In some cases of single-phase reclosing it may not be necessary to obtain simultaneous tripping at both terminals, because the permissible de-energization time is so great that sequential tripping could be tolerated.

Interpretation in Terms of Present-Day Standard Breakers

Although the previously presented results cover a wide range of possible system conditions and breaker speeds, they may require some interpretation in terms of present-day standard-breaker clearing and reclosing times. It was found that this could be conveniently done by cross-plotting the results for the clearing and de-energization times corresponding to standard breakers for the series of systems shown in Figure 10. All of these four system arrangements have essentially the same transfer reactance for normal conditions, neglecting resistance and capacitive susceptance. If it is assumed that the inertia constants of the two interconnected systems correspond to $H=5$ per unit on the kilovolt-ampere rating of the generator capacity of each system (four times the per-unit power of the preceding studies or $10(\text{kv})^2$), the transfer reactance is 120 per cent on the kilovolt-ampere capacity of each interconnected system. The ratio of the normal transfer reactance to the transfer reactance with the faulted section switched out can be used as an indication of the shock to the system resulting from switching out the faulted section. In the right-hand column of Figure 10 are tabulated these ratios.

(*a*). Three-Phase Faults

Figure 11 shows the per cent power (based on the generating capacity of the individual interconnected systems) which can be transferred with stability through a three-phase fault at the sending-end line terminal, plotted against the ratio of transfer reactance for the different standard-breaker times. Zero ratio of transfer reactance represents a single-circuit tie, whereas increasing ratios indicate an increasing number of intermediate stations on parallel lines.

In Figures 11 and 12 it is assumed that

(*a*) Relay delay is one cycle at each end of the circuit.

(*b*) Breakers with eight cycles interrupting time rating are used.

The circuit de-energized time is eight cycles less than the reclosing time rating. From Figure 11 several important effects are apparent:

1. The greatest possible gain with reclosing may be realized for systems which approach the single-circuit tie (system *A*, Figure 10).

2. The smallest possible gain is realized for systems which approach a multiple-circuit tie sectionalized by a large number of intermediate switching stations (system *D*, Figure 10). Except for the possibility of simultaneous double-circuit outages, there is little reason for using reclosing breakers in a system of this type. If double-circuit faults can occur, the performance is almost the same as that of the shorter single-circuit line (system *A*, Figure 10).

3. A point of diminishing returns is soon reached for further sectionalizing beyond that represented by the double-circuit tie with one intermediate switching station (system *C*, Figure 10).

4. The advantages of 20-cycle over the slower 35- or 60-cycle reclosing breakers are apparent.

5. If single-phase reclosing is slower than three-phase reclosing, the allowable power transfer during three-phase faults is correspondingly less.

6. The successful power transfer is very appreciably increased even when one strong tie is paralleled by another of relatively low capacity. If two such circuits have equivalent lengths of 150 and 300 miles, the transfer reactance ratio is approximately 0.4 and the allowable power transfer is at least 25 per cent greater than for a single 100-mile circuit.

(*b*). Line-to-Ground Faults

Figure 12 shows the performance of the same four systems analyzed in the same manner for line-to-ground faults, using both single-phase and three-phase reclosing breakers. Because a longer deionization time is required for single-phase reclosing than for three-phase reclosing, 35 and 60 cycles were taken as the reclosing times for the former, and 20 and 35 cycles for the latter. The general form of the curves is about the same as for Figure 11. From Figure 12 several important effects are apparent:

1. Appreciably greater power can be transmitted for the single-circuit system with three-phase reclosing, if 20-cycle rather than 35-cycle reclosing is used. A further but much smaller gain is realized by the use of 35-cycle single-phase reclosing.

2. With single-phase reclosing, the difference between 60 and 35 cycles reclosing is quite small. The speed of reclosing for single-phase switching on line-to-ground faults is less important than that for three-phase switching.

(*c*). Other Considerations

Figures 11 and 12, though limited to one value of normal transfer reactance (120 per cent) indicate the relative importance of several of the essential factors during line-to-ground and three-phase faults. A similar interpretation for double-line-to-ground faults shows that, where high-speed reclosing is applicable, 20-cycle three-phase reclosing gives appreciably better results than 35-cycle single-phase reclosing. Further interpretations show that, with increase in system inertia, the stability limits with high-speed reclosing are materially increased. This indicates that the use of high-speed reclosing will naturally tend to increase with the trend toward interconnection of large systems by ties of relatively small capacity.

High-speed reclosing involves the risk that occasionally the fault will not be self-clearing, and any attempt to reclose may do harm rather than good. This risk may be evaluated in two ways. First, the decrease in power limit due to an unsuccessful reclosure below that obtained with no reclosing. Second, the decrease in power limit due to an unsuccessful reclosure below that obtained with successful reclosing.

Calculations for both systems *B* and *D* of Figure 10 indicate that quick single-phase switching and reclosing of line-to-ground faults can involve negligible risk of either the first or second kind. The advantage of the possible small risk of the second kind may be largely only of theoretical rather than of practical value because to obtain it would require an unusually long period of unbalanced operation with one phase open. As shown by the points (marked x) on Figure 12, automatic three-phase unsuccessful reclosure against line-to-ground faults involves negligible risk of the first kind but appreciable risk of the second kind. For either single-phase or three-phase unsuccessful reclosure against the more severe faults, double-line-to-ground or three-phase (for three-phase faults points marked x on Figure 11), the risk of both the first and second kinds is appreciable. Calculations made for the case of delayed or manual reclosure showed no risk of the first kind. Calculations were also made for the 200-mile tie with an intermediate bussing station (system *C*) for the special case of a double-line-to-ground fault due to a single-line-to-ground fault on different phases

of each circuit. Both circuits were assumed to be cleared in nine cycles, closed after 12 cycles de-energization time, unsuccessful reclosure on one circuit, and with subsequent nine cycles clearing on this faulted circuit. The critical loading for this case with three-phase reclosing was found to be about the same as for a self-clearing three-phase fault on one circuit of system-*A* type. With single-phase reclosing for this case, the critical loading is nearly double the value obtained with three-phase reclosing.

From both Figures 11 and 12, it is apparent that the risks are least where the possible gain from reclosing is greatest.

General Conclusions

1. Under favorable conditions for its use, high-speed reclosing provides a simple means for substantially increasing the system reliability.

2. The choice of the type and available time ratings for reclosing breakers requires an analysis to weigh properly their relative advantages.

3. With three-phase reclosing, de-energization time is important for all types of faults, and clearing time is important for double-line-to-ground and three-phase faults but not for single-line-to-ground faults.

4. For single-phase switching, both clearing and de-energization time are relatively unimportant for single-line-to-ground faults but are important for faults involving more than one phase.

5. Until more is known about the deionization time requirements with single-phase switching, it appears logical to limit single-phase reclosing to line-to-ground faults and to applications where moderate reclosing delay carries no particular stability penalty.

6. High-speed reclosing will show the greatest advantage and will tend to be more generally used as the number of system interconnections and the size of systems increase, relative to the strength of their individual interconnecting ties.

Appendix I. Study of System Interconnections

A series of cases was set up for study of three-phase and single-phase reclosing, having constants which were considered representative for illustrating the factors involved in system interconnections. These cases were studied on an a-c network analyzer. The following representative line constants of a 60-cycle overhead transmission line were used:

$x_1=0.8$ ohm per mile, positive sequence reactance.

$r_1=0.16$ ohm per mile, positive sequence resistance.

$Y_1=5.2\times10^{-6}$ mhos per mile, positive sequence susceptance.

$x_0=2.4$ ohms per mile, zero sequence reactance.

$r_0=0.43$ ohm per mile, zero sequence resistance.

$Y_0=3.12\times10^{-6}$ mhos per mile, zero sequence susceptance.

For study of double-circuit lines the zero-sequence mutual capacitance and reactance effects were neglected because

(*a*). These assumptions would apply for lines not on the same right of way.

(*b*). These are secondary effects only and would not modify appreciably the results or conclusions of this study even for lines on the same tower.

The base kilovolt-amperes and kilowatts were taken as 2.5 $(\text{kv})^2$ corresponding to the surge-impedance or unity power-factor loading of a line having the constants selected for study.[5] The sending-end and receiving-end systems were assumed to have equal impedances. The positive-, negative-, and zero-sequence impedances of sending- and receiving-end systems were assumed to be the same and equal to $0.002+j0.05$ per unit on a base kilovolt-ampere equal to 2.5 $(\text{kv})^2$. See Figure 13. The system was set up three-phase on the network analyzer so that the simultaneous dissymmetries produced by opening single-phase switches at either end of the line, with or without a fault on one or more phases, could be more easily represented. Also in this way the capacitive ground current and the fundamental frequency voltage on the cleared conductor would be determined directly for any condition.

The voltages back of system impedances were held fixed for all loadings corresponding to values which would give normal or unit voltage at each line terminal for a power transfer per circuit at the sending end of 1.10 per unit. For higher initial loadings the results give somewhat lower limits than may be actually obtained; whereas for lower initial loadings, the limits are somewhat higher. However, these differences are small because of the comparatively small terminal or system impedances.

The faults were all taken at the sending-end terminal and assumed to be cleared in six or nine cycles. The maximum permissible time for de-energization of the faulted conductor or conductors was determined by calculation.[6] The line length was varied from 0 to 300 miles. Both single- and double-circuit lines with and without intermediate bussing were studied. Some of the results obtained are shown on Figures 1–7. These results are given for equal sending- and receiving-end system inertias of $H=20$ per unit based on 2.5 $(\text{kv})^2$. A typical system may have an inertia constant (H) of 5.0 per unit on its connected kilovolt-amperes of generator capacity. Accordingly, with an $H=20$ on 2.5 $(\text{kv})^2$ and a transmission-line loading of unity, corresponding to unity power-factor transmission, the connected generator capacity of the sending- or receiving-end systems corresponds to about four times the power being transferred.

Since results have been obtained for both six-cycle and nine-cycle clearing, the curves for six-cycle clearing and $H_1=H_2=20$ can be readily interpreted for nine-cycle clearing with $H_1=H_2=45$ by increasing de-energization times given on the curves by a factor of 1.5.

Similarly the nine-cycle clearing results for $H_1=H_2=20$ may be interpreted as applicable for six-cycle clearing with $H_1=H_2=20/2.25=8.86$ if the de-energization times are decreased by dividing by 1.5.

The concept of equivalent or effective system inertia constant may be applied approximately (could be correctly applied if resistance were negligible) so that the above results may be interpreted to apply to systems having effective inertia constants corresponding to $H_0=H_1H_2/(H_1+H_2)$.[7,8]

The pull-out power shown in the curves corresponds to the receiving pull-out power.[9] This may also be used as the power limit for a line-to-ground fault for ground-fault neutralizer operation as compared with the other methods of fault clearing.

Appendix II. Conditions for Study of Hydroelectric Systems

A series of cases was studied corresponding to a hydroelectric station delivering power over a single-circuit line to a large system. The line constants were taken to be the same as for the interconnection study outlined in appendix I. The remaining system constants are, see Figure 14,

$x_d'=0.30$ on generator kva

$x_{T1}=x_{T2}=0.10$ on generator kva

$x_s=0.10$ on generator kva

$P_r=$ kw rating of generator in per unit of 2.5$(\text{kv})^2$

Rated generator power factor $=0.9$

Generator kva $=P_r/0.9$

Normal voltage was assumed at the sending- and receiving-end high-voltage terminals under initial conditions. The faults were taken at the sending end.

The maximum permissible de-energization times were determined for a power transfer of $1.1\times P_r$ corresponding to a ten per cent stability margin or a power practically equal to the kilovolt-ampere rating of the generator. The results of the calculations made for these cases are shown on Figures 8 and 9 for nine- and six-cycle clearing. The maximum permissible deenergization times for faults involving more than one phase with either single-phase or three-phase switching were all less than five cycles.

The results for the six-cycle clearing can

be interpreted for nine-cycle clearing when the inertia constant is increased from 3.0 to $(1.5)^2\times 3.0=6.75$ by increasing the de-energization times by a factor of 1.5.

Appendix III. Self-Clearing Characteristics of Arcs to Ground With Single-Phase Switching

H. A. PETERSON*
MEMBER AIEE

In the case of single-phase switching, the capacity coupling from the sound phase or phases to the stricken phase or phases tends to maintain an arc to ground once it is established. This is illustrated in Figure 15 of this appendix. Figure 15a shows the capacitance circuit involved. If it is assumed that phase a has been de-energized, the effective voltages in the circuit are V_b and V_c of Figure 15b. These can be resolved into components approximately as shown. The components V_b-V_a' and V_c-V_a' will have no effect on the voltage or current of conductor "a", since they are equal and opposite. The resultant effective component is $V_a'=0.5V_b=0.5V_c$. This is effective in the single-phase equivalent circuit shown in Figure 15c where conductor "a" retains its identity while conductors "b" and "c" are shown as a common point.

With switch S closed, a current flows through it to ground corresponding to the arc current which must be extinguished before conductor "a" can be normally energized for carrying power. The current flowing through S is

$$I_s=\frac{0.5V_b}{\dfrac{1}{\omega(C_1-C_0)}+\dfrac{1}{2\omega(C_1-C_0)}}$$

$$=\frac{0.5V_b}{\dfrac{3}{2\omega(C_1-C_0)}}=\frac{\omega(C_1-C_0)V_b}{3}$$

In terms of normal charging current for the section of line being switched out dividing by ωC_1 this becomes

$$\frac{I_s}{I_{nc}}=\frac{\omega(C_1-C_0)V_b}{3\omega C_1}=\frac{(C_1-C_0)V_b}{3C_1}$$

where I_{nc} is normal positive phase sequence line charging current. In a typical overhead line, $C_0=0.6C_1$ is representative. Therefore,

$$\frac{I_s}{I_{nc}}=\frac{(C_1-0.6C_1)V_b}{3C_1}=\frac{0.4V_b}{3}=0.133V_b$$

or the current to be extinguished is 13.3 per cent of the normal line-charging current of the line section being switched with normal line-to-ground voltage on the other phases. Thus the arc current is proportional to line length switched out and system voltage.

The recovery voltage V_a appearing across the switch S following the extinction of the arc current is

$$V_a=\frac{0.5/\omega C_0V_b}{\dfrac{3}{2\omega(C_1-C_0)}+\dfrac{1}{\omega C_0}}$$

$$=\frac{0.5/C_0V_b}{\dfrac{3C_0+2(C_1-C_0)}{2C_0(C_1-C_0)}}=\frac{(C_1-C_0)V_b}{C_0+2C_1}$$

Again, assuming $C_0=0.6C_1$

$$V_a=\frac{(C_1-0.6C_1)V_b}{0.6C_1+2C_1}=\frac{0.4V_b}{2.6}=0.154V_b$$

or the voltage on "a" due to capacitance coupling following the extinction of the arc is 15.4 per cent of normal line-to-neutral voltage.

Similarly, from Figure 15a, it can be shown that with two phases "b" and "c" switched out, each having an arc to ground, the current magnitude in each arc is the same as for the single-phase case just considered. Furthermore, the voltage on the conductor first to clear is also the same in magnitude as the voltage for the single-phase case. However, the arc current for the last phase to clear of the two stricken phases will be

*H. A. Peterson is with central station engineering department, General Electric Company, Schenectady, New York.

increased when the first arc goes out. If conductor "b" clears first

$$\frac{I_e}{I_{nc}}=\frac{C_1-C_0}{2C_1+C_0}V_a$$

which, if $C_o=0.6C_1$, becomes

$$\frac{I_e}{I_{nc}}=\frac{(C_1-0.6C_1)V_a}{2C_1+0.6C_1}=\frac{0.4V_a}{2.6}=0.154V_a$$

or the arc current has increased from 13.3 per cent to 15.4 per cent of normal line-charging current in the section being switched out. The voltage on this phase when it has cleared will become

$$V_c=\frac{(C_1-C_0)V_a}{C_1+2C_0}=V_b$$

as the voltage magnitudes are equal on both conductors after both are cleared. If $C_o=0.6C_1$

$$V_c=V_b=\frac{(1-0.6)V_a}{1+1.2}=\frac{0.4V_a}{2.2}=0.182V_a$$

or the voltage on the conductors when both are cleared is 18.2 per cent of normal line-to-neutral voltage as compared to 15.4 per cent for either the single-phase case or the first conductor to clear for the two-phase case. Thus, it might be repeated that deionization times will be longer for double-line-to-ground than for single-line-to-ground faults.

In the extinction of these arcs, the *transient* recovery characteristic is also of importance. In order to study this phase of the problem, the transient analyzer was used. The system shown in Figure 16 was set up in miniature with the line open at the receiving end and only phase "a" open at both ends. By means of synchronous switching devices,[10] the arc current through switch S was interrupted at current zero. Oscillogram 90-11 shows the nature of this recovery voltage. It is important to note that the a-c component is completely offset, so that the instantaneous voltage to be cleared in each case is actually twice the sustained fundamental frequency component, or approximately from 30 to 35 per cent of normal line-to-neutral crest voltage. Furthermore, this voltage is reached one-half cycle after the assumed instant of clearing.

It is of interest to observe the effect of arc restriking. This is shown in oscillogram 90-12. Two restrikes, at approximately maximum voltage, were imposed for this case which gave rise to a voltage on the de-energized conductor "a" of approximately 65 per cent of normal line-to-neutral crest. These restrikes were controlled so as to give the maximum possible voltage per restrike. In the actual case, two restrikes would be extremely unlikely to give voltages this high. However, it is very likely that a good many more half cycles of arc current will flow before final interruption takes place, thus making possible a far greater number of restrikes.

A comparison of this voltage recovery characteristic and that of a ground-fault neutralizer system following the self-extinction of an arc to ground is enlightening. For the same system shown in Figure 16, but grounded through a neutralizer, the recovery characteristic is as shown in oscillogram 90-8. This illustrates the relatively slow "drift" of recovery back to normal restored voltage, taking three or four cycles to get up to 50 per cent of normal line-to-neutral voltage. Furthermore, arc restriking cannot increase this rate of voltage recovery, because each restrike simply causes the entire process to be started over again.

The preceding discussion has dealt with the dissimilarities of these two recovery characteristics. If only the first cycle following arc extinction without restriking is considered, there are also important similarities. In this interval, the recovered voltage versus time is of the same order of magnitude for both cases. Since this is likely to be the most significant interval of time during the extinction period, it is likely that arc extinction times may be expected to be somewhat similar for both cases. This time varies over wide limits, depending upon several factors, such as tower-footing resistance, atmospheric conditions, system voltage, system losses, and so on. Even with all of these factors fixed, there is an inherent randomness in arc behavior which makes arc clearing time subject to wide variation.

4. The Compressed-Air Circuit Breaker and the Importance of Its Short Opening Time for the Protection of the Line, H. Thommen. Association Suisse des Electriciens *Bulletin*, volume 30, October 27, 1939, pages 702–17.

5. Stability Limitations of Long-Distance A-C Power-Transmission Systems, Edith Clarke and S. B. Crary. AIEE Transactions, volume 60, 1941, pages 1051–9.

6. Calculation of Two-Machine Stability, With Resistance, S. R. Pritchard, Jr. and Edith Clarke. *General Electric Review*, February 1934, pages 87–92.

7. System Stability as a Design Problem, R. H. Park and E. H. Bancker. AIEE Transactions, volume 48, 1929, pages 170–90.

8. Progress in the Study of System Stability, I. H. Summers and J. B. McClure. AIEE Transactions, volume 49, 1930, pages 132–58.

9. Power Limits of Synchronous Machines, Edith Clarke and R. G. Lorraine. Electrical Engineering, volume 52, November 1933, pages 780–7.

10. An Electric-Circuit Transient Analyzer, H. A. Peterson. *General Electric Review*, September 1939, page 394.

11. An Analysis of Transient and Sustained Voltages in Ground-Fault Neutralizer Systems, S. B. Farnham, E. M. Hunter, and H. A. Peterson. AIEE Transactions, volume 60, 1941, pages 1257–66.

12. Damper Windings for Water-Wheel Generators, C. F. Wagner. AIEE Transactions, volume 50, 1931, pages 140–52.
